The MD Anderson Manual of Medical Oncology

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Dedication

Charles A. Koller, MD
1948-2013

This third edition of *The MD Anderson Manual of Medical Oncology* is dedicated to Charles A. Koller, a valued member of MD Anderson's Leukemia Department for nearly three decades, a committed physician, and an editor of the first and second editions of *The MD Anderson Manual of Medical Oncology*.

Contents

Contributors xi
A Brief History of MD Anderson Cancer Center xxi
Foreword xxv
Preface xxvii

I LEUKEMIA

Section Editor: William G. Wierda

- 1. Acute Lymphoblastic Leukemia** 3
Muhammed Baljevic, Elias Jabbour, Susan O'Brien, Hagop M. Kantarjian
- 2. Adult Acute Myeloid Leukemia** 19
Jasleen K. Randhawa, Joseph Khoury, Farhad Ravandi-Kashani
- 3. Chronic Lymphocytic Leukemia and Associated Disorders** 41
Nitin Jain, Carlos Bueso-Ramos, Susan O'Brien, William G. Wierda
- 4. Chronic Myeloid Leukemia** 61
Muhammed Baljevic, Elias Jabbour, Jorge Cortes, Hagop M. Kantarjian
- 5. Myelodysplastic Syndromes: The MD Anderson Cancer Center Approach** 81
Carlos Bueso-Ramos, Guillermo Garcia-Manero
- 6. Philadelphia Chromosome-Negative Myeloproliferative Neoplasms** 103
Srdan Verstovsek, Kate J. Newberry, Hesham M. Amin

II LYMPHOMA AND MYELOMA

Section Editor: Nathan H. Fowler

- 7. Indolent Lymphomas** 133
Loretta J. Nastoupil, Chan Yoon Cheah, L. Jeffrey Medeiros, Nathan H. Fowler
- 8. Aggressive B-Cell Lymphomas** 153
Jason R. Westin, Sergej N. Konoplev, Luis E. Fayad, L. Jeffrey Medeiros
- 9. T-Cell Lymphomas** 181
Dai Chihara, Casey Wang, Madeleine Duvic, L. Jeffrey Medeiros, Yasuhiro Oki

10. Hodgkin Lymphoma

201

Dai Chihara, Fredrick B. Hagemeister, L. Jeffrey Medeiros, Michelle L. Fanale

11. Multiple Myeloma and Other Plasma Cell Dyscrasias

229

Hans C. Lee, Krina Patel, Piyanuch Kongtim, Simrit Parmar, Pei Lin, Muzaffar H. Qazilbash, Sheeba Thomas, Elisabet E. Manasanch

III STEM CELL TRANSPLANTATION

Section Editor: Elizabeth J. Shpall

- 12. Autologous Hematopoietic Progenitor Cell Transplantation** 257
Riad El Fakih, Nina Shah, Yago Nieto
- 13. Allogeneic Transplantation** 267
Jonathan E. Brammer, Borje S. Andersson, Chitra Hosing
- 14. Alternative Donor Transplants: Cord Blood Transplant** 291
Rohtesh S. Mehta, Betul Oran, Elizabeth J. Shpall
- 15. Alternative Donor Transplants: Haploidentical Hematopoietic Stem Cell Transplantation** 301
Sameh Gaballa, Richard E. Champlin, Stefan O. Ciurea
- 16. Cellular Therapy in Allogeneic Hematopoietic Cell Transplantation** 307
Philip A. Thompson, Katayoun Rezvani, Partow Kebriaei

IV LUNG CANCER

Section Editor: Bonnie S. Glisson

- 17. Small Cell Carcinoma of the Lung** 323
Tina Cascone, Kathryn A. Gold, Bonnie S. Glisson
- 18. Non-Small Cell Lung Cancer** 343
Diogo Bugano Diniz Gomes, Kathryn A. Gold, Don L. Gibbons, Commentary: George A. Eapen

V HEAD AND NECK CANCER

Section Editor: Bonnie S. Glisson

19. Head and Neck Cancer 379

Jennifer McQuade, G. Brandon Gunn, William Nassib William Jr., Merrill S. Kies

VI GASTROINTESTINAL CANCERS

Section Editor: Robert A. Wolff

20. Gastric, Gastroesophageal Junction, and Esophageal Cancers 401

Elena Elimova, Roopma Wadhwa, Nikolaos Charalampakis, Alexandria T. Phan, Prajnam Das, M. Blum Murphy

21. Pancreatic Cancer 439

Jennifer B. Goldstein, Rachna T. Shroff, Robert A. Wolff, Milind M. Javle

22. Hepatocellular Carcinoma 463

Marc Uemura, Sunil Krishnan, Ahmed O. Kaseb, Nishin A. Bhadkamkar, Milind M. Javle, Rony Avritscher

23. Small Bowel Cancer and Appendiceal Tumors 479

Michael J. Overman, Kanwal Raghav, Christopher Lieu, Commentary: Keith F. Fournier

24. Colorectal Cancer 501

Van Morris, Ishwaria M. Subbiah, Scott Kopetz, Cathy Eng

25. Anal Cancer 525

Van Morris, Christopher Crane, Cathy Eng

26. Neuroendocrine Tumors 537

Daniel M. Halperin, James C. Yao

VII BREAST CANCER

Section Editor: Gabriel N. Hortobagyi

27. Early-Stage and Locally Advanced Breast Cancer 551

Aron S. Rosenstock, Gabriel N. Hortobagyi

28. Metastatic Breast Cancer 573

Meghan Karuturi, Vicente Valero, Mariana Chavez-MacGregor

29. Inflammatory Breast Cancer 599

Tamer M. Fouad, Vicente Valero, Naoto T. Ueno

30. Special Situations in Breast Cancer 623

Stacy Moulder-Thompson, Zahi Mitri

VIII GYNECOLOGIC MALIGNANCIES

Section Editor: Karen H. Lu

31. Ovarian Cancer 641

Kari L. Ring, Jubilee Brown, Amir A. Jazaeri

32. Tumors of the Uterine Corpus 665

Michaela A. Onstad, Janelle B. Pakish, Karen H. Lu

33. Tumors of the Uterine Cervix 689

Maria D. Iniesta, Kathleen M. Schmeler, Pedro T. Ramirez

34. Gestational Trophoblastic Disease 709

Jubilee Brown

IX GENITOURINARY MALIGNANCIES

Section Editor: Nizar M. Tannir

35. Renal Cell Carcinoma 733

Matthew T. Campbell, Eric Jonasch, Christopher G. Wood, Nizar M. Tannir

36. Bladder Cancer 753

Arlene Siefker-Radtke, Bogdan A. Czerniak, Colin P. N. Dinney, Commentary: David J. McConkey

37. Prostate Cancer 773

Mehmet A. Bilen, Christopher J. Logothetis, Paul G. Corn

38. Penile Cancer 793

Lance C. Pagliaro

39. Testicular Cancer 807

Lance C. Pagliaro, Maryam N. Shafaei, Nizar M. Tannir

X NEUROLOGIC TUMORS

Section Editors: John de Groot and Michael Fisch

40. Tumors of the Central Nervous System 829

Shiao-Pei Weathers, Barbara O'Brien, John de Groot, Commentary: Anita Mahajan, Commentary: Sujit S. Prabhu

XI MALIGNANT MELANOMA AND SARCOMAS

Section Editors: Michael A. Davies and Sapna P. Patel

41. Melanoma 857

Dae Won Kim, Jeffrey E. Gershenwald, Sapna P. Patel, Michael A. Davies

42. Soft Tissue and Bone Sarcomas 875

*J. Andrew Livingston, Anthony Conley, Vinod Ravi,
Shreyaskumar Patel*

XII OTHER TUMORS

Section Editors: Michael Fisch and John de Groot

43. Endocrine Malignancies 903

*Lily Kwatampora, Steven Weitzman,
Mouhammed Habra, Naifa L. Busaidy*

44. The Acquired Immunodeficiency Syndrome–Related Cancers 933

Adan Rios, Fredrick B. Hagemeister

XIII NOVEL AND OTHER CANCER TOPICS OF INTEREST

*Section Editors: Apostolia-Maria Tsimberidou and
Nizar M. Tannir*

45. Carcinoma of Unknown Primary 961

Gauri R. Varadhachary

46. Pediatric Cancers 977

Ryuma Tanaka, Patrick A. Zweidler-McKay

47. Cancer Genomics 985

Jennifer Goldstein, Zhijing Zhang, Andy Futreal

48. Immuno-Oncology 995

Sangeeta Goswami, James P. Allison, Padmanee Sharma

49. Targeted Therapy in Cancer 1003

Apostolia-Maria Tsimberidou

50. Applied Biostatistics 1021

Xuelin Huang

XIV SUPPORTIVE CARE

Section Editor: Karen H. Lu

51. Fungal and Viral Infections in Cancer Patients 1031

Bruno P. Granwehr, Roy F. Chemaly, Dimitrios P. Kontoyiannis

52. Endocrine and Metabolic Complications of Cancer Therapy 1055

*Levent Ozsari, Naifa Lamki Busaidy,
Mouhammed Amir Habra*

53. Oncologic Emergencies 1073

Sai-Ching Jim Yeung, Ellen F. Manzullo

54. Onco-Cardiology 1099

*Elie Mouhayar, Danielle El-Haddad, Peter Kim, Kara
Thompson*

55. Pulmonary Complications of Cancer Therapy 1121

Saadia A. Faiz, Horia B. Grosu, Vickie R. Shannon

56. Cancer-Associated Thrombosis 1147

Rachel A. Sanford, Michael H. Kroll

XV PALLIATIVE CARE AND SYMPTOM MANAGEMENT

Section Editors: Eduardo Bruera and Michael Fisch

57. Palliative and Supportive Care 1159

David Hui, Eduardo Bruera

58. Pain Management and Symptom Control 1169

Kaoswi Shih, Rony Dev, Suresh K. Reddy

59. Rehabilitation 1189

Sunny S. Dhah, Jack B. Fu, Ki Y. Shin

60. Long-Term Survivorship in Adult and Pediatric Cancer 1211

*Ravin Ratan, Joann Ater, Alyssa G. Rieber,
Maria Alma Rodriguez*

Index 1227

Contributors

James P. Allison, PhD

Professor of Immunology
Chair, Department of Immunology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Hesham M. Amin, MD

Professor of Hematopathology Adm.
The University of Texas MD Anderson Cancer Center
Houston, Texas

Borje Andersson, MD, PhD

Professor of Stem Cell Transplantation
The University of Texas MD Anderson Cancer Center
Houston, Texas

Joann Ater, MD

Professor of Pediatrics
Department of Pediatrics
The University of Texas MD Anderson Cancer Center
Houston, Texas

Rony Avritscher, MD

Associate Professor
Interventional Radiology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Muhamed Baljevic, MD

Fellow, Hematology and Medical Oncology
Department of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Nishin A. Bhadkamkar, MD

Assistant Professor
General Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Mehmet A. Bilen, MD

Fellow, Cancer Medicine - Fellowship Program
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jonathan E. Brammer, MD

Instructor
Department of Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jubilee Brown, MD

Department of Gynecologic Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Eduardo Bruera, MD

Department of Palliative Care and Rehabilitation Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Carlos Bueso-Ramos, MD, PhD

Professor of Hematopathology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Naifa Lamki Busaidy, MD

Associate Professor of Endocrine Neoplasia and HD
The University of Texas MD Anderson Cancer Center
Houston, Texas

Matthew T. Campbell, MD

Assistant Professor of Genitourinary Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Tina Cascone, MD, PhD

Fellow, Hematology and Medical Oncology
Division of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Richard E. Champlin, MD

Chairman of Department of Stem Cell Transplantation
and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Nikolaos Charalampakis, MD, PhD

Former Postdoctoral Fellow
 Department of Gastrointestinal Medical Oncology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas
 Oncology Unit, Department of 2nd Internal Medicine
 Propedeutics
 Attikon University Hospital - National Kapodistrian University of
 Athens
 Athens, Greece

Chan Yoon Cheah, MBBS, DMedSc

Fellow, Lymphoma and Myeloma Research
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Roy F. Chemaly, MD, MPH, FIDSA, FACP

Professor of Medicine
 Chair, Infection Control Committee
 Department of Infectious Diseases,
 Infection Control, and Employee Health
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Dai Chihara, MD

Fellow, Leukemia
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Stefan O. Ciurea, MD

Associate Professor
 Department of Stem Cell Transplantation and Cellular Therapy
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Anthony Conley, MD

Assistant Professor
 Department of Sarcoma Medical Oncology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Paul G. Corn, MD, PhD

Associate Professor of Genitourinary Medical Oncology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Jorge Cortes, MD

Jane and John Justin Distinguished Chair in Leukemia Research
 Chief, CML and AML Sections
 Deputy Chair, Department of Leukemia
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Christopher H. Crane, MD

Professor
 Program Director and Section Chief, Gastrointestinal Section
 Department of Radiation Oncology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Bogdan Czerniak, MD, PhD

Professor of Pathology
 Department of Pathology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Prajnam Das, MD

Associate Professor, Radiation Oncology Department
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Michael A. Davies, MD, PhD

Department of Melanoma Medical Oncology
 Department of Systems Biology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Rony Dev, DO

Associate Professor, Palliative Care Medicine
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Sunny S. Dhah, DO

Fellow, Department of Palliative Care and Rehabilitation
 Medicine
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Colin P. N. Dinney, MD

Chair Department of Urology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Madeleine Duvic, MD

Professor of Medicine and Dermatology
 Blanche Bender Professorship in Cancer Research
 Deputy Chair, Department of Dermatology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

George A. Eapen, MD

Professor of Pulmonary Medicine
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Elena Elimova, MD, MSc, FRCPC

Staff Physician, Division of Medical Oncology Assistant Professor,
 Department of Medicine University of Toronto Princess
 Margaret Cancer Centre
 Toronto, Ontario

Cathy Eng, MD, FACP

Professor
 Associate Medical Director, Colorectal Center
 Director, Network Clinical Research, Gastro-intestinal
 Medical Oncology
 Department of Gastrointestinal Medical Oncology
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Saadia A. Faiz, MD

Associate Professor of Pulmonary Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Michelle Fanale, MD

Associate Professor of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Luis E. Fayad, MD

Associate Professor of Medicine
Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Tamer M. Fouad, MD, PhD

Assistant Professor (Adjunct)
Department of Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Keith Fournier, MD

Assistant Professor of Surgery
Department of Surgical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Nathan H. Fowler, MD

Associate Professor
Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jack B. Fu, MD

Assistant Professor
Department of Palliative Care and Rehabilitation Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Andy Futreal, PhD

Chair Ad Interim of Genomic Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sameh Gaballa, MD, MS

Fellow, Department of Stem Cell Transplantation
and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Guillermo Garcia-Manero, MD

Professor of Leukemia
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jeffrey E. Gershenwald, MD

Department of Surgical Oncology
Department of Cancer Biology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Don L. Gibbons, PhD

Assistant Professor
Department of Thoracic/Head and Neck Medical Oncology,
Department of Molecular and Cellular Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Bonnie S. Glisson, MD

Professor of Medicine
Thoracic/Head and Neck Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Kathryn A. Gold, MD

Assistant Professor
Department of Thoracic/Head and Neck Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jennifer B. Goldstein, MD

Instructor of Gastrointestinal Medical Oncology-Research
The University of Texas MD Anderson Cancer Center
Houston, Texas

Diogo Bugano Diniz Gomes, MD

Medical Oncology
Hospital Israelita Albert Einstein
Brazil

Sangeeta Goswami, MD, PhD

Fellow, Medical Oncology
Department of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Bruno P. Granwehr, MD, MS

Associate Professor of Infectious Diseases
The University of Texas MD Anderson Cancer Center
Houston, Texas

John de Groot, MD

Department of Neuro-Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Horiana B. Grosu, MD

Assistant Professor of Pulmonary Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

G. Brandon Gunn, MD

Associate Professor
Department of Radiation Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Mouhammed Amir Habra, MD

Associate Professor
Department of Endocrine Neoplasia and Hormonal Disorders
The University of Texas MD Anderson Cancer Center
Houston, Texas

Danielle El-Haddad, MD

Clinical Research Resident
Department of Cardiology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Fredrick B. Hagemeister, MD

Professor of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Daniel M. Halperin, MD

Assistant Professor
Department of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Gabriel N. Hortobagyi, MD, FACP, FASCO

Professor, Department of Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Chitra Hosing, MD

Professor of Medicine
Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Xuelin Huang, PhD

Professor
Department of Biostatistics
The University of Texas MD Anderson Cancer Center
Houston, Texas

David Hui, MD, MSc

Department of Palliative Care and Rehabilitation Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Maria D. Iniesta

Senior Coordinator of Research Data, Gynecology
Oncology and Reproductive Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Elias Jabbour

Department of Leukemia
The University of Texas MD Anderson Cancer Center
Houston, Texas

Nitin Jain, MD

Assistant Professor
Department of Leukemia
The University of Texas MD Anderson Cancer Center
Houston, Texas

Milind M. Javle, MD

Professor
Department of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Amir A. Jazaeri, MD

Department of Gynecologic Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Faye Johnson, MD, PhD

Associate Professor of Thoracic/Head and
Neck Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Eric Jonasch, MD

Professor of Genitourinary Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Hagop M. Kantarjian, MD

Professor of Medicine
Chair, Department of Leukemia
The University of Texas MD Anderson Cancer Center
Houston, Texas

Meghan Karuturi, MD

Assistant Professor of Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Ahmed Kaseb, MD

Associate Professor
Department of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Partow Kebriaei, MD

Department of Stem Cell Transplantation and Cellular Therapy
Division of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Joseph Khoury, MD

Assistant Professor of Hematopathology Adm.
The University of Texas MD Anderson Cancer Center
Houston, Texas

Merrill S. Kies, MD

Clinical Professor of Thoracic/Head and Neck Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Dae Won Kim, MD

Department of Melanoma Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Peter Kim, MD

Assistant Professor of Medicine
Department of Cardiology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Piyanuch Kongtim, MD

Department of Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sergej N. Konoplev, MD, PhD

Associate Professor
Department of Hematopathology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Dimitrios P. Kontoyiannis, MD, ScD

Professor of Infectious Disease
The University of Texas MD Anderson Cancer Center
Houston, Texas

Scott Kopetz, MD, PhD.

Associate Professor of Gastro-Intestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sunil Krishnan, MD

Professor
Department of Radiation Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Michael H. Kroll

Section of Benign Hematology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Lily Kwatampora, MBChB, MPH

Fellow, Clinical Research
Department of Endocrinology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Hans C. Lee, MD

Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Christopher H. Lieu, MD

Assistant Professor of Medicine
University of Colorado Cancer Center
Aurora, Colorado

Pei Lin, MD

Department of Hematopathology
The University of Texas MD Anderson Cancer Center
Houston, Texas

J. Andrew Livingston, MD

Fellow, Medical Oncology
Division of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Christopher J. Logothetis, MD

Chair, Genitourinary Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Karen H. Lu, MD

Chair and Professor, Department of Gynecologic Oncology and
Reproductive Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Anita Mahajan, MD

Department of Radiation Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Mariana Chavez-MacGregor, MD

Assistant Professor of Health Services Research-Clinical
The University of Texas MD Anderson Cancer Center
Houston, Texas

Elisabet E. Manasanch, MD, MHSc

Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Ellen F. Manzullo, MD, FACP

Professor of Medicine
Deputy Division Head (Clinical)
The University of Texas MD Anderson Cancer Center
Houston, Texas

David J. McConkey, PhD

Professor of Urology Research
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jennifer L. McQuade, MD

Fellow, Medical Oncology
Division of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

L. Jeffrey Medeiros, MD

Chair and Professor, Department of Hematopathology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Rohtesh S. Mehta, MD, MPH, MS

Fellow, Department of Stem Cell Transplantation
and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Zahi Mitri, MD

Fellow, Hematology and Medical Oncology
Department of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Van Morris, MD

Assistant Professor, Department of Gastrointestinal Medical
Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Elie Mouhayar, MD, FACC, FSVM

Associate Professor of Medicine
Department of Cardiology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Stacy Moulder-Thompson, MD, MSCI

Associate Professor
Chief, Section of Clinical Research and Drug Development
Department of Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

M. Blum Murphy, MD

Assistant Professor of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Loretta J. Nastoupil, MD

Assistant Professor
Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Kate J. Newberry

Senior Research Scientist of Leukemia Research
The University of Texas MD Anderson Cancer Center
Houston, Texas

Barbara O'Brien, MD

Department of Neuro-Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Susan O'Brien, MD

Associate Director for Clinical Science
Chao Family Comprehensive Cancer Center
Medical Director
Sue and Ralph Stern Center for Clinical Trials and Research
Professor of Medicine
Division of Hematology/ Oncology
Department of Medicine
University of California
Irvine, California

Yasuhiro Oki, MD

Associate Professor
Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Michaela A. Onstad, MD

Fellow, Gynecologic Oncology and Reproductive Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Betul Oran, MD

Assistant Professor
Department of Stem Cell Transplantation and Cellular Therapy
Division of Cancer Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Michael J. Overman, MD

Associate Professor of Medicine
Department of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Levent Ozsari

Istanbul, Turkey

Lance C. Pagliaro, MD

Professor of Oncology
Mayo Clinic College of Medicine
Senior Associate Consultant
Department of Oncology, Division of Medical Oncology
Mayo Clinic
Rochester, Minnesota

Janelle B. Pakish, MD

Fellow, Gynecologic Oncology and Reproductive Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas

Simrit Parmar, MD

Department of Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Krina Patel, MD

Department of Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sapna P. Patel, MD

Department of Melanoma Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Shreyaskumar Patel, MD

Professor
Department of Sarcoma Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Alexandria T. Phan, MD

Professor, Gastrointestinal Medical Oncology
Hematology-Oncology
Houston Methodist Cancer Center
Houston, Texas

Katherine M. Pisters, MD

Professor of Thoracic/Head and Neck Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sujit S. Prabhu, MD

Department of Neurosurgery
The University of Texas MD Anderson Cancer Center
Houston, Texas

Muzaffar H. Qazilbash, MD

Department of Stem Cell Transplantation and Cellular Therapy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Kanwal Raghav, MD

Assistant Professor of Medicine
Department of Gastrointestinal Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Pedro T. Ramirez, MD

A Brief History of MD Anderson Cancer Center

Houston's evolution into the fourth largest city in the United States was propelled by four seminal events. First was the Great Galveston Hurricane of 1900, which destroyed the city port of Galveston and led to the realization that Houston could become a viable and safer deep-water port; this led to the widening of the Ship Channel to offer direct access to Houston. Second was the discovery of oil at Spindletop in Beaumont, Texas in 1901. This prompted the development of the oil industry in Texas and transformed Houston from a small town into a large city. Third was (of course) the commercialization of air conditioning in 1950's, which made Houston (and many Southern cities of the United States) more livable. And lastly, the allocation of land for the Texas Medical Center created the largest medical center in the world with one of the highest densities of clinical facilities for patient care, basic science, and translational research. The Texas Medical Center is a major contributor to Houston's economy and growth.

Several additional factors contributed to the creation of The University of Texas MD Anderson Cancer Center in Houston and its development into one of the most important cancer centers in the world. First was the generous philanthropy of visionary Texans such as Monroe Dunaway Anderson (Fig. 1) (his nephew died of leukemia in 1936) and his partner Will Clayton, who founded the charitable MD Anderson Foundation, which helped create the Texas Medical Center in 1945. The charter

FIGURE 1.

FIGURE 2.

of the Anderson Foundation did not specify how the money should be used, but Mr. Anderson's trustees and close friends—Colonel William Bates, John Freeman and Horace Williams—leaned strongly in favor of health care. Soon after taking possession of the estate from its executors, the trustees turned to Dr. Ernest Bertner (Fig. 2) for advice. Dr. Bertner was a

prominent Houston surgeon and gynecologist who was well known to the trustees because of his care for cancer patients, despite inadequate facilities and treatment options (he was later called the “father of the Texas Medical Center”).

The trustees and Dr. Bertner noted that the 1941 Texas legislature authorized the University of Texas to create a hospital for cancer research and treatment, allocating \$500,000 for the purpose. Today, that figure would be approximately \$8 million. The Anderson trustees, with Dr. Bertner's guidance, seized the opportunity and offered to match the \$500,000 legislative appropriation, if the hospital was to be named for Monroe Dunaway Anderson and located in Houston. The legislature accepted their offer. The trustees then purchased 134 acres of mosquito-infested land to create the Texas Medical Center, stating that the new cancer hospital would be located there. They made it known that the new state hospital should be an academic institution. In fact, MD Anderson was the first comprehensive cancer hospital to be associated with a major university as an independent free-standing unit.

In 1942, The University of Texas Board of Regents appointed Dr. Bertner as the director of the new hospital. A 6-acre property near downtown was purchased from the estate of Captain James A. Baker, grandfather of former Secretary of State James Baker III, and became the first campus of the hospital. An empty

carriage house became the office and stables were the research laboratories. Twelve surplus army barracks were procured for patient clinics (Figs. 3A-C). With the addition of 22 leased beds at Hermann Hospital, the dream became reality, and the “MD Anderson Hospital and Tumor Institute” was created. A small

FIGURE 3A.

FIGURE 3B.

**FIGURE 3C.**

faculty of physicians and scientists was recruited from the University of Texas Medical Branch in Galveston, and cancer patients finally had a home. It was renamed “MD Anderson Hospital for Cancer Research” in 1942.

In 1946, Dr. Bertner persuaded Dr. Randolph Lee Clark, a native Texan, to become president of what was to become The University of Texas MD Anderson Cancer Center. Dr. Clark, a widely recognized surgeon,

concentrated on recruiting an excellent surgical faculty and then set upon acquiring all the basic and clinical scientists and clinicians. From the outset, all efforts, whether administrative, clinical or research, were focused on developing excellence in research-driven cancer care. Forty-six patients were receiving treatment in these early quarters when the hospital moved to its current site in March 1954 (Figs. 4A and B).

**FIGURE 4A.****FIGURE 4B.**

FIGURE 5.

FIGURE 6A.

FIGURE 6B.

Additional resources to expand the MD Anderson infrastructure (Fig. 5) and research capacities came from several venues: (1) generous donations from the oil industry; (2) the visionary research and administrative leadership under its four presidents, Drs. Randolph Lee Clark (1946–1978) (Fig. 6A), Charles A. LeMaistre (1978–1996) (Fig. 6B), John Mendelsohn (1996–2011) (Fig. 6C), and Ronald DePinho (2011–present) (Fig. 6D); (3) the recruitment of world-renowned cancer research pioneers (some of the early legends included Drs. Emil J. Freireich, Emil Frei, Gilbert Fletcher, James Butler, Felix Rutledge, Gerald Dodd, and Sidney Wallace); and (4) the relentless research efforts of the cancer experts on the MD Anderson’s faculty.

Today, MD Anderson is one of the largest cancer centers in the world, with more than 21,000 employees and 1800 faculty; serving more than 150,000 patients with cancer in Houston every year; operating a 700-bed cancer hospital; and being ranked as the No. 1 hospital for cancer care by the *U.S. News and World Report* in 11 of the past 14 years. The MD Anderson Cancer Center research has resulted

FIGURE 6C.

FIGURE 6D.

in numerous discoveries that became standards of care across many types of cancers, and that have saved the lives and/or improved survivals and outcomes of millions of patients with cancer around the world.

One component of MD Anderson’s mission is to spread its knowledge about cancer research and discoveries across the globe. This educational mission is furthered by the hematology/oncology fellowship that currently trains more than 40 medical hematology-oncology cancer specialists on its premises. *The MD Anderson Manual of Medical Oncology*, created as part of our educational mission, is written by our fellows as first authors and supported in depth by senior tumor specialty faculty

as co-authors. We envision this third edition expanding into a continuously updated electronic version that educates and spreads knowledge and discoveries in cancer research and therapy rapidly and widely.

Charles A. LeMaistre, M.D.
John Mendelsohn, M.D.
Ronald A. DePinho, M.D.

Foreword

The MD Anderson Manual of Medical Oncology, third edition, articulates the personalized, multidisciplinary approach to cancer management pioneered by the University of Texas MD Anderson Cancer Center. This approach has contributed to our ranking as number one in cancer care in 11 of the past 14 years in the *US News & World Report's* “America’s Best Hospitals” survey. Our unique perspective has evolved from decades of clinical practice and research with more than a million patients treated. The book is designed to bring a pragmatic approach to cancer management that may serve as a guide for oncologists around the world. The text reflects how MD Anderson currently operates, including many patient care practices that would not have been recognized by practitioners just a decade ago. In a single year, 96,500 people with cancer—33,200 of them new patients—seek care at MD Anderson. Since the first edition, we have improved our ability to identify biomarkers that are predictive for survival, a major triumph in medical oncology that is demonstrated throughout the text.

The current edition emphasizes and discusses recent developments in precision medicine and immunotherapies.

Reflecting new advances in our approach to cancer management, the third edition of *The MD Anderson Manual of Medical Oncology* features several new chapters. For example, there are new chapters on important aspects of stem cell transplantation: cord blood transplant, haploidentical stem cell transplantation, and cellular therapy in allogeneic hematopoietic cell transplantation. In addition, new chapters on pediatric cancers, molecular biomarkers and cancer, immuno-oncology, targeted therapies in cancer, applied biostatistics, oncocardiology, pulmonary complications of cancer therapy, and cancer-associated thrombosis have been added.

To help clinicians quickly assess cancer management options, every chapter includes abundant tables, diagrams, and imaging photos. These include, for example, treatment algorithms and decision trees developed at MD Anderson for specific cancers or disease subtypes; promising novel therapy targets and the latest clinical trial phase of drugs targeting them; and new molecular therapies recommended to overcome resistance to previously effective therapies.

The new era of novel personalized, targeted therapeutics has also sparked the recent evolution of another crucial advancement in management of metastatic disease: the transition from sequential care culminating in the sole delivery of palliative care, to integration of ongoing active disease treatment with simultaneous interdisciplinary symptom control, palliative care, and rehabilitation to improve quality of life. Clinicians at MD Anderson no longer approach advanced metastatic disease management with palliative care goals alone; now, these patients are often offered frontline cancer treatment and the opportunity to participate in clinical trials for investigational drugs.

In recognition of the growing pool of patients who are surviving their cancer, MD Anderson has greatly expanded programs for cancer survivors since the publication of the first edition.

The University of Texas MD Anderson Cancer Center
Houston, Texas
May 2016

Preface

When we first envisioned *The MD Anderson Manual of Medical Oncology*, we hoped that it would fill an important void in oncology reference material by serving as a hands-on resource for the practicing oncologist. The first edition, published in 2006, was written exclusively by our faculty and fellows with the idea of giving a bird's-eye view of how multidisciplinary care was practiced at our institution. We were proud of that initial effort and pleased that the book received positive reviews from several high-impact journals, including *JAMA*, *The Lancet*, and *The New England Journal of Medicine*.

The second edition, published in 2011, moved closer to the aims of providing more illustrations, figures, tables, and algorithms. In addition, the second edition included new chapters on myelodysplastic syndromes, Philadelphia chromosome-negative myeloproliferative neoplasms, T-cell lymphomas, small bowel cancer and appendiceal tumors, inflammatory breast cancer, and penile cancer.

In the third edition, we have continued the tradition of including evidence-based management algorithms in the form of flowcharts and diagrams, shaped by the clinical experience of our world-class faculty at MD Anderson. Readers are also provided with a practical

guide to the diagnostic and therapeutic strategies used at MD Anderson.

The new edition of *The MD Anderson Manual of Medical Oncology* contains new chapters on cord blood transplant, haploidentical stem cell transplantation, cellular therapy in allogeneic hematopoietic cell transplantation, pediatric cancers, molecular biomarkers and cancer, immuno-oncology, targeted therapies in cancer, applied biostatistics, oncocardiology, pulmonary complications of cancer therapy, and cancer-associated thrombosis. In addition, there is expanded coverage of the rapidly growing areas of biological and immune therapies of cancer.

The new edition of *The MD Anderson Manual of Medical Oncology* will also be a continually updated version of the book, online, with the latest science and clinical recommendations from the world-renowned clinical investigators at MD Anderson.

We hope that this edition serves to help oncologists everywhere provide high-quality, state-of-the-art cancer care to their patients.

Hagop M. Kantarjian

EPIDEMIOLOGY AND ETIOLOGY

Acute lymphoblastic leukemia (ALL) is characterized by the proliferation and accumulation of lymphoid progenitor cells in the blood, bone marrow, and other tissues. It has a bimodal distribution. The overall age-adjusted incidence is 1.7 per 100,000 persons, but ALL affects 4 to 5 per 100,000 persons during age 4 to 5 years and half that number around the fifth decade of life. Approximately 60% of cases are diagnosed in patients ≤ 20 years old, with a median age at diagnosis of 14 years. In 2014, the American Cancer Society estimated that approximately 6,000 individuals would be diagnosed with ALL that year^(1,2). Acute lymphoblastic leukemia represents 20% of adult leukemias but is the most common childhood acute leukemia, representing approximately 80% of cases^(1,2).

The etiology of ALL is unknown in most cases⁽³⁻⁷⁾. Chromosomal translocations occurring in utero during fetal hematopoiesis have suggested genetic factors as the primary cause for pediatric ALL and postnatal genetic events as secondary contributors. Monozygotic and dizygotic twins of patients with ALL and individuals with genetic disorders, such as Klinefelter (XXY and variants) and Down (trisomy 21) syndromes, or inherited diseases with excessive chromosomal fragility, such as Bloom syndrome, Fanconi anemia, and ataxia telangiectasia, have all been found to have higher incidence of ALL, implicating a possible genetic predisposition. Additional studies have postulated infectious etiologies⁽⁴⁾. Human T-cell lymphotropic

virus type-1 is known to cause adult T-cell leukemia/lymphoma⁽⁵⁾; Epstein-Barr virus has been associated with lymphoproliferative disorders, including Burkitt lymphoma and mature B-cell ALL⁽⁶⁾; and varicella has been linked to childhood ALL⁽⁷⁾.

CLINICAL PRESENTATION AND LABORATORY ABNORMALITIES

Presenting symptoms can be nonspecific, particularly in children. They largely reflect bone marrow failure and include malaise, fatigue, bleeding or bruising, and secondary infections. The B symptoms, such as fever, night sweats, and weight loss, are frequent. White blood cell (WBC) count at presentation varies widely, and circulating blasts are generally noted. Symptoms related to hyperleukocytosis are rare in ALL, given the lymphoblast morphology, even when WBC counts are high.

Leukemic involvement of the central nervous system (CNS) ranging from cranial neuropathies to meningeal infiltration occurs in $<10\%$ of patients at presentation. It is more common in mature B-cell ALL (Burkitt leukemia)⁽⁸⁾. A history or findings of abdominal masses, significant spontaneous tumor lysis syndrome, and chin numbness (mental nerve) indicating cranial nerve involvement are also more common in this subtype of ALL⁽⁹⁾. Lymphadenopathy and hepatosplenomegaly, although rarely symptomatic, are noted in approximately 20% of patients⁽⁹⁾.

DIAGNOSIS

Immunophenotyping

The diagnosis of ALL is largely based on flow cytometric immunophenotyping, although identification of cytogenetic-molecular abnormalities plays a significant role (Fig. 1-1). The World Health Organization (WHO) proposed new guidelines for the diagnosis of neoplastic diseases of hematopoietic and lymphoid tissues (¹⁰). The French-American-British (FAB) Cooperative Group diagnostic approach, which recognizes L1 to L3 morphologic subtypes, has been essentially abandoned. A blast count of $\geq 20\%$ was established as sufficient for diagnosis.

Flow cytometric analysis successfully assigns lineage in more than 95% of cases. True mixed phenotype acute leukemia is rare (¹¹). Concomitant expression of markers from more than one lineage is seen in 15% to 50% of adult and 5% to 35% of pediatric ALL (¹²⁻¹⁴), but this is not prognostically relevant. Targeted genomic profiling may further define ALL subtypes with different response profiles to therapy and prognoses, which are only partially discriminated by current diagnostic tools.

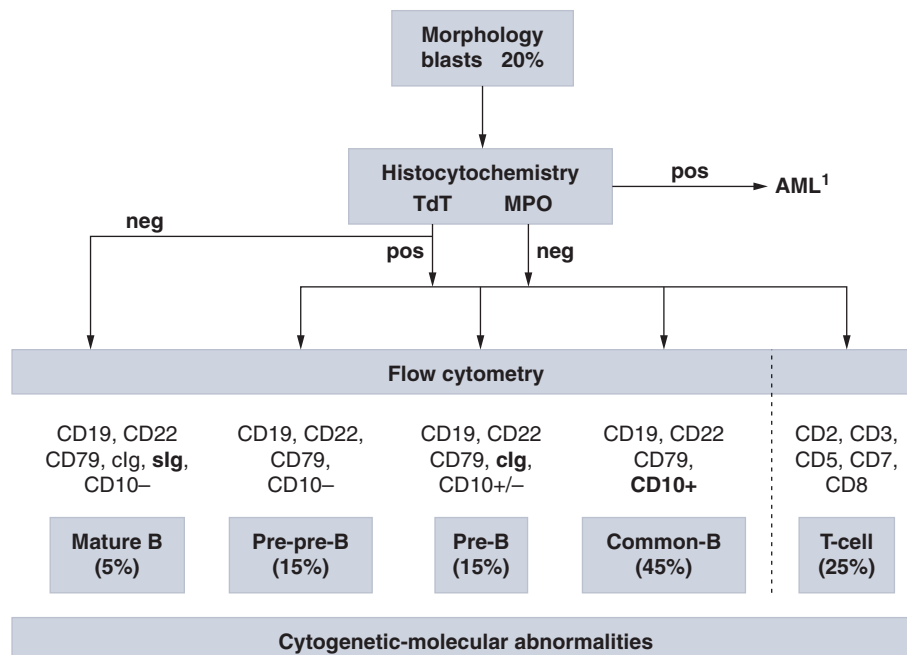

Immunophenotypically, ALL blasts are negative for myeloperoxidase (MPO), although low-level MPO positivity (3%-5%) may occur in rare cases that otherwise lack expression of myeloid markers by flow cytometry (¹⁵). Terminal deoxynucleotidyl transferase

(TdT), although not a specific marker of ALL, helps separate malignant lymphocytosis from reactive processes and distinguish L3 ALL (TdT negative) from other ALL subtypes (¹⁶).

Both the prior FAB and current WHO classification systems rely heavily on morphologic assessment (¹⁷), which accounts for cell size, cytoplasm, nucleoli, basophilia, and vacuolation. The former FAB L3 morphology, characterized by a high rate of cell turnover, is associated with mature B-cell ALL (Burkitt leukemia) and gives rise to the “starry sky” pattern on marrow biopsies.

Three broad immunophenotypic ALL groups can be distinguished: precursor B-cell, mature B-cell, and T-cell ALL (Table 1-1). Precursor B-cell ALL (B-ALL) stains positive for TdT, HLA-DR, CD19, and CD79a. According to the stages of maturation, further B-cell subgroups have been defined as pre-pre-B-ALL (pro-B-ALL), common ALL, and pre-B-ALL. Although they all stain positive for CD19, CD79a, or CD22, expression of CD10 (common ALL antigen [CALLA]) distinguishes common ALL (early pre-B-ALL), and cytoplasmic immunoglobulins with or without CD10 identify pre-B-ALL. Mature B-ALL (Burkitt leukemia) is TdT negative but expresses surface immunoglobulins (usually immunoglobulin M), as well as κ or λ light chains in a clonal fashion. It has almost ubiquitous expression of CD20, which has therapeutic implications (¹⁸).

T-cell ALL (T-ALL) further stratifies into subtypes based on different stages of thymic differentiation (¹⁹).

¹Low-level myeloperoxidase (MPO) positivity (3%-5%) may occur in rare cases that otherwise lack expression of myeloid markers by flow cytometry.

FIGURE 1-1 Diagnosis of acute lymphoblastic leukemia. AML, acute myeloid leukemia.

Table 1-1 Immunophenotypic Classification of ALL

B Lineage		T Lineage	
CD19/CD79a/CD22		CD3 (Surface/Cytoplasmic)	
Pre-pre-B-ALL (pro-B-ALL)	—	Precursor T-ALL	CD1a, CD2, CD5, CD7, CD8, cCD3
Common ALL	CD10 (CALLA)	Mature T-ALL	Surface CD3 (plus any other T-cell markers)
Pre-B-ALL	Cytoplasmic IgM		
Mature B-ALL	Cytoplasmic or surface Ig κ or λ		

As the most lineage-specific marker for T-cell differentiation, surface CD3 (sCD3) is typically positive in mature T-ALL, which is also positive for either CD4 or CD8, but not both. However, pre-T-ALL is negative for CD4, CD8, and sCD3 but may still express cytoplasmic CD3. A more simplified classification divides T-ALL into early T-ALL (sCD3⁻, CD1a⁻), thymic T-ALL (sCD3^{+/+}, CD1a⁺), and mature T-ALL (sCD3⁺, CD1a⁺). Only thymic T-ALL has excellent outcome with chemotherapy alone.

Cytogenetic-Molecular Profiling

Frequent cytogenetic and molecular abnormalities associated with adult ALL offer insight into the events leading to leukemic progression (Table 1-2)⁽²⁰⁾. They are of both prognostic and predictive significance and have varying frequencies in children and adults, which explains some of the differences in outcomes in these two groups. This is particularly true in the case of ALL harboring Philadelphia chromosome [t(9;22)] (Ph) or

Table 1-2 Cytogenetic and Molecular Abnormalities in ALL

^cIn T-cell ALL, overall incidence <10%.

other chromosomal changes with prognostic relevance such as Burkitt karyotypes [t(8;14), t(2;8), t(8;22)] or t(4;11). Next-generation sequencing, expression proteomics, and oligonucleotide microarrays have transformed our understanding of the genomic landscape of ALL and are yielding new molecular subgroups with actionable defects⁽²¹⁻²³⁾.

Recently, a Ph-like signature in 10% of children with standard-risk ALL and as many as 25% to 30% of young adults with ALL has been defined using genome-wide gene expression arrays. This subgroup lacks the expression of BCR-ABL1 fusion protein but does have a gene expression profile similar to BCR-ABL1 ALL⁽²⁴⁻²⁶⁾. The vast majority of these patients have deletions in key transcription factors involved in B-cell signaling, such as IKZF1, TCF3, EBF1, PAX5, and VPB1, as well as kinase-activating alterations involving ABL1, ABL2, CRLF2, CSF1R, EPOR, JAK2, NTRK3, PDGFRB, PTK2B, TSLP, or TYK2 and sequence mutations involving *FLT3*, *IL7R*, or *SH2B3*. The most common alterations (~50%) are rearrangements of CRLF2, which activate downstream signaling through JAK kinases, and approximately half of these cases have activating mutations in *JAK1* or *JAK2* (Fig. 1-2). Importantly, patients with ABL1, ABL2, CSF1R, and PDGFRB expression fusions were sensitive in vitro and in vivo human xenograft models to ABL class tyrosine kinase inhibitors (TKIs; eg, dasatinib); rearrangements in *EPOR*, *IL-7R*, and *JAK2* mutations and fusions were sensitive to JAK kinase inhibitors (eg, ruxolitinib); and patients with ETV6-NTRK3 fusion were sensitive to ALK kinase inhibitors (eg, crizotinib)⁽²⁵⁾, further expanding therapeutic options in this subgroup with poor outcome.

Observations of epigenetic alterations regulating distinct molecular pathways that occur frequently at presentation and relapse have identified a “hypermethylator” phenotype of ALL⁽²⁷⁾. These patients may respond favorably to treatment with hypomethylating agents (azacitidine or decitabine). Identification of these and other molecular and cytogenetic changes in adult ALL drives the development of risk-adapted and targeted therapies, particularly in high-risk groups (Table 1-3)⁽²⁸⁾.

FRONTLINE THERAPY

Therapy for ALL consists of complex and comprehensive regimens consisting of several phases: induction, intensified consolidation, maintenance, and CNS prophylaxis^(9,29). Each involves the use of a core group of agents considered the backbone of therapy in a time- and dose-dependent manner, with a goal of restoring normal hematopoiesis, eradicating resistant subclones, providing adequate prophylaxis of sanctuary sites (eg, CNS, testicles), and eliminating minimal residual disease (MRD) during the consolidation and maintenance phases^(9,30). Combining anthracyclines (eg, daunorubicin or doxorubicin), vincristine, and dexamethasone (for better CNS penetration), often coupled with cyclophosphamide or asparaginase with growth factor support, represents the cornerstone of ALL induction regimens. This results in complete remission (CR) rates of 70% to 90% and median remission durations of 18 months^(30,31). Patients who achieve CR subsequently transition to the consolidation phase, which, depending on the risk-oriented subtype, may consist of consolidation chemotherapy (cytarabine, methotrexate, cyclophosphamide, and 6-mercaptopurine) or allogeneic hematopoietic stem-cell transplantation (AH SCT). Consolidation is followed by prolonged maintenance therapy with daily 6-mercaptopurine, weekly methotrexate, and monthly pulses of vincristine and prednisone or dexamethasone, given over 2 to 3 years (POMP or DOMP, depending on corticosteroid used)⁽³⁰⁻³²⁾. Maintenance, which is omitted in mature B-ALL due to high cure rates, may also involve the use of TKIs for patients with Ph-positive ALL. Primary CNS involvement at diagnosis is rare (<10%) but is as high as 50% to 75% at 1 year without prophylactic administration of intrathecal chemotherapy (IT)⁽³¹⁾. Although high-dose cytarabine (1-7.5 mg/m²) and methotrexate (5-8 g/m²) successfully penetrate the blood-brain barrier, they are too toxic to serve as the sole CNS prophylaxis. The inclusion of IT prophylaxis (methotrexate, cytarabine, liposomal cytarabine, hydrocortisone, or thiotepe) reduces the incidence of CNS relapse to 4% by allowing sustained therapeutic concentration of the agents in the cerebrospinal fluid. The number of ITs varies according

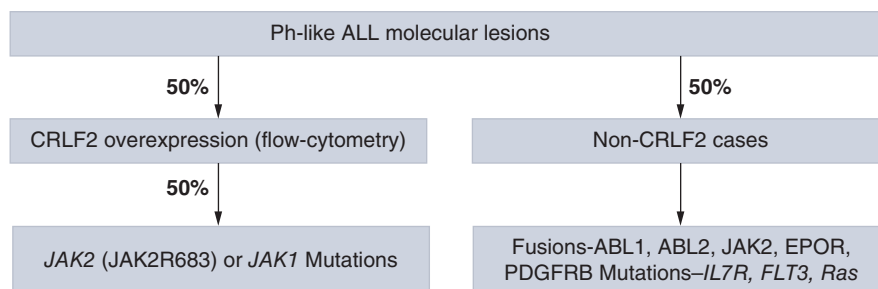

FIGURE 1-2 Ph-like acute lymphoblastic leukemia (ALL) molecular lesions and associated molecular fusions or mutations.

Table 1-3 Recent Genetic Determinants in ALL by Lineage

ALL Lineage	Cytogenetic Aberration	Involved Genes	Protein	Comments
B cell	BCR/ABL+ (Ph+)	<i>IKZF1</i>	Ikaros	Poor outcome. 80% of Ph+ cases.
		<i>CRLF2</i> + the Ig heavy chain locus; or an interstitial <i>PAR1</i> deletion	<i>CRLF2</i>	5%-10% of cases with no molecular rearrangement. Poor outcome. 50% of children with Down syndrome.
	BCR/ABL-like	<i>IKZF1</i> deletions; rearrangements/mutations in <i>CRLF2</i> , <i>IGH-CRLF2</i> , and <i>NUP214-ABL1</i> ; in-frame fusions of <i>EBF1-PDGFRB</i> , <i>BCR-JAK2</i> , or <i>STRN3-JAK2</i> ; cryptic <i>IGH-EPOR</i> rearrangements		15% of cases. Potential use of TKIs and/or mTOR and JAK2 inhibitors.
	Near hypodiploid	<i>NRAS</i> , <i>KRAS</i> , <i>FLT3</i> , and <i>NF1</i>		70% of cases.
	Low hypodiploid	<i>IKZF2</i> , and by <i>TP53</i> disruptions, <i>CDKN2A/B</i> locus deletion		91% of cases.
	Hyperdiploid	<i>CREBBP</i>		
		<i>NT5C2</i> mutations	<i>NT5C2</i>	
		<i>TP53</i> mutations		6% of cases.
T cell		<i>PICALM-MLLT10</i> , <i>NUP214-ABL1</i> fusion, <i>EML-ABL1</i> , <i>SET-NUP214</i> fusion, <i>MLL</i> , <i>NOTCH1</i> , <i>FBW7</i> , <i>BCL11B</i> , <i>JAK1</i> , <i>PTPN2</i> , <i>IL7R</i> , <i>PHF6</i> , <i>RAS/PTEN</i>		<i>NOTCH1</i> (>60%) and/or <i>FBW7</i> (~20%) mutations associated with a favorable outcome. <i>RAS/PTEN</i> and <i>JAK1</i> usually poor outcome.

mTOR, mammalian target of rapamycin; TKI, tyrosine kinase inhibitor.

to protocol (usually 8 for standard risk, 12 for Ph positive, and 16 for Burkitt), and in rare cases of extramedullary disease spread (eg, masses or chloromas), IT may even be supplemented by radiation therapy.

One extensively studied regimen used in treatment of adult ALL is the hyper-CVAD (HCVAD) regimen, where patients receive hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate and cytarabine for a total of eight alternating cycles approximately every 3 to 4 weeks (Table 1-4)^(30,31). This is followed by 2 years of POMP maintenance therapy, interspersed with intensification courses during months 6, 7, 18, and 19. The number of IT injections (two per course) depends on the risk of CNS relapse, which has been identified as high for patients with mature B-ALL. Our current approach is giving 8 ITs for nonmature B-ALL and 16 ITs for mature B-ALL, resulting in a 5-year overall survival (OS) between 38% and 50%⁽³⁰⁾. Due the improved cure rates of Ph-positive ALL patients, an increase in the CNS relapse rate was observed, which is the reason the protocol was modified to include 12 ITs for Ph-positive ALL.

Mature B-Cell and Burkitt Acute Lymphoblastic Leukemia

The addition of rituximab to short intensive chemotherapy has also improved outcome in adult Burkitt

and Burkitt-type lymphoma or ALL^(29, 33, 34). Hoelzer and colleagues have recently reported the benefit of adding rituximab to short intensive chemotherapy in 363 patients with Burkitt lymphoma/leukemia; the addition of rituximab resulted in CR and 5-year survival rates of 88% and 80%, respectively⁽³³⁾. Higher rates of survival were reported in adolescents compared to adults and elderly patients (90% vs 84% vs 62%, respectively)⁽³³⁾. Low-intensity chemotherapy with infused etoposide, doxorubicin, and cyclophosphamide with vincristine, prednisone, and rituximab (EPOCH-R) was recently tested in 30 adult patients with Burkitt lymphoma⁽³⁵⁾. The progression-free survival (PFS) and OS rates were 90% and 100%, respectively. Of note, marrow involvement was present in only 13% of patients, and CNS involvement was present in only 3% of patients⁽³⁵⁾.

CD20-Positive Pre-B-Cell Acute Lymphoblastic Leukemia

There have been several alterations to traditional protocols with further refining of the disease. Expression of cell surface marker CD20 in adult ALL ranges from 35% to ubiquitous depending on the subtype and has been associated with an inferior prognosis⁽¹⁸⁾. The addition of two doses of monoclonal CD20 antibody

Table 1-4 Doses and Schedule of the Hyper-CVAD Regimen

Therapy Segment	Dose and Schedule
Induction and intensified consolidation	Hyper-CVAD (courses 1, 3, 5, and 7)
	• Cyclophosphamide 300 mg/m ² IV over 3 h every 12 h for 6 doses on days 1-3
	• Mesna 600 mg/m ² as an IV continuous infusion over 24 h daily on days 1-3 (starting approximately 1 h prior to cyclophosphamide and finishing 12 h after the last dose)
	• Doxorubicin 50 mg/m ² IV continuous infusion over 24 h on day 4
	• Vincristine 2 mg IV on days 4 and 11
	• Dexamethasone 40 mg daily on days 1-4 and 4-11
	Methotrexate (MTX) and high-dose cytarabine (courses 2, 4, 6, and 8)
	• MTX 200 mg/m ² IV over 2 h followed by 800 mg/m ² IV over 22 h on day 1
	• Leucovorin rescue 15 mg every 6 h for eight doses (starting 12 h after completion of MTX)
	• Cytarabine 3 g/m ² IV over 2 h every 12 h for 4 doses on days 2 and 3
	• Methylprednisolone 50 mg IV twice daily on days 1-3
CNS prophylaxis	IT MTX 12 mg (6 mg if via Omayo reservoir) on day 2 and cytarabine 100 mg on day 7 of each course
	Low risk: 6 IT
	High risk: 8 IT
	Mature B cell: 16 IT
Maintenance therapy	POMP
	• 6-Mercaptopurine 50 mg orally three times per day
	• MTX 20 mg/m ² orally weekly
	• Prednisone 200 mg orally days 1-5 every month
	• Vincristine 2 mg IV every month
	• Intensification with four additional courses of hyper-CVAD plus MTX/cytarabine
Supportive care	• Antibiotic prophylaxis (levofloxacin, fluconazole, valacyclovir)
	• Hematopoietic growth factor support during induction and consolidation
	• Laminar air flow rooms (for patients ≥60 years old)

CNS, central nervous system; IT, intrathecal; IV, intravenous.

(rituximab) administered with the first four cycles of chemotherapy and during maintenance intensification at months 6 and 18 resulted in improved OS in younger patients compared with similar chemotherapy historical controls (75% vs 47% at 3 years; $P = .003$)⁽³⁶⁾. Improvement in the 5-year remission duration and survival rates was also reported in patients <55 years old by the German Multicenter Study Group for ALL (GMALL) when rituximab was added to standard induction and consolidation therapy⁽³⁷⁾.

Ofatumumab is a more potent second-generation anti-CD20 monoclonal antibody that binds to a membrane proximal small-loop epitope on the CD20 protein. A phase II study in CD20-positive pre-B-ALL combined ofatumumab with HCVAD during induction, resulting in a 96% rate of both CR and MRD negativity. At a median follow-up of 14 months, the 1-year PFS and OS rates were 94% and 92%, respectively⁽³⁸⁾.

Philadelphia-Positive Acute Lymphoblastic Leukemia

Philadelphia-positive ALL used to have a very poor outcome in general. The incorporation of TKIs into treatment regimens has significantly improved patient outcomes, as supported by several reports⁽³⁹⁻⁴²⁾. Incorporation of early, daily, and concurrent TKI with chemotherapy has proven more effective than intermittent pulses^(41, 42).

Second-generation TKIs, such as the dual src and abl inhibitor dasatinib, which is more potent than imatinib and crosses the blood-brain barrier⁽⁴³⁾, have also been investigated in combination with chemotherapy. In an attempt to improve on the outcomes with imatinib, dasatinib was administered at 100 mg daily for 14 days with induction chemotherapy, followed by 70 mg continuous dosing with the consolidation cycles, and at

100 mg daily continuously during the maintenance phase⁽⁴⁴⁾. Overall, 94% of patients achieved CR, 96% achieved complete cytogenetic response (CCyR), and 65% achieved complete molecular response (CMR). Allogeneic hematopoietic stem-cell transplantation was performed in 22 patients (12 in first CR and 10 in second CR), with 3-year disease-free survival (DFS) and OS rates of 49% and 61%, respectively.

Attempting to reduce exposure to cytotoxic chemotherapy by intensifying chemotherapy with TKIs can be very effective but toxic^(45, 46). Patients in the GRAAPH-2005 study were randomized to imatinib 800 mg daily for 4 weeks combined with weekly vincristine and dexamethasone versus imatinib 800 mg daily for 2 weeks combined with HCVAD chemotherapy⁽⁴⁵⁾. The CR rate was higher in the low-intensity group due to induction-related mortality in the HCVAD group (7% vs <1%; $P = .01$). An equal number of patients in each group proceeded to autologous stem cell transplantation and allogeneic stem cell transplantation, and at 3 years, OS was similar between the two arms (53% for low intensity vs 49% for HCVAD; $P = .61$).

Studies have also evaluated the use of dasatinib and nilotinib with low-intensity chemotherapy⁽⁴⁶⁻⁴⁸⁾. In the EWALL-Ph-01 study, dasatinib with low-intensity chemotherapy was administered to 71 patients with newly diagnosed Ph-positive ALL age ≥ 55 years⁽⁴⁶⁾. Dasatinib was dosed at 140 mg once daily during induction and at 100 mg daily during consolidation, yielding a CR rate of 94%. The estimated 3-year OS was 45%.

Many Ph-positive ALL patients can relapse with threonine-to-isoleucine mutation at position 315 (T315I), which is refractory to imatinib and second-generation TKIs. A third-generation TKI, ponatinib, which has activity against T315I, was evaluated in phase I and II trials in patients with Ph-positive leukemias and was shown to have significant antileukemic activity^(49, 50). More recently, 39 patients with newly diagnosed Ph-positive ALL were treated with HCVAD and ponatinib 45 mg daily for 14 days during induction and then continuously thereafter until CCyR and CMR were obtained, when decreases to 30 mg and 15 mg daily could be instituted, respectively. The CR, CCyR, and CMR rates were 100%, 100%, and 74%, respectively. After a median follow-up of 20 months, 1-year PFS and OS were 97% and 87%, respectively⁽⁵¹⁾.

Although current standard of care still advocates AHSCT consolidation in first CR⁽³⁹⁾, new information regarding the status of MRD in Ph-positive ALL has raised a question as to who should be referred for it. The predictive value of MRD assessment by quantitative reverse transcriptase polymerase chain reaction (RT-PCR) and multiparameter flow cytometry (FCM) was recently assessed in patients with Ph-positive ALL treated with combination chemotherapy and TKIs who did not undergo AHSCT. Achieving major molecular

response at 3, 6, 9, and 12 months ($P = .02, .04, .05$, and $.01$, respectively) and having negative FCM at 3 and 12 months were associated with improved survival ($P = .04$ and $.001$, respectively)⁽⁵²⁾. This information suggests that patients with early and sustained molecular response may not need consolidation with AHSCT.

T-Cell Acute Lymphoblastic Leukemia

Treatment of adult T-ALL and T-cell lymphoblastic lymphoma (T-LL) results in a long-term survival rate of 40% to 60%, and the outcome is strongly associated with T-cell phenotype^(53, 54). Adding nelarabine, a selective anti-T-ALL agent may further improve the outcome. In a single-arm, phase II study, 48 patients with newly diagnosed T-ALL or T-LL were treated with HCVAD and nelarabine⁽⁵⁵⁾. The CR rate was 93%; the 5-year survival rate was 66% after a median follow-up of 41 months. These rates were 38% and 70% for patients with early T-cell precursor (ETP) and mature T-ALL, respectively. Indeed, ETP-ALL is a distinct T-cell entity characterized by the absence of CD1a, sCD3, and CD8 expression; weak CD5 expression; and expression of one or more myeloid or stem cell-associated markers⁽⁵⁴⁾. It confers poor prognosis with the use of standard intensive chemotherapy, which results in high rates of remission failure and relapse compared to patients with typical T-ALL (72% at 10 years vs 10% at 10 years). This phenotype is in part a reflection of the higher degree of genomic instability (number and size of genetic defects) that ETP-ALL harbors, with over 60% of adult patients carrying mutations in *DNMT3A*, *FLT3*, or *NOTCH1*, which may allow for tailored induction regimens with targeted therapies⁽⁵⁶⁾. Following induction, AHSCT should be considered in first remission for all ETP-ALL patients.

Adolescent and Young Adult Acute Lymphoblastic Leukemia

Retrospective studies have shown that pediatric regimens resulted in better outcomes than adult regimens (which had deviated significantly from the established principles of ALL therapy in pediatric regimens). Pediatric-inspired regimens, such as the Berlin-Frankfurt-Münster (BFM) regimen (Table 1-5), deliver more intensive nonmyelosuppressive agents like vincristine, asparaginase, corticosteroids, and CNS therapy^(54, 55).

The Group for Research on Adult Acute Lymphoblastic Leukemia (GRAALL) evaluated a pediatric-inspired regimen in patients up to age 60 years and compared the results to a historical control group treated with an adult regimen. In patients treated with the pediatric-inspired regimen, the CR rate was 93%, and at 42 months, event-free survival (EFS) and OS rates were 55% (95% CI, 48%-52%) and 60% (95% CI, 53%-66%), respectively⁽⁵⁷⁾.

Table 1-5 Doses and Schedule of the Augmented Berlin-Frankfurt-Münster (BFM) Regimen

Therapy Segment	Dose and Schedule
Induction (4 weeks)	IT cytarabine 100 mg within 3 days prior to start of induction
	Daunorubicin 25 mg/m ² IV weekly for 4 doses
	Vincristine 2 mg IV weekly for 4 doses
	Prednisone 60 mg/m ² /d orally in divided doses on days 1-28
	PEG-asparaginase 2,500 international units/m ² IV during week 1
	IT Methotrexate 12 mg during weeks 2 and 5
Extended induction (2 weeks)	Daunorubicin 25 mg/m ² IV during week 1
	Vincristine 2 mg IV weekly for 2 doses
	Prednisone 60 mg/m ² /day orally in divided doses for 14 days
	PEG-asparaginase 2500 international units/m ² IV during week 1
Consolidation 1 (8 weeks)	Cyclophosphamide 1 g/m ² IV during weeks 1 and 5
	Cytarabine 75 mg/m ² subcutaneously or IV on days 1-4 and 8-11 of each month
	6-Mercaptopurine 60 mg/m ² /day orally on days 1-14 of each month
	Vincristine 2 mg IV during weeks 3 and 4 of each month
	PEG-asparaginase 2500 international units/m ² IV during weeks 3 and 6
	IT methotrexate 12 mg weekly for 4 weeks
Consolidation 2 (7 weeks)	Vincristine 2 mg IV every 10 days for 5 doses
	Methotrexate, starting at 100 mg/m ² and escalating by 50 mg/m ² /dose every 10 days for 5 doses
	PEG-asparaginase 2,500 IU/m ² IV during weeks 1 and 4
	IT methotrexate 12 mg during weeks 1 and 5
Consolidation 3—part A (4 weeks)	Vincristine 2 mg IV weekly for 3 doses
	Dexamethasone 10 mg/m ² /d orally in divided doses on days 1-7 and days 15-21
	Doxorubicin 25 mg/m ² IV weekly for 3 doses
	PEG-asparaginase 2,500 IU/m ² IV during week 1
	IT methotrexate 12 mg during week 1
Consolidation 3—part B (4 weeks)	Cyclophosphamide 1 g/m ² IV during week 1
	Cytarabine 75 mg/m ² subcutaneously or IV for 4 consecutive days during weeks 1 and 2
	Thioguanine 60 mg/m ² /d orally for 14 days
	Vincristine 2 mg IV during weeks 3 and 4
	PEG-asparaginase 2,500 IU/m ² IV during week 3
	IT methotrexate 12 mg during weeks 1 and 2
Maintenance (24 months)	Vincristine 2 mg IV monthly
	Dexamethasone 6 mg/m ² /d orally for 5 days every month
	6-Mercaptopurine 75 mg/m ² /d in divided doses
	Methotrexate 20 mg/m ² orally weekly
	IT methotrexate 12 mg every 3 months for the first 12 months of maintenance
Supportive care	Antibiotic prophylaxis (levofloxacin, trimethoprim/sulfamethoxazole [start week 2 of induction], fluconazole, valacyclovir)

Slow early responders repeat consolidation 2 and consolidation 3A and 3B prior to maintenance therapy. If central nervous system disease is present at start of therapy, then give methotrexate 12 mg IT weekly until negative for blasts, methotrexate 12 mg IT every other week for 8 doses, and then methotrexate 12 mg IT monthly for 6 months.

IT, intrathecal; IV, intravenous.

Although the pediatric-inspired regimen resulted in improved survival compared with the control (66% vs 44%; $P < .001$), the cumulative incidence of treatment-related death in patients age 40 to 60 years old was 23%, erasing the margin of benefit gained with enhanced activity of pediatric regimens. Thus, the toxicity threshold can be reached and crossed in the adult population in attempts to reach higher cure rates, limiting the usefulness of intensifying chemotherapy to the pediatric-inspired strength.

The UKALL14 study of 91 adults with a median age of 47 years (range, 25-65 years) used PEG-asparaginase at a dose of 1,000 units/m² on days 4 and 18 during induction, resulting in a CR rate of 66%, with induction-related mortality rate of 20% and hepatotoxicity rate of 56%, prompting the omission of PEG-asparaginase in patients ≥ 40 years old⁽⁵⁸⁾.

A recent US Intergroup study of 318 adolescent and young adult (AYA) patients (median age, 24 years) treated with a pediatric-inspired regimen was reported. With a median follow-up of 28 months, the estimated 5-year EFS and OS rates were 45% and 55%, respectively⁽⁵⁹⁾. Presence of MRD at day 28 following initiation of induction therapy and presence of a Ph-like gene expression signature were significantly associated with worse EFS and OS. The Ph-like signature, which was detected in 28% of patients, resulted in 2-year EFS of only 52%, compared to 81% for those without Ph-like disease.

Our internal review of 85 AYA patients up to age 40 (median age, 21 years) treated with pediatric-like augmented BFM showed CR and MRD negativity rates of 94% and 69%, respectively⁽⁶⁰⁾. The 5-year CR rate was 58%, and the 5-year OS rate was 62%. Compared with a historical control group of similar patients who received HCVAD with or without rituximab, 3-year OS rates were 72% and 71%, respectively. However, in patients age 25 years and older, the pediatric-inspired regimen was inferior and caused more liver dysfunction, pancreatitis, osteonecrosis, and thrombosis compared to HCVAD with CD20-targeted therapies.

Hence, HCVAD-based regimens that use the backbone ALL agents but eliminate or reduce the exposure to asparaginase show similar CR and remission rates and survival outcomes compared with the pediatric-inspired regimens in similar patient populations.

Acute Lymphoblastic Leukemia in Elderly Patients

Conventional ALL chemotherapy is associated with high mortality rates (30%-35%) during consolidation/maintenance in elderly patients (>60 years)⁽⁶⁰⁾. A low-intensity regimen may improve outcome. In a phase II study with inotuzumab ozogamicin and low-intensity hyper-CVD therapy, 26 patients with a median age of 67 years (range, 60-79 years) were treated for newly

diagnosed ALL⁽⁶¹⁾. Inotuzumab, which is a CD22-directed monoclonal antibody bound to calicheamicin (chemotoxin), was administered at a dose of 1.3 to 1.8 mg/m² once with each of the first four courses; doxorubicin was eliminated in induction; cyclophosphamide and steroids were 50% reduced; methotrexate was reduced to 250 mg/m² on day 1 and cytarabine to 0.5 mg/m² $\times 4$ on days 2 and 3 of even courses. The overall response rate (ORR) was 96% (CR, 79%; CR with incomplete platelet recovery [CRp], 17%), with all patients with cytogenetic abnormalities achieving CCyR. All responders also achieved MRD-negative status, 75% of which occurred after cycle 1. The 1-year PFS and OS rates were 86% and 81%, respectively. The 1-year survival rate was superior to previous results obtained with HCVAD with or without rituximab in similar patient populations (1-year OS, 81% vs 60%, respectively).

Role of Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation has traditionally been reserved for patients with high-risk features including B-lineage with WBC $\geq 30 \times 10^9/L$, T-lineage with WBC $\geq 100 \times 10^9/L$, hypodiploid, Ph-positive, or mixed-lineage leukemia translocation ALL [eg, t(4;11)]. However, there has been some debate regarding who should be referred for AHSCT in first CR based on recent data that indicate that patients with standard-risk disease, and not high-risk disease, benefit the most⁽⁶²⁾. As an alternative, many centers have incorporated MRD via FCM or RT-PCR after induction or consolidation to stratify patients based on their response to chemotherapy⁽⁶³⁾. In fact, when controlled for other known risk factors, failure to achieve MRD has emerged as a powerful indicator of future relapse⁽⁵²⁾ and therapeutic approach (ie, AHSCT vs more chemotherapy). In one study, MRD status at various time points after CR was used to guide treatment in adult patients with ALL⁽⁶⁴⁾. Patients who remained MRD positive at the end of consolidation were deemed to be higher risk and underwent AHSCT instead of receiving prolonged maintenance therapy. Patients who achieved MRD-negative status had a significantly improved 5-year OS (75% vs 33%; $P = .001$). Furthermore, in a recent update of the GRAALL experience in 423 younger adults with Ph-negative ALL in first remission (265 B-cell precursor ALL and 158 T-ALL patients), postinduction MRD level $\geq 10^{-4}$ and unfavorable genetic characteristics (ie, *MLL* gene rearrangement or focal *IKZF1* gene deletion in B-cell precursor ALL and no *NOTCH1/FBXW7* mutation and/or *N/K-RAS* mutation and/or *PTEN* gene alteration in T-ALL) were independently associated with worse outcome⁽⁶⁵⁾. Therefore, for patients with standard-risk ALL, MRD status should guide the

postremission therapy, whereby patients who fail to achieve MRD negativity can be transplanted in first CR. In addition to the MRD status, new genomic and immunophenotyping technologies were essential in identifying patients with poor prognosis. Patient with Ph-like ALL and ETP-ALL should be considered for AHSCT in first CR ^(24, 54).

Minimal Residual Disease

Postinduction assessment for persistence or reemergence of MRD in patients with ALL is the most important adverse prognostic factor and identifies chemorefractory disease ^(64, 66, 67). Virtually all adults with ALL and molecular failure exhibit poor prognosis despite continued chemotherapy and are candidates for stem-cell transplantation and targeted therapies ⁽⁶⁸⁾.

The Programa Español de Tratamientos en Hematología (PETHEMA) ALL-AR-03 trial in adolescent and adult patients with high-risk Ph-negative ALL showed poor MRD clearance by FCM after early consolidation and identified the pattern of MRD clearance as the only prognostic factor for DFS and OS ⁽⁶⁹⁾.

Blinatumomab is a bispecific T-cell engaging (BiTE) antibody and is the first agent in its class that engages host T cells to the target cell surface antigen-expressing cancer cells. It contains the variable domains of a CD19 and a CD3 antibody, joined via nonimmunogenic linker ⁽⁷⁰⁾. Cytotoxic T cells are activated upon binding to CD19, inducing cell death through the perforin system. Given the pharmacokinetics of the construct (short half-life and the mechanism of action), continuous infusion over several weeks resulted in significantly improved drug activity in ALL and minimization of side effects. Twenty-one patients in hematologic and morphologic CR with persistent or reappearing MRD during consolidation were first studied with a blinatumomab dose of 15 $\mu\text{g}/\text{m}^2/\text{d}$ as a continuous infusion for 28 days every 6 weeks for a total of 4 cycles or proceeded to AHSCT if a donor was available ⁽⁷¹⁾. Minimal residual disease conversion following one cycle of therapy was seen in 80% of patients. After a median follow-up of 33 months, 60% of patients remained in CR, with the same percentage of patients experiencing estimated 3-year refractory-free survival ⁽⁷²⁾. Nontransplanted patients had a similar favorable outcome compared to the nine patients who underwent AHSCT.

A recent confirmatory, open-label, multicenter, phase II trial of blinatumomab in 116 patients with MRD-positive B-cell precursor ALL in CR resulted in overall MRD eradication in 80% of patients, almost all (78%) after a single cycle of therapy ⁽⁷³⁾. As a result, the MD Anderson Cancer Center (MDACC) will open a trial evaluating the role of blinatumomab in patients with positive MRD in CR.

SALVAGE THERAPY

The prognosis of adult patients with relapsed ALL remains poor, with limited effective therapies available. Relapsed disease carries a median survival of only 24 weeks, and patients who have short duration of first CR or primary refractory disease do particularly poorly, with a median OS of less than 5 months ⁽⁷⁴⁾. The goal of salvage therapy is to reinduce CR and consolidate with an AHSCT. Given that we currently lack agents or regimens that can singularly achieve cure in the relapsed setting, patients should be enrolled on a clinical trial if possible. Choice of salvage is contingent upon the previous treatment history, remission duration, ongoing comorbidities, and the relapse-specific features that may be targetable.

Asparaginase could be incorporated into salvage for patients without previous exposure to it. This can be achieved through the augmented HCVD protocol designed at MDACC, which intensifies the standard vincristine and corticosteroid backbone and adds the pegylated asparaginase ⁽⁷⁵⁾. In an initial study, 80% of 88 evaluable patients initially received conventional HCVD and 76% were receiving this regimen in first salvage. The ORR was 64%; 47% of patients achieved CR, whereas the remainder achieved partial response (PR) or CRp. Twenty-eight patients (32%) underwent AHSCT, 19 of whom were in CR at the time of transplantation. Despite the favorable response rate, median OS was 6 months, with some long-term responders. As such, regardless of whether they have received conventional HCVD previously, this regimen represents a reasonable choice for relapsed patients with good performance status who can tolerate intensive chemotherapy.

Clofarabine is a new-generation purine nucleoside analog modeled after fludarabine and cladribine that is approved as a third-line therapy for pediatric ALL ⁽⁷⁶⁾. Attempts have been made in both pediatric and adult population to build on its modest activity as a single agent by combining it with other chemotherapeutics ⁽⁷⁷⁻⁷⁹⁾. In a phase II multicenter study evaluating clofarabine added to cyclophosphamide and etoposide in 25 heavily relapsed refractory pediatric patients, ORR was 44% (7 patients with CR), and 10 patients eventually underwent AHSCT ⁽⁷⁷⁾. Patients with prior AHSCT were excluded due to a high rate of veno-occlusive disease (VOD). In the adult population, a French group evaluated clofarabine in patients with relapsed ALL by combining it with dexamethasone, mitoxantrone, etoposide, and asparaginase (VANDEVOL, $n = 37$) or with cyclophosphamide (ENDEVOL, $n = 18$) ⁽⁷⁸⁾. Complete remission was achieved in 41% and 50% of patients, respectively, and less than one-third of patients received subsequent AHSCT. The median OS was 6.5 months. The PETHEMA group reported on 31 heavily pretreated relapsed/refractory

adult ALL patients, of whom 84% had received two or more previous treatment regimens⁽⁷⁹⁾. Complete remission was achieved in 26% of patients, with a median OS of approximately 3 months.

Nelarabine is soluble prodrug of 9- β -D-arabinofuranosylguanine and is approved as a nucleoside analog. It has predominant activity in patients with relapsed T-ALL who have failed two prior regimens. By selectively accumulating in T cells, it lends itself as particularly useful in this subset of patients. The GMALL group analyzed 126 patients with relapsed T-ALL/lymphoma who received two cycles of nelarabine as a single agent, with a goal to consolidate patients in CR with AHSCT (partial responders appeared to have potential to achieve CR with continued therapy)⁽⁸⁰⁾. After one to three cycles, the CR rate was 36%, with 80% receiving AHSCT. Median OS for the entire cohort was only 6 months, with a 12% probability of survival at 3 years; those who underwent AHSCT after CR had a far better outcome, with a 3-year OS probability of 36%. The major toxicity of nelarabine is neurotoxicity; however, this study noted a low rate of grade 3/4 neurotoxicity, even in patients with prior heavy exposure to vincristine. Nelarabine remains a viable salvage option, and its use continues to be optimized in the frontline combination setting or with alternative dosing schedules⁽⁸¹⁾.

Vincristine is a standard component of almost all regimens in both adult and pediatric ALL and is frequently capped at 2 mg due to compromising dose-limiting neurotoxicity manifested as peripheral neuropathy or moderate to severe constipation. In an effort to optimize its pharmacodynamics and delivery, a liposomal formulation was synthesized. A phase II study evaluated 65 patients with relapsed and refractory ALL with vincristine sulfate liposome administered as a weekly intravenous infusion at 2.25 mg/m² with no capping parameter⁽⁸²⁾. In this heavily pretreated population, the ORR was 35%, and 12 patients underwent AHSCT. Grade 3 peripheral neuropathy was observed in 15% of patients, and the median OS was 4.6 months (five patients were alive at 12 months).

NOVEL STRATEGIES WITH IMMUNOTHERAPY

Monoclonal Antibodies

Further intensification of conventional regimens has been limited by unfavorable toxicity/antileukemic profile. The development of monoclonal antibodies directed against cell surface antigens that are better tolerated has since led to significant improvement in outcomes for a number of malignancies, including ALL.

Blinatumomab, a bispecific antibody (anti-CD3 and anti-CD19), was studied in patients with relapsed/refractory ALL as a continuous infusion for 28 days every 6 weeks. The ORR (CR or CRp) with two cycles of therapy was 68%, with an estimated median OS of 9 months⁽⁸³⁾. In an open-label, single-arm, multicenter phase II study in 189 patients with relapsed/refractory disease, the ORR was 43%, with 80% of the responses during the first cycle. The median response duration and OS were 9 and 6 months, respectively⁽⁸⁴⁾. Blinatumomab causes constitutional symptoms (fever, chills) that coincide with a rapid rise in activated T cells, leading to secondary cytokine release syndrome (CRS) that occurs shortly after the start of therapy⁽⁸⁵⁾. It can be mitigated with the short course of steroids. Blinatumomab is currently being evaluated in a phase II study in patients with relapsed Ph-positive ALL and in a phase III trial in patients with ALL in first or second relapse (blinatumomab vs investigator's choice of therapy). In a priority review designated by the US Food and Drug Administration, blinatumomab was granted accelerated approval in December 2014 for the treatment of patients with Ph-negative, relapsed or refractory B-ALL.

Inotuzumab ozogamicin is a CD22 immunoconjugate linked to calicheamicin, which is a potent cytotoxic inducer of double-strand DNA breaks. A single-institution phase II study of inotuzumab in 49 patients with highly relapsed/refractory ALL (73% receiving two or more salvage therapies) treated every 3 to 4 weeks resulted in an ORR of 57%, with a median OS of 5.1 months. Survival was comparable between patients who underwent a subsequent AHSCT and those who did not. Serious toxicity in the transplant group included the development of VOD in five patients (23%), although four of these patients had multiple prior alkylating therapies. A modified weekly dosing schedule developed based on preclinical studies yielded a similar ORR to the single-dose schedule (59% vs 57%), with a median survival of 9.5 months. This mode of delivery was less toxic, and hepatotoxicity was also significantly reduced, including a 7% incidence of VOD after autologous stem cell transplantation. An additional multicenter phase I/II study of 37 patients with relapsed/refractory ALL, in which 54% of patients were receiving two or more salvage therapies, also evaluated weekly inotuzumab. The CR and CRp rates were 79% (19/24) and 46% (6/13) in the dose-expansion and dose-escalation cohorts, respectively. Among the responders, 22 patients achieved MRD negativity. Furthest along in the development process, inotuzumab was investigated and compared in a randomized trial to physician's choice of therapy in patients with ALL in first and second salvage. Early results have shown a significant improvement in the response rate (CR/CR with incomplete hematologic

recovery) favoring inotuzumab versus standard-of-care intensive chemotherapy (80.7% vs 33.3%, $P < .0001$)⁽⁸⁶⁾. Survival data are maturing.

Chimeric Antigen Receptor T Cells

Autologous T cells can be engineered to express a receptor directed at CD19. Response can be durable given the ability of T cells to expand and persist in vivo. As such, chimeric antigen receptor (CAR) T cells have become an effective approach for targeting lymphoid malignancies^(87, 88). In a pilot study with 25 children and 5 adults who were treated for relapsed/refractory ALL with CTL019, 27 patients (90%) achieved CR, with 6-month EFS and OS rates of 67% and 78%, respectively⁽⁸⁹⁾. In a recent phase I trial of 21 children and young adults with relapsed/refractory ALL treated with CAR T cells after lymphodepletion, 21 evaluable patients (70%) achieved CR, with 12 (60%) achieving MRD negativity. At a median follow-up of 10 months, the OS rate was 52%⁽⁹⁰⁾. In another study

of relapsed refractory ALL with antecedent detectable disease before T-cell infusion, 14 patients (88%) showed response, 10 (63%) with CR and 4 (25%) with CRp. Overall, 75% of treated patients achieved MRD negativity⁽⁹¹⁾. Patients responding to this form of therapy invariably develop some degree of CRS, which is usually very manageable with steroids or tocilizumab. Ongoing research is trying to identify the most optimal use of this innovative therapeutic strategy.

EMERGING THERAPIES: MD ANDERSON APPROACH

A number of innovative therapies for various stages of disease, tailored to risk-adapted strategies, are transforming the treatment of adult ALL and are beginning to result in significant improvements in long-term outcomes. There are several ongoing trials available for patients with ALL at our institution and elsewhere in the frontline and salvage setting (Table 1-6). Our

Table 1-6 Ongoing Trials at MD Anderson Cancer Center and Elsewhere Available for Patients With ALL (Frontline and Salvage Setting)

ALL Subgroup	Trial Characteristics	
	Frontline Setting	Salvage Setting
Pre-B-cell ALL	<i>Age <40 years</i> 1. Ofatumumab + augmented BFM <i>Age 40-59 years</i> 1. Hyper-CVAD + ofatumumab 2. Hyper-CVAD + liposomal vincristine <i>Elderly (≥60 years)</i> 1. Mini-hyper-CVD + inotuzumab	1. Mini-hyper-CVD + inotuzumab 2. Low-dose inotuzumab (0.9 mg/m ²) 3. Chimeric antigen receptor (CAR) T-cell therapies
Pre-B-cell ALL, MRD+ disease	Blinatumomab	
T-cell ALL	Hyper-CVAD + nelarabine	
Burkitt leukemia, de novo or relapsed refractory	1. Dose-adjusted EPOCH + ofatumumab/rituximab 2. Hyper-CVAD + ofatumumab	
Philadelphia-positive ALL	Hyper-CVAD + ponatinib	Inotuzumab + bosutinib
Philadelphia-like ALL		A phase II study assessing the combination of ruxolitinib or dasatinib + chemotherapy for refractory/relapsed disease
Mixed phenotype acute leukemia (MPAL), de novo and relapsed	Clofarabine, idarubicin, cytarabine, vincristine, and corticosteroid +/- rituximab	
Novel treatment strategies	1. Nelarabine (single-agent) continuous infusion 2. BMS-906024 (NOTCH inhibitor) 3. Ibrutinib 4. Intrathecal rituximab in patients with lymphoid malignancies involving the central nervous system	

BFM, Berlin-Frankfurt-Münster; CVAD, cyclophosphamide, vincristine, doxorubicin, dexamethasone; CVD, cyclophosphamide, vincristine, dexamethasone; EPOCH, etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin; MRD, minimal residual disease.

Table 1-7 MD Anderson Cancer Center Choice of Therapy for ALL Subtypes

Subtype of ALL	Therapy
Pre-B-cell ALL CD20 ⁺	Hyper-CVAD + ofatumumab
T-cell ALL	Hyper-CVAD + nelarabine
Elderly (≥60 years) B-cell ALL	Mini-hyper-CVD + inotuzumab
Burkitt lymphoma/leukemia	Hyper-CVAD + ofatumumab/ Dose adjusted EPOCH-ofatumumab/ rituximab
Ph-positive ALL	Hyper-CVAD + ponatinib
Ph-like-positive ALL	Chemotherapy + ruxolitinib/ dasatinib
Mixed phenotype acute leukemia	Clofarabine, idarubicin, cytarabine, vincristine, corticosteroids +/- rituximab
Adolescent and young adult	Hyper-CVAD + ofatumumab Augmented BFM + ofatumumab

CVAD, cyclophosphamide, vincristine, doxorubicin, dexamethasone;
CVD, cyclophosphamide, vincristine, dexamethasone; EPOCH, etoposide,
prednisolone, vincristine, cyclophosphamide, doxorubicin.

choice of therapy for particular ALL subtypes is outlined in [Table 1-7](#).

CONCLUSION

Therapeutic capabilities in adult ALL have rapidly reached new heights over the past decade with the introduction of highly promising monoclonal antibodies, immune conjugates, CAR T cells, and new-generation TKIs. Rituximab has repeatedly been shown to improve OS, and blinatumomab and inotuzumab have demonstrated significant activity in a highly relapsed/refractory population. Genomic profiling has identified new prognostic markers (eg, *IKZF1*), as well as new therapeutic targets (eg, ABL, JAK, ETV6-NTRK3) that are amenable to targeted therapies that can improve the adverse prognosis of Ph-like ALL. As many of the newer agents advance through the final stages of development, we will be seeking to determine optimal combination and order of delivery and the role of cytotoxic chemotherapy in the safest achievement of durable cure rates. Although the role of these agents still continues to be defined, frontline introduction of most effective therapies can be expected to increase the rate of MRD negativity, optimizing responses and closing the outcome gap separating pediatric from adult ALL. Harnessing the full potential of the immune system with the durable presence of autologous T-cell constructs may ultimately lead to obviation of stem cell transplantation in search of better cure rates in adult ALL.

Adult Acute Myeloid Leukemia

Jasleen K. Randhawa
Joseph Khoury
Farhad Ravandi-Kashani

Acute myeloid leukemia (AML) consists of a heterogeneous group of hematologic neoplasms characterized by clonal proliferation of myeloid blasts in the peripheral blood, bone marrow, and extramedullary tissues. Despite advances in our understanding of the molecular biology of AML, its treatment remains challenging and outcomes vary greatly depending on the cytogenetic and molecular features as well as age and comorbidities.

INTRODUCTION

Acute myeloid leukemia is thought to be the culmination of genetic mutations and chromosomal aberrations within myeloid precursors resulting in disrupted differentiation, excessive proliferation, and suppressed apoptosis of neoplastic cells referred to as *blasts*.

Over the last several decades, improvements in chemotherapeutic regimens and supportive care have resulted in significant but modest progress in treating AML. Better understanding of the biology of AML has resulted in the identification of new therapeutic targets. Despite this, currently, the majority of patients with AML die from the complications of their disease. With better definition of molecular abnormalities and elucidation of the pathogenic events in various AML subtypes and with the development of novel targeted agents, a better outcome for patients with AML may be achievable in the future.

EPIDEMIOLOGY, ETIOLOGY, AND RISK FACTORS

Approximately 13,000 individuals are diagnosed annually in the United States with leukemia. The incidence of AML is 4.3 per 100,000 (¹). The median age at presentation is about 65 years. The incidence of AML, as well as myelodysplastic syndrome (MDS), appears to be rising, particularly in individuals over 60 years of age. The incidence of AML is slightly higher in males and in populations of European descent. Acute promyelocytic leukemia (APL), a distinct subtype of AML, has been reported to be more common among populations of Hispanic background (²).

An increased incidence of AML is seen in patients with disorders associated with increased chromatin fragility such as Bloom syndrome, Fanconi anemia, Kostmann syndrome, and Wiskott-Aldrich syndrome or ataxia-telangiectasia. Other syndromes, such as Down (trisomy of chromosome 21), Klinefelter (XXY and variants), and Patau (trisomy of chromosome 13) syndromes, have also been associated with a higher incidence of AML (³).

Therapeutic radiation increases AML risk, particularly if given concomitantly with alkylating agents. Two categories of therapy-related AML have been described. Patients exposed to alkylating agents (eg, cyclophosphamide, melphalan, nitrogen mustard) can develop AML after a latency period of 4 to 8 years, which is often associated with abnormalities of chromosomes

5 and/or 7. Exposure to agents that inhibit the DNA repair enzyme topoisomerase II (eg, etoposide) is also associated with secondary AML with a shorter latency period, usually 1 to 3 years (⁴). Benzene, smoking, dyes, herbicides, and pesticides have been implicated as potential risk factors for development of AML (⁵).

Acute myeloid leukemia may also be secondary to transformation of an antecedent myeloid disorder, such as MDS, myeloproliferative neoplasm (MPN), or MDS/MPN, or other bone marrow disorders, such as aplastic anemia.

CLINICAL PRESENTATION

Fatigue, bruising or bleeding, fever, and infection, reflecting a state of bone marrow failure, are common in AML. Only 10% of patients present with white blood cell (WBC) count greater than $100 \times 10^9/L$ (¹). These patients are at higher risk of tumor lysis syndrome, central nervous system involvement, and leukostasis. Leukostasis may manifest as dyspnea, chest pain, headaches, altered mental status, cranial nerve palsies, or priapism. Leukostasis and tumor lysis syndrome are oncologic emergencies and require prompt recognition and management.

Physical findings other than bleeding and infection may include organomegaly, lymphadenopathy, sternal tenderness, retinal hemorrhages, and infiltration of gingivae, skin, soft tissues, or meninges (more common with monocytic variants, M4 or M5). Disseminated intravascular coagulopathy (DIC) with bleeding diathesis is a common presentation in APL.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of AML is typically based on the presence of 20% myeloid blasts in the bone marrow or peripheral blood in accordance with World Health Organization (WHO) classification criteria (Table 2-1) (⁶). Acute myeloid leukemia subtypes in the WHO classification are defined on the basis of morphology, immunophenotype, and molecular/genetic features. In some patients, AML presents as a mass in extramedullary tissues (myeloid sarcoma). Patients who have the cytogenetic abnormalities $t(8;21)(q22;q22)$, $inv(16)(p13q22)$ or $t(16;16)(p13;q22)$, and $t(15;17)(q22;q12)$ are diagnosed with AML regardless of the blast percentage.

Bone marrow sampling is essential for the initial workup of a patient with suspected acute leukemia. Sampling should include a core biopsy as well as aspiration material. The core biopsy should be used to perform touch preparations, which are invaluable in case

of a dry tap. The aspiration material is used to prepare a clot and aspirate smears, in addition to having portions submitted for flow cytometry, cytogenetics, and molecular diagnostics.

Confirmation of myeloid lineage is commonly accomplished using flow cytometry. In most AML cases, blasts express one or more markers of immature hematopoietic precursors such as CD34 and HLA-DR, in addition to dim CD45 (common leukocyte antigen). Myeloid lineage is predicated on the expression of antigens associated with granulocytic, monocytic, erythroid, and/or megakaryocytic differentiation by blasts (Table 2-2). Expression of myeloperoxidase (MPO) is considered specific for myeloid differentiation, although AML blasts may lack MPO expression. Although aberrant expression of lymphoid antigens is commonly seen in some cases with a bona fide AML phenotype, such expression is generally limited to one or a few lymphoid antigens. Acute leukemia with ambiguous lineage is beyond the scope of this discussion; briefly, it refers to acute leukemia with overlapping expression of myeloid and lymphoid antigens or lack of both.

Molecular diagnostics play a critical role in the laboratory workup of AML. Whereas the scope of known molecular alterations in AML was limited until a few years ago, the advent of next-generation sequencing (NGS) has dramatically increased our understanding of the molecular landscape of AML. As a result, the limited number of polymerase chain reaction (PCR)-based assays that used to be performed during AML workup have been gradually replaced at most large facilities by NGS-based panels that simultaneously assess the mutation status of tens to hundreds of genes. The current NGS mutation panel for new and relapsed myeloid malignancies used at our institution assesses the coding sequences of the 28 genes listed in Table 2-3.

RISK STRATIFICATION OF ACUTE MYELOID LEUKEMIA

Once a diagnosis of AML has been made, the next step is to risk stratify the patient. Several variables are predictive of outcome, including patient-related variables, such as age and performance status, as well as disease-related predictors, such as cytogenetic and molecular characteristics.

The karyotype remains one of the best predictors of outcome in patients with AML. The European LeukemiaNet (ELN) guidelines have proposed a risk stratification system based on cytogenetics and molecular analysis (⁷). As listed in Table 2-4, the patients are classified as having favorable-, intermediate-, and unfavorable-risk disease.

Table 2-1 Acute Myeloid Leukemia and Related Precursor Neoplasms and Acute Leukemias of Ambiguous Lineage (World Health Organization 2008)**Myeloproliferative neoplasms (MPN)**

Chronic myelogenous leukemia, *BCR-ABL1*–positive
 Chronic neutrophilic leukemia
 Polycythemia vera
 Primary myelofibrosis
 Essential thrombocythemia
 Chronic eosinophilic leukemia, not otherwise specified
 Mastocytosis
 Myeloproliferative neoplasms, unclassifiable

Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

Myeloid and lymphoid neoplasms associated with *PDGFRA* rearrangement
 Myeloid neoplasms associated with *PDGFRB* rearrangement
 Myeloid and lymphoid neoplasms associated with *FGFR1* abnormalities

Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)

Chronic myelomonocytic leukemia
 Atypical chronic myeloid leukemia, *BCR-ABL1*–negative
 Juvenile myelomonocytic leukemia
 Myelodysplastic/myeloproliferative neoplasm, unclassifiable
Provisional entity: refractory anemia with ring sideroblasts and thrombocytosis

Myelodysplastic syndrome (MDS)

Refractory cytopenia with unilineage dysplasia
 Refractory anemia
 Refractory neutropenia
 Refractory thrombocytopenia
 Refractory anemia with ring sideroblasts
 Refractory cytopenia with multilineage dysplasia
 Refractory anemia with excess blasts
 Myelodysplastic syndrome with isolated del(5q)
 Myelodysplastic syndrome, unclassifiable
 Childhood myelodysplastic syndrome
Provisional entity: refractory cytopenia of childhood

Acute myeloid leukemia and related neoplasms

Acute myeloid leukemia with recurrent genetic abnormalities
 AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
 AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
 APL with t(15;17)(q22;q12); *PML-RARA*
 AML with t(9;11)(p22;q23); *MLL3-MLL*
 AML with t(6;9)(p23;q34); *DEK-NUP214*
 AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
 AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*

Provisional entity: AML with mutated NPM1
Provisional entity: AML with mutated CEBPA
 Acute myeloid leukemia with myelodysplasia-related changes

Therapy-related myeloid neoplasms**Acute myeloid leukemia, not otherwise specified**

AML with minimal differentiation
 AML without maturation
 AML with maturation
 Acute myelomonocytic leukemia
 Acute monoblastic/monocytic leukemia
 Acute erythroid leukemia
 Pure erythroid leukemia
 Erythroleukemia, erythroid/myeloid
 Acute megakaryoblastic leukemia
 Acute basophilic leukemia
 Acute panmyelosis with myelofibrosis

Myeloid sarcoma**Myeloid proliferations related to Down syndrome**

Transient abnormal myelopoiesis
 Myeloid leukemia associated with Down syndrome
 Blastic plasmacytoid dendritic cell neoplasm

Acute leukemias of ambiguous lineage

Acute undifferentiated leukemia
 Mixed phenotype acute leukemia with t(9;22)(q34;q11.2); *BCR-ABL1*
 Mixed phenotype acute leukemia with t(v;11q23); *MLL* rearranged
 Mixed phenotype acute leukemia, B-myeloid, NOS
 Mixed phenotype acute leukemia, T-myeloid, NOS
Provisional entity: natural killer (NK) cell lymphoblastic leukemia/lymphoma

B lymphoblastic leukemia/lymphoma

B lymphoblastic leukemia/lymphoma, NOS
 B lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
 B lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11.2); *BCR-ABL1*
 B lymphoblastic leukemia/lymphoma with t(v;11q23); *MLL* rearranged
 B lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) *TEL-AML1 (ETV6-RUNX1)*
 B lymphoblastic leukemia/lymphoma with hyperdiploidy
 B lymphoblastic leukemia/lymphoma with hypodiploidy
 B lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) *IL3-IGH*
 B lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*

T lymphoblastic leukemia/lymphoma

Table 2-4 Risk Stratification of AML European LeukemiaNet Criteria

Genetic group	Subsets
Favorable	t(8;21)(q22;q22); <i>RUNX1-RUNX1T1</i> inv(16)(p13.1q22) or t(16;16)(p13.1;q22); <i>CBFB-MYH11</i> Mutated <i>NPM1</i> without <i>FLT3</i> -ITD (normal karyotype) Mutated <i>CEBPA</i> (normal karyotype)
Intermediate-I ^a	Mutated <i>NPM1</i> and <i>FLT3</i> -ITD (normal karyotype) Wild-type <i>NPM1</i> and <i>FLT3</i> -ITD (normal karyotype) Wild-type <i>NPM1</i> without <i>FLT3</i> -ITD (normal karyotype)
Intermediate-II	t(9;11)(p22;q23); <i>MLLT3-MLL</i> Cytogenetic abnormalities not classified as favorable or adverse ^b
Adverse	inv(3)(q21q26.2) or t(3;3)(q21;q26.2); <i>RPN1-EVI1</i> t(6;9)(p23;q34); <i>DEK-NUP214</i> t(v;11)(v;q23); <i>MLL</i> rearranged –5 or del(5q); –7; abn(17p); complex karyotype ^c

Frequencies, response rates, and outcome measures should be reported by genetic group, and, if sufficient numbers are available, by specific subsets indicated; excluding cases of acute promyelocytic leukemia.

^a Includes all AMLs with normal karyotype except for those included in the favorable subgroup; most of these cases are associated with poor prognosis, but they should be reported separately because of the potential different response to treatment.

^b For most abnormalities, adequate numbers have not been studied to draw firm conclusions regarding their prognostic significance.

^c Three or more chromosome abnormalities in the absence of one of the WHO designated recurring translocations or inversions, that is, t(15;17), t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23), t(6;9), inv(3) or t(3;3); indicate how many complex karyotype cases have involvement of chromosome arms 5q, 7q, and 17p.

Reproduced with permission from Dohner H, Estey EH, Amadori S, et al. Diagnosis and management of acute myeloid leukemia in adults: recommendations from an international expert panel, on behalf of the European LeukemiaNet, *Blood*. 2010 Jan 21;115(3):453–474.

The drawback of this classification system is that it takes into account few mutations for prognostication. More recent data suggest that the favorable prognosis attributed to mutant *CEBPA* is true in cases of bilallelic *CEBPA* mutation rather than the monoallelic mutation⁽⁸⁾. Of note, in patients with *FLT3*-negative/*NPM1*-positive AML, *DNMT3A* assessment is of importance. Lohhavi et al showed that in patients with karyotypically normal AML with *NPM1* mutations, presence of concurrent *DNMT3A* mutation has an adverse effect on outcomes, with the effect being more detrimental than either *FLT3-ITD* or *FLT3-TKD* mutations⁽⁹⁾. This analysis showed that of patients with de novo karyotypically normal AML, particularly those <60 years old, AML^{*DNMT3A/FLT3/NPM1*} patients seem to have the worst clinical outcomes, followed by those with AML^{*FLT3/DNMT3A*} and then those with AML^{*NPM1/DNMT3A*}⁽⁹⁾. Currently, normal karyotype AML patients with *NPM1*-positive/*FLT3*-negative disease are considered favorable risk according to the ELN guidelines.

The presence of *TP53* mutations is associated with a poor outcome. A recent report by German/Austrian investigators indicated that the outcome of patients with *TP53* mutations is worse than that of patients with the monosomal karyotype known to be an adverse prognostic indicator⁽¹⁰⁾. In this study, the analysis showed that the *TP53* mutation was commonly associated with older patients and a monosomal karyotype and correlated with a low complete remission (CR) rate and shorter relapse-free survival (RFS), event-free survival (EFS), and overall survival (OS). On multivariate analysis, *TP53* mutations were associated with the worst prognosis⁽¹⁰⁾.

Several novel molecular aberrations, including mutations of the *IDH*, *ASXL1*, *DNMT3A*, *TET2*, *MLL*, and *PHF6* genes, have been described, particularly in patients with a normal karyotype⁽¹¹⁾. However, their utility in clinical practice remains limited, and they have limited value in determining best treatment strategies for patients.

TREATMENT OF ACUTE MYELOID LEUKEMIA

In the 1960s, Freireich et al demonstrated the significance of achieving a CR to improve survival⁽¹²⁾. Since then, the objective of therapy has been to produce and maintain CR, the only currently accepted approach to AML cure. Criteria for CR have been defined by the International Working Group and are followed in the clinic and in clinical trials for response assessment⁽¹³⁾. After 3 years in CR, the probability of AML recurrence sharply declines to less than 10%⁽¹⁴⁾, and patients in continuous CR for 3 or more years can be considered “potentially cured.” However, clearly the definition of CR is an arbitrary one, and with improved technology,

the precision for detection of residual disease after the initial therapy has increased. Whether this improved detection and application of novel strategies to eradicate the residual leukemia will translate to improved cure rates will be the subject of future trials.

Once AML is diagnosed, the need for emergency therapy must be assessed. Emergency treatment is required (1) in cases of APL, (2) if the circulating blast count is >50 to $100 \times 10^9/L$, and (3) in the presence of DIC or organ dysfunction (especially pulmonary) attributed to leukemic infiltration (mostly seen in patients with $>10 \times 10^9/L$ circulating blasts and/or M4 or M5 French-American-British [FAB] morphology). In the latter situation, it is important to initiate immediate chemotherapy. Leukapheresis for severe leukocytosis and/or leukostasis should also be considered⁽¹⁵⁾. In patients with low presenting WBC count, several studies have demonstrated that initiation of therapy can be delayed for several days until all the necessary diagnostic information is available⁽¹⁶⁾.

At University of Texas MD Anderson Cancer Center (MDACC), most patients are enrolled on clinical trials, if eligible. The therapy is tailored to the individual patient characteristics including their cytogenetic and molecular profile. We discuss here the therapies for the various patient groups with AML.

INDUCTION THERAPY IN ACUTE MYELOID LEUKEMIA

Conventional treatment for AML, divided into remission induction and postremission therapy, has been with combinations of anthracyclines and cytarabine (ara-C).

Anthracyclines and Cytarabine

At MDACC, young patients with AML (<60 years old) are treated with idarubicin (IDA) plus cytarabine-based regimens. The dose of IDA is 12 mg/m^2 for 3 days, and ara-C is given as a continuous infusion at a dose of 1.5 g/m^2 for 4 days. An alternative used by many cooperative groups is the “3+7 regimen,” where the anthracycline (ie, IDA or daunorubicin [DNR]) is usually given daily for 3 days and ara-C is given at 100 to 200 mg/m^2 daily for 7 days by continuous infusion.

In clinical practice, a bone marrow aspirate is usually obtained 2 to 3 weeks after beginning therapy. A biopsy is needed only if the quality of the aspirate does not permit determination of cellularity. If the day 21 marrow is hypoplastic, therapy is usually delayed until it is clear that leukemia has reappeared, at which time the second course begins. A second repeated course of therapy can produce remissions, but these are usually of shorter duration than remissions produced after one course of therapy. The timing of a second course with

persistent AML is controversial. Several cooperative groups advocate starting a second course if there is persistent AML on days 10 to 15 of chemotherapy. With high-dose ara-C (HDAC), a delay of a second course with persistent disease on days 21 to 28 may be indicated if the blasts are decreasing because most (90%) CRs are obtained after the first course and response to a second course is poor. It is important to recognize that the initial marrow obtained after a period of hypoplasia may demonstrate up to 30% to 50% blasts as a reflection of the regeneration of normal, not “leukemic,” marrow recovery. In this circumstance, follow-up (eg, at 1- to 2-week intervals) marrows may show reduction in blast percentages concomitant with a rise in neutrophils and platelets.

Typically, once in remission after treatment with the induction course, patients receive postremission therapy, with the same drugs administered at approximately monthly intervals for 4 to 12 months.

Choice of Anthracyclines

Randomized trials have attempted to identify which anthracycline (eg, IDA, DNR, mitoxantrone [MTZ], aclarubicin) is better (¹⁷). In a three-arm randomized study comparing DNR, IDA, and MTZ as part of the induction regimen for older patients, there was no advantage for any one arm (¹⁸). In contrast, in a three-arm randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) and Italian Group for Hematological Diseases in Adults (GIMEMA) comparing the same three agents, the 5-year disease-free survival (DFS) and OS were significantly better for patients receiving IDA and MTZ ($P = .03$ and $.02$, respectively). The recovery time was longer with IDA and MTZ ($P < .0001$) (¹⁹). Gardin et al analyzed pooled data from trials conducted in AML patients age ≥ 50 years (²⁰). These trials compared the efficacy of IDA versus DNR in induction and consolidation. They assessed the outcomes of these patients and showed that IDA resulted in a higher CR rate of 69% (vs 61% with DNR, $P = .02$) but did not lead to superior OS (median OS, 14.2 months; $P = .13$) (²⁰).

Different doses of DNR have been evaluated in several trials, in addition to standard-dose ara-C (100 or 200 mg/m² daily for 7 days). Two studies showed that using DNR 90 mg/m² had better outcomes than DNR 45 mg/m², regardless of age. Both studies showed higher CR rates and OS in patients receiving a higher dose of DNR, without any additional toxicity. The beneficial effect was mostly seen in patients less than 50 years old and with more favorable cytogenetics (^{21,22}). More recently, a French group also showed that DNR 60 mg/m² had similar relapse rate, RFS, and OS compared to DNR 90 mg/m² (²³).

Even though the studies do not show survival advantage with IDA over DNR, the CR rates are definitely higher with IDA. Hence, at MDACC, IDA is the preferred anthracycline of choice.

CPX-351

CPX-351 is a novel formulation for delivery of ara-C and DNR synergistically to the leukemic cells. In this formulation, ara-C and DNR are encapsulated in a 5:1 fixed molar ratio that was found to be consistently synergistic in vitro. A multicenter, open-label, phase II study was conducted across 18 centers in the United States in the first-line setting. Patients >60 years old with de novo AML were randomized to receive the CPX-351 versus the 7+3 regimen. Higher response rates were noted with CPX-351, with an overall response rate (ORR) of 66.7% (vs 57.6%, $P = .06$). Patients with adverse cytogenetics had an improved response with CPX-351 (77% vs 38%). Improvements in the median OS (14.7 months vs 12.9 months) and EFS (6.5 months vs 2 months) were noted in the CPX-351 cohort (²⁴). A phase III trial is currently ongoing.

High-Dose Cytarabine

Several randomized trials have assessed the efficacy of HDAC (1-3 g/m²) versus standard-dose ara-C (SDAC) (100-200 mg/m²) for induction therapy. The Cancer and Leukemia Group B (CALGB) and the Eastern Cooperative Oncology Group (ECOG) restricted their analysis to patients in CR, whereas the Southwestern Oncology Group (SWOG) compared HDAC with SDAC during induction and randomized SDAC patients to SDAC or HDAC once the patients were in CR (²⁵). Finally, the Australian Leukemia Study Group (ALSG) randomized patients to HDAC or SDAC during induction only (Table 2-5) (²⁶). These trials concluded that

Table 2-5 Standard Versus High-Dose Cytarabine (HDAC) in Newly Diagnosed AML

Study	HDAC During:	No. of Patients	Beneficial Effect of HDAC
ALSG	Induction	279	CR duration
SWOG	Induction and/or consolidation	723	Event-free survival
ECOG	Consolidation	170	If age <60 years
CALGB	Consolidation	596	If age <60 years

ALSG, Australian Leukemia Study Group; CALGB, Cancer and Leukemia Group B; CR, complete response; ECOG, Eastern Cooperative Oncology Group; SWOG, Southwest Oncology Group.

(1) the toxicity of HDAC (eg, cerebellar) outweighs the anti-AML effect in patients >65 years; (2) patients >60 years benefit from HDAC given during induction (SWOG, ALSG), in CR (CALGB, ECOG), and perhaps both (SWOG); and (3) HDAC potentially increases the cure rates to 70% to 80% in patients with inversion 16 or t(8;21) and to 30% to 40% in patients with normal karyotype, but little, if at all, in patients with adverse karyotypes. In a meta-analysis of three trials in 1,691 patients, induction with HDAC was compared to SDAC. Although there was no difference in CR rates, the 4-year RFS ($P = .03$), 4-year OS ($P = .0005$), and 5-year EFS ($P < .0001$) were better with HDAC ⁽²⁷⁾.

Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin (GO) is a CD33-targeted immunoconjugate linking an anti-CD33 antibody to calicheamicin. It received an accelerated approval by the US Food and Drug Administration for use in relapsed/refractory elderly AML patients but was withdrawn voluntarily by the manufacturer from the market in 2010 due to toxicity concerns. However, in a recent trial by the French Leukemia Association, patients age 50 to 70 years with previously untreated de novo AML were randomized to receive standard chemotherapy with 7+3 (DNR, ara-C) with or without GO. Gemtuzumab was administered in fractionated doses. The ORR was 78%, with 73% achieving CR and 5% achieving CR with incomplete platelet recovery (CRp). The OS (34 months vs 19 months, $P = .036$), EFS (15.6 months vs 9.7 months, $P = .0003$), and RFS (28 months vs 11 months, $P = .0003$) were significantly better in the GO group. Another study by the Medical Research Council (MRC) in the United Kingdom showed a benefit for the addition of GO to ara-C and anthracycline-based induction regimens ⁽²⁸⁾. A recent meta-analysis examined five randomized trials in untreated patients with AML and demonstrated a benefit of GO in the frontline therapy of some subsets of patients with AML. The available data suggest utility of GO in patients with AML allowing the argument for the reconsideration of its approval in the United States.

TREATMENT OF YOUNGER PATIENTS WITH ACUTE MYELOID LEUKEMIA

Clofarabine, Idarubicin, and Cytarabine

Clofarabine is a second-generation nucleoside analogue that has activity in adult patients with AML. A phase I trial of clofarabine, conducted at MDACC, in combination with IDA alone versus IDA and ara-C (CIA) in patients with relapsed, refractory AML

showed a CR rate of 13% versus 48%, respectively. The median duration of remission was also longer with the CIA combination (15 months) as compared to clofarabine and IDA (4.5 months) ⁽²⁹⁾. This was followed by a phase II trial that investigated the CIA regimen in patients ≤60 years old with newly diagnosed AML. Patients who achieved a response (CR or CRp) went on to receive up to six cycles of consolidation therapy. The cycles were administered every 4 to 6 weeks. All patients received prophylactic antibiotics, antifungals, and antivirals. The median age of the patients was 48 years (range, 19-60 years), 66% had intermediate-risk cytogenetics, and 36% had diploid and 34% adverse karyotype. The ORR was 79%, with 74% CR and 3% CRp. Eighteen percent of patients received two induction cycles to achieve a CR/CRp, and 42% went on to receive an allogeneic stem cell transplantation (SCT) in first CR. The median OS and RFS were not reached, whereas the median EFS was 13.5 months. A subset analysis showed better OS ($P = .04$) and EFS ($P = .04$) in patients ≤40 years old as compared to >40 years old ⁽³⁰⁾.

Purine Analogues

The addition of purine analogues, cladribine and fludarabine, to anthracyclines and ara-C has been associated with improved outcomes in a number of studies.

Cladribine/Fludarabine

Holowiecki et al conducted a randomized phase III trial evaluating the addition of cladribine or fludarabine to DNR/ara-C in younger patients with untreated AML. Six hundred fifty-two patients, with a median age of 47 years (range, 17-60 years), were randomized to receive DNR plus ara-C (DA), DA plus cladribine (DAC), and DA plus fludarabine (DAF). The consolidation regimen was the same for all arms and included two consecutive courses of ara-C (1.5 g/m² intravenously [IV] days 1-3) plus MTZ (10 mg/m² IV days 3-5) and HDAC (2 g/m² IV twice a day on days 1, 3, and 5). Overall CR rate was 61%, with 56% achieving a CR after one cycle of induction and 5% after two cycles. The CR rate was higher in the DAC arm compared to the DA arm (62% vs 51%, $P = .02$). The CR rates were similar in the DA and DAF arms. The median OS was significantly higher in the DAC arm (24 months) compared to the DA arm (14 months, $P = .02$). There was no significant difference in the median OS between the DAF and DA arms ⁽³¹⁾.

Vorinostat

Vorinostat is an oral histone deacetylase inhibitor that has been shown to have single-agent activity in AML ⁽³²⁾. It was studied in combination with the IDA plus ara-C

regimen at MDACC in a phase II trial in the frontline setting in patients with AML or intermediate-2/high-risk MDS. Induction was given as vorinostat 500 mg orally three times a day (days 1-3) along with IDA (12 mg/m² days 4-6) and ara-C (1.5 mg/m² continuous infusion days 4-7). Subsequently, patients achieving a remission could be treated with five cycles of consolidation and up to 12 months of single-agent vorinostat for maintenance. At a median follow-up of 82 weeks, the median OS was 82 weeks (range, 3-134 weeks) and median EFS was 47 weeks (range, 3-134 weeks). There was trend for a longer survival in the *FLT3-ITD*-mutated patients (91 weeks; range 6-134 weeks). The overall remission rate was 85%, with 76% achieving a CR and 9% achieving a CRp; 25% of the patients went on to undergo an allogeneic SCT in first CR.

TREATMENT OF PATIENTS ≥60 YEARS OLD

Acute myeloid leukemia in older adults (≥60 years) is considered a biologically and clinically distinct entity. The outcomes of older AML patients are poor with the standard anti-AML therapies. The analysis of the Swedish Acute Leukemia Registry (1976-2005) showed that the early death rates in all AML patients, regardless of age, were lower with intensive therapy compared to palliative therapy⁽³³⁾.

Acute myeloid leukemia in the elderly has adverse biologic features such as higher frequency of stem-cell-like phenotype of leukemic blasts, higher frequency of multilineage involvement with dysplastic features, higher frequency of antecedent hematologic disorders, and higher frequency of *MDR-1* gene expression, which leads to higher potential for cytotoxic drug extrusion by the leukemic blasts, causing resistance to chemotherapeutic agents⁽³⁴⁾. Acute myeloid leukemia in older patients is more frequently associated with poor-risk cytogenetics (up to 50% vs 10%-15% in younger patients)⁽³⁵⁾. Hence, the majority of elderly AML patients should be considered for investigational clinical trials. Other factors contributing to worse outcome in elderly patients include poor performance status, organ dysfunction, and a higher incidence of an antecedent hematologic disorders. In general, patients with three or more of these factors have expected CR rates of less than 20%, 8-week mortality rates greater than 50%, and 1-year survival rates of less than 10% using conventional regimens. These patients constitute 25% to 30% of elderly patients with AML. Approximately 20% of elderly patients have none or one of these adverse factors and have a reasonable outcome with expected CR rates above 60%, 8-week mortality rates of 10%, and 1-year survival rates of ≥50%⁽³⁶⁾.

Low-Dose Cytarabine

Low-dose ara-C (LDAC) was superior to hydroxyurea in a randomized trial enrolling 204 elderly patients with AML considered unfit for chemotherapy⁽³⁷⁾. The CR rates were 15% with LDAC and 1% with hydroxyurea ($P = .0003$); the 1-year survival rates were 27% versus 3% ($P = .0004$).

Clofarabine

A randomized phase II study compared clofarabine (30 mg/m² IV × 5 days) versus clofarabine and ara-C (20 mg/m² subcutaneously daily × 14 days) in 70 elderly patients with AML⁽³⁸⁾. Combination therapy achieved a better CR (63% vs 31%; $P = .025$) and better EFS (7.1 months vs 1.7 months; $P = .04$) but did not improve OS (11.4 months vs 5.8 months; $P = .1$).

Hypomethylating Agents

Kantarjian et al conducted a randomized phase III trial comparing decitabine 20 mg/m² for 10 days with physician's choice in 485 patients⁽³⁹⁾. This study showed that decitabine improved CR/CRp rates compared with physician's choice (18% vs 8%; $P = .001$). Decitabine was well tolerated with a good safety profile. The primary analysis showed a non-significant improvement in the OS, but an unplanned analysis 2 years later demonstrated an improvement in the OS in the decitabine arm ($P = .03$)⁽³⁹⁾. Quintas-Cardama et al showed that patients with newly diagnosed AML who are >65 years old have an ORR of 47% (CR rate, 42%) with intensive chemotherapy and an ORR of 29% (CR rate, 28%) with epigenetic therapy (azacitidine, decitabine) ($P \leq .001$)⁽⁴⁰⁾. The median OS was similar in both the groups (6.5 months; $P = .413$)⁽⁴⁰⁾. These studies show that hypomethylating agents have similar survival outcomes in elderly AML patients when compared to intensive chemotherapy.

Recently, the results of the AML-AZA001 trial were presented. Four hundred forty-eight patients ≥65 years old with newly diagnosed de novo or secondary AML who were deemed ineligible for transplant and with intermediate- or poor-risk cytogenetics were enrolled. Patients were randomized to receive either azacitidine or a conventional care regimen. Azacitidine was administered at 75 mg/m²/d for 7 days subcutaneously. A prolongation in the median OS was observed in the azacitidine arm (6.4 months vs 3.2 months; $P = .0185$). The conventional care regimen included best supportive care in 18%, LDAC in 64%, and intensive chemotherapy in 18%⁽⁴¹⁾. Several groups have consistently

shown a CR rate of 31% to 47% with decitabine 20 mg/m² administered daily for 10 days, with a median OS of 9 to 12 months. However, the associated increased myelosuppression leads to increased rates of hospitalization for infections ⁽⁴²⁾.

Vosaroxin

Vosaroxin is an anticancer quinolone that was shown to have activity in older patients with poor-risk AML in the REVEAL-1 study ⁽⁴³⁾. In this study, patients ≥60 years old with unfavorable-risk AML were treated with single-agent vosaroxin. An ORR of 32% was observed including 29% CR and 32% CR/CRp. The median OS was about 7 months, and the 1-year OS rate was 38% ⁽⁴³⁾. Overall, vosaroxin resulted in low early mortality and an encouraging response rate. Subsequently, a combination of vosaroxin and decitabine was evaluated in older patients with newly diagnosed AML and high-risk MDS. The ORR was 76% (including 59% CR, 14% CRp, and 3% CR with incomplete blood count recovery [CRi]). Interestingly, the response rate in the patients with adverse cytogenetics was 69%. The median OS was 8.3 months, and the median remission duration had not been reached ⁽⁴⁴⁾.

Volasertib

Polo-like kinases (Plks) are serine/threonine protein kinases that play a role in mitotic checkpoint regulation and cell division. The Plk-1 is expressed in dividing cells, and its expression peaks during the G₂/M phase of cell cycle. It has been shown to be overexpressed in AML cells ⁽⁴⁵⁾. Volasertib is a Plk inhibitor that was evaluated in a phase II trial in older patients with AML considered not to be candidates for intensive induction therapy ⁽⁴⁶⁾. Patients were randomized to LDAC 20 mg subcutaneously twice a day for 10 days with or without volasertib 350 mg IV on days 1 to 15 every 4 weeks. Eighty-seven patients with a median age of 76 years (range, 57-86 years) were enrolled. The ORR (CR+CRi) was 13.3% for the LDAC alone arm versus 31% for the LDAC plus volasertib arm ($P = .052$). The time to response was a median of 63.5 days (range, 30-120 days). Patients received a median of 8 cycles of therapy (range, 2-22 cycles) in the combination arm compared with 7 in the LDAC alone arm (range, 5-11 cycles). At a median follow-up of 28.2 months, the median EFS was 5.6 months in the LDAC plus volasertib arm compared with 2.3 months in the LDAC alone arm ($P = .021$). The addition of volasertib led to a longer RFS of 18.5 months (vs 10 months) and a longer median OS of 8 months (vs 5.2 months; $P = .047$). A higher incidence of grade 3 gastrointestinal toxicity,

febrile neutropenia, and infections was noted in the combination arm, but there was no difference in early mortality noted between the two arms.

Nonchemotherapy Options

Nonchemotherapy options are also being explored for this subset of patients with AML. Pollyea et al reported the results of upfront combination of azacitidine (75 mg/m² × 7 days) and lenalidomide (escalating doses, starting at day 8 of each cycle, every 6 weeks) in patients ≥60 years old ⁽⁴⁷⁾. They reported an ORR of 40%, with a median time to response of 3 months and median duration of response of 7 months. The median OS was 5 months for all patients ⁽⁴⁷⁾. Wetzler et al evaluated octogenarian patients with AML who had been enrolled in cooperative group trials and concluded that intensive induction (7+3 or similar) is effective therapy, with a 30% CR rate ⁽⁴⁸⁾. In these patients, *FLT3-ITD* did not impact median OS (10 months; $P = .31$) in contrast to *NPM1* mutations, which were associated with a prolonged median OS (91 months; $P = .002$) ⁽⁴⁸⁾.

Several groups have proposed predictive models for geriatrics assessment prior to determining what therapy to assign older patients ^(49,50). These models look at several prognostic factors, including functional status, cytogenetics, age, and molecular status, to predict mortality and survival with therapy. This suggests that a careful assessment of the patient and disease characteristics is needed before assigning therapy to older patients.

Investigational treatment and palliative care options are more plausible in poorer-prognosis elderly patients, and the patients and their families should be involved in discussions of treatment decisions.

Consolidation Therapy

There is debate as to the best therapy for consolidation following achievement of CR after initial induction therapy. The number of cycles of therapy is also not agreed upon. However, for patients treated with hypomethylating agents, it is recommended that the treatment is continued indefinitely until disease progression, as is the practice for patients with MDS.

TREATMENT OF *FLT3*-MUTATED ACUTE MYELOID LEUKEMIA

FMS-like tyrosine kinase 3 (*FLT3*) is a member of the class III receptor tyrosine kinase family that plays an important role in the survival, proliferation, and differentiation of hematopoietic progenitor cells. *FLT3* is overexpressed in most patients with AML, and

Table 2-6 Major *FLT3* Inhibitors

<i>FLT3</i> Inhibitor	Patient Characteristics	Regimen	CR	OS
Sorafenib	Relapsed, refractory ⁽⁹³⁾	IA + sorafenib	93% in <i>FLT3</i> -mutated	74% at 1 year
	Frontline ⁽⁹⁴⁾	7+3 + sorafenib	60%	63% at 3 years
Quizartinib	Relapsed, refractory ⁽⁹⁵⁾	Single agent	13%	14 weeks
	Relapsed, refractory ⁽⁹⁶⁾	Quizartinib + LDAC/AZA	60%	—
Crenolanib	Relapsed, refractory ⁽⁹⁷⁾	Single agent	<i>FLT3</i> -ITD: 23% <i>FLT3</i> -TKD: 20%	6 months

AZA, azacitidine; CR, complete response; IA, idarubicin plus cytarabine; LDAC, low-dose cytarabine; OS, overall survival.

activating mutations of *FLT3* are among the most prevalent molecular abnormalities in AML, with internal tandem duplication (ITD) occurring in 25% to 35% of patients with normal karyotype ⁽⁵¹⁾. In addition, 5% to 7% of patients may have point mutations within the activation loop of the kinase domain or in the juxtamembrane domain. Patients with *FLT3* activating mutations have an inferior outcome with a shorter RFS and OS. In addition, after exposure to *FLT3* inhibitors, nearly a quarter of patients with *FLT3*-ITD develop mutations in the kinase domain as a mechanism of resistance. The major *FLT3* inhibitors are summarized in Table 2-6. Table 2-7 lists the *FLT3* inhibitors currently under development.

TREATMENT OF CORE-BINDING FACTOR ACUTE MYELOID LEUKEMIA

Core-binding factor (CBF) AML is a distinct entity. It is considered a favorable karyotype. It includes patients with a pericentric inversion of chromosome 16 (inversion 16; associated with FAB subtype M4EO) and translocation (16;16) or a translocation between chromosomes 8 and 21 (t(8;21); associated with FAB subtype M2). Each of these abnormalities disrupts the function of a transcription factor (CBF), regulating the expression of genes important in hematopoietic differentiation. inv(16) and t(16;16) lead to the formation of the

CBF-MYH11 fusion gene. t(8;21) leads to the formation of the *RUNX1-RUNX1T1* fusion gene. The *CBF-MYH11*– and *RUNX1-RUNX1T1*–related leukemias represent CBF-AML. These leukemias are very sensitive to induction and consolidation and have high response rates. About 10% of unselected patients (typically younger patients) have CBF-AML. At MDACC, all newly diagnosed patients with CBF-AML are treated with fludarabine (30 mg/m²/d on days 1-5) and HDAC (2 g/m²/d on days 1-5) regimens with or without the addition of granulocyte colony-stimulating factor (G-CSF). This is followed by up to six courses of an HDAC-containing regimen. A CR rate of 93% and an EFS of 20 months in 114 newly diagnosed CBF-AML patients were previously reported ⁽⁵²⁾. A frontline regimen of fludarabine, ara-C, and G-CSF (FLAG)-GO was evaluated at MDACC and showed a remission rate of 95% and a 3-year OS and RFS of 78% and 85%, respectively ⁽⁵³⁾. In the UK MRC-AML15 trial, 1,113 patients with AML were randomized to receive or not receive a small dose of GO (3 mg/m²) with their induction therapy. A benefit for adding GO to the induction regimen was seen in patients with CBF-AML ⁽²⁸⁾. In a meta-analysis of five clinical trials wherein addition of GO to induction chemotherapy was evaluated, a significant improvement in OS was noted in patients with favorable- and intermediate-risk cytogenetics ($P = .01$). The improvement in survival was attributed to reduced relapse ($P = .00006$) ⁽⁵⁴⁾. All of these studies strongly support the use of FLAG-based regimens for CBF-AML and advocate the addition of GO to the induction to improve survival and RFS in these patients.

Approximately 25% of CBF-AML patients carry a gain-of-function mutation in the *KIT* gene, which results in a constitutively activated tyrosine kinase. Hence, the CALGB 10801 alliance and a group in Germany are evaluating the addition of a *KIT* inhibitor, dasatinib, to the standard induction therapy. The initial results showed a 92% CR rate and 1-year DFS and OS rates of 90% and 87%, respectively. Long-term outcomes of this study are awaited ⁽⁵⁵⁾.

The treatment for newly diagnosed AML is summarized in Figs. 2-1 and 2-2.

TREATMENT OF RELAPSED/REFRACTORY ACUTE MYELOID LEUKEMIA

Although the outcome of patients with AML has improved, relapse remains frequent and constitutes the leading cause of mortality. Breems et al defined a prognostic score for patients with AML in first relapse based on the following variables: (1) relapse-free interval from first CR; (2) cytogenetics at diagnosis; (3) age at first relapse; and (4) SCT before first relapse⁽⁵⁶⁾. In an analysis of 594 patients who underwent second salvage therapy for relapsed AML at MDACC, 13% achieved CR (median CR duration, 7 months), and 1-year survival was 8%⁽⁵⁷⁾ (Fig. 2-3).

Allogeneic transplant appears superior to HDAC- or intermediate-dose ara-C-containing regimens in patients with duration of first CR less than 1 year; the great majority of these transplants were from a human leukocyte antigen (HLA)-matched sibling donor^(58,59). However, because few patients are cured with conventional therapy, all patients with relapsed or refractory AML should be treated in clinical trials. Gemtuzumab,

a conjugate composed of a humanized anti-CD33 antibody linked to the antitumor antibiotic calicheamicin, was the only approved treatment for relapsed AML in patients older than 60 years of age with the CR1 duration (CRD1) of 3 months or longer. Complete response rates of 30% were reported with this agent. Veno-occlusive disease was observed in 5% to 10% of patients. Gemtuzumab is no longer commercially available.

For relapsed/refractory AML patients, enrollment in a clinic trial remains the first consideration. Recently, results of VALOR, a phase III trial of vosaroxin or placebo with ara-C in patients with refractory AML or in first relapse, were reported⁽⁶⁰⁾. The vosaroxin and ara-C arm had a higher complete CR rate of 30% (vs 16%; $P < 0.0001$). The median OS was statistically prolonged in the patients ≥ 60 years old who received vosaroxin and ara-C (7.1 months vs 5 months; $P = 0.003$). The 30- and 60-day mortality rates were similar in both arms. These results suggest that the combination of vosaroxin and ara-C could become a new standard for treatment of older patients with refractory or relapsed AML.

STEM-CELL TRANSPLANTATION

High-dose chemotherapy with or without radiation followed by SCT is increasingly used as therapy for AML patients in first CR. In prospective, nonrandomized trials in Europe and the United States, patients younger than age 55 years in first CR with an HLA-matched sibling were assigned to allogeneic transplantation or, if no donor, to autologous transplantation or one further course of HDAC (with DNR in the European study)⁽⁶¹⁻⁶⁴⁾ (Table 2-8).

In a meta-analysis of 24 prospective clinical trials involving more than 6,000 patients with AML in first CR, Koreth et al showed that allogeneic SCT has significant survival benefit in patients with intermediate- and poor-risk AML but not with good-risk AML⁽⁶⁵⁾. This finding contrasts with the retrospective review of 999 patients by Ferrant et al that observed similar benefit with allogeneic and autologous transplantation for patients with poor-risk karyotype and a benefit with allogeneic SCT only in patients with good- and intermediate-risk cytogenetics⁽⁶⁶⁾. However, further stratification of risk groups based on molecular markers within individual karyotypes suggests that only specific subsets of patients may benefit from allogeneic SCT. Schlenk et al demonstrated superior OS with allogeneic SCT compared to intensive chemotherapy in only the following groups of normal karyotype de novo AML patients: (1) *FLT3-ITD* positive and (2) *NPM1/CEBPA/FLT3-ITD* negative⁽⁶⁷⁾. Patients with inversion 16 or t(8;21) do better with chemotherapy⁽⁶⁸⁾.

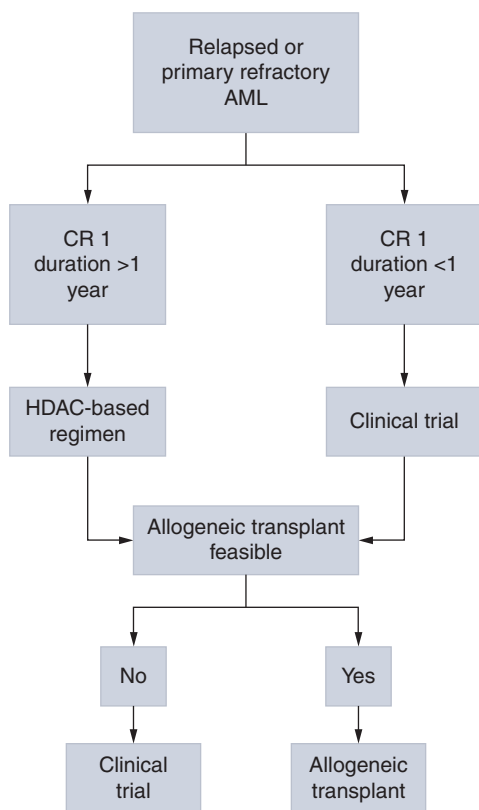

FIGURE 2-3 A proposed algorithm for management of relapsed/refractory acute myeloid leukemia (AML). CR1, first complete remission; HDAC, high-dose cytarabine.

Table 2-8 Allogeneic Stem-Cell Transplantation (ASCT) Versus Chemotherapy in AML in First Complete Remission (CR)

Study	No. of Patients	% Match	% ASCT in CR	Significant Difference Favoring ASCT
Archimbaud et al ⁽⁶¹⁾	58	74	34	No

Burnett et al ⁽⁶⁴⁾	656	58	23	No

LFS, leukemia-free survival.

Patients with AML who are younger than 20 years old have relatively low transplant-related mortality and may do better with allogeneic SCT.

New concepts in both transplantation and chemotherapy have emerged. These include the use of peripheral blood rather than marrow as the source of SCT ⁽⁶⁹⁾, the use of nonmyeloablative regimens to allow engraftment and take advantage of the graft-versus-leukemia effect, and the use of IV busulfan to overcome the erratic pharmacology of the oral form ⁽⁷⁰⁾. In particular, nonmyeloablative regimens (reduced-intensity conditioning or “mini-transplant”) have gained particular traction in elderly patients who have traditionally experienced high treatment-related mortality with conventional myeloablative regimens. The principles of this approach include reduction of regimen-related toxicities and shifting the burden of tumor cell kill from high-dose cytotoxic therapy to graft-versus-leukemia effects. A number of recent studies have reported 2- to 5-year survival rates of 25% to 64% after nonmyeloablative allogeneic SCT for older patients with high-risk MDS and AML. Survival was similar for recipients of related and unrelated HLA-matched grafts. The nonrelapse mortality was 16% to 39%, resulting mainly from complications of graft-versus-host disease and comorbidities preceding SCT. Relapse rates ranged from 16% to 53% and were influenced both by disease burden and cytogenetics at the time of SCT ⁽⁷¹⁾. Further details on this subject are beyond the scope of this chapter.

SUPPORTIVE CARE

Adequate and close supportive care is extremely important in the care of acute leukemia. Both G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) have reduced the median time to neutrophil recovery by an average of 5 to 7 days ⁽⁷²⁾. Antileukemic therapeutic efficacy is not compromised by these agents. Therapy of acute leukemia often results in rapid reduction of elevated WBC counts.

This is often associated with the development of tumor lysis, characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, and renal failure. Prevention of tumor lysis syndrome requires administration of IV fluids and allopurinol (or rasburicase) if the blast count is above $10 \times 10^9/L$. Saline or steroid eye drops daily should be given to patients undergoing HDAC therapy until 24 hours after completion of chemotherapy. In these patients, neurologic assessments for cerebellar neurotoxicity should be performed before each dose of HDAC.

Acute pulmonary failure during induction therapy for AML is a serious complication. Predictive factors identified at diagnosis include male sex, diagnosis of APL, poor ECOG performance status, lung infiltrates at diagnosis, and an increased serum creatinine. Fluid restriction, high-dose steroids, and continuous venovenous hemofiltration have been shown to be effective strategies in treating acute pulmonary failure.

Infectious complications are a major cause of morbidity and death. Prophylactic administration of antibiotics in the absence of fever is usually offered. The development of fever ($>101^\circ F$), unrelated to administration of chemotherapy, calls for administration of broad-spectrum antibiotics, such as imipenem or a third- (eg, ceftazidime) or fourth-generation cephalosporin (eg, cefepime). Antibiotic selection should be prompt, individualized, and in accordance with the updated antibiotic susceptibility profile of each institution. If infection persists, G-CSF should be started, and if indicated, granulocyte transfusions, using G-CSF to increase the donors' granulocyte counts, should be given. Close fluid balance is critical because fluid retention is common, can radiologically mimic pneumonia, and may increase the risk of diffuse alveolar hemorrhage during induction.

Another controversial area is whether adherence to a neutropenic diet (avoidance of fresh fruits and vegetables) during induction chemotherapy decreases the risk of infection. One hundred fifty-three patients with AML diagnosed at MDACC were admitted to a high-efficiency particulate air-filtered room for induction

chemotherapy (⁷³). They were randomized to receive a diet containing no raw fruits or vegetables (cooked diet) or to a diet containing fresh fruits and vegetables (raw diet). Twenty-nine percent of patients in the cooked group and 35% of patients in the raw group developed a major infection ($P = .60$). Time to major infection and survival time were similar in the two groups, thereby suggesting that a neutropenic diet did not prevent major infection or death.

INVESTIGATIONAL AGENTS

In the new era of molecular prognostication, targeted therapies and immunotherapies are the new kids on the block. *FLT3* inhibitors have been discussed earlier in the section on *FLT3* AML.

IDH Inhibitors

IDH mutations occur in approximately 20% of AML. The reported frequency is 6% to 16% for *IDH1* and 8% to 18% for *IDH2* mutations. The majority (85%) occur in patients with diploid or trisomy 8 cytogenetics. The prevalence increases with increasing age, and these mutations are strongly associated with *NPM1*-positive and MPN-derived AML (21%-31%) (⁷⁴). AG221 is an oral *IDH2* inhibitor that has been shown to have the ability to trigger differentiation of leukemic blast cells, leading to objective durable responses, including CRs. At the American Society of Hematology 2014 annual meeting, Stein et al reported response rates of 62% (CR, CRp, CRi, and partial response) in AML patients treated with AG221 in a phase I trial (⁷⁵). The median duration of response was 3 months, noted in 90% of the patients.

Venetoclax (ABT199)

ABT199 (venetoclax) is a selective, oral, BCL-2 inhibitor that was evaluated in a phase II trial at MDACC in relapsed/refractory AML patients unfit for intensive chemotherapy. Thirty-two patients were enrolled, of whom 11 had *IDH* mutations. An ORR of 19% (CR and marrow CR) was noted, with a suggestion that patients with *IDH* mutations might benefit more than other patients (⁷⁶).

Immunotherapy with monoclonal antibodies in AML is also an area of interest in the treatment of AML. Newer agents are being developed in this area, and we should have more agents in the arsenal to treat AML in the near future.

ACUTE PROMYELOCYTIC LEUKEMIA

Acute promyelocytic leukemia is a distinct subtype of AML accounting for 5% to 15% of cases, with unique clinical, morphologic, and cytogenetic features.

It results from a translocation between the retinoic acid receptor α (*RAR α*) locus on chromosome 17 and the promyelocytic leukemia protein (*PML*) locus located on chromosome 15 (⁷⁷). This *PML-RAR α* fusion is demonstrable in 95% to 100% of cases. Independent risk factors for a diagnosis of APL in a patient with AML are younger age, Hispanic ethnicity, and obesity (²). The main clinical presentation is bleeding diathesis resulting both from plasmin-dependent primary fibrinolysis and DIC (⁷⁸). Cytogenetic analysis detects the distinctive $t(15;17)$. In the rare case where such analysis does not show the $t(15;17)$ but the clinical or morphologic picture is suggestive, molecular test for *PML-RAR α* can be confirmatory. The POD test, an immunohistochemical test that can be performed in few hours, can detect the characteristic disruption of *PML* in virtually all cases and is a rapid and reliable quick test for APL. Recognition of APL is crucial because appropriate treatment with all-*trans*-retinoic acid (ATRA) and arsenic trioxide is different than for other types of AML and is curative in most patients (⁷⁹). A stratification system has been developed that distinguishes newly diagnosed patients with APL as low, intermediate, or high risk. Low-risk patients present with WBC count less than $10 \times 10^9/L$ and platelet count above $40 \times 10^9/L$; a WBC count above $10 \times 10^9/L$ identifies high-risk patients. Others are at intermediate risk. Anticipated cure rates are close to 100%, 90%, and 70% in low-, intermediate-, and high-risk patients, respectively (⁸⁰) (Table 2-9).

Several findings have contributed recently to the increased cure rates in APL. Anthracyclines were historically the first effective treatment, inducing a cure rate of 30% to 40% in APL. The role of ara-C is questionable and probably beneficial only in the setting of suboptimal anthracycline therapy. Addition of ATRA 45 mg/m² twice daily to chemotherapy (eg, IDA 12 mg/m² on days 2, 4, 6, and 8) increases CR rate and, more dramatically, increases the cure rate from 40% to 70%. The major toxicity of ATRA is a potentially fatal APL differentiation syndrome characterized by fever and leakage of fluid into the extravascular space producing fluid retention, effusions, dyspnea, and hypotension; it is effectively treated with dexamethasone.

Table 2-9 Risk Stratification of APL

Risk Group	WBC Count ($\times 10^9/L$)	Platelet Count ($\times 10^9/L$)	% RFS
Low	≤ 10	> 40	98
Intermediate	≤ 10	≤ 40	89
High	> 10		70

RFS, relapse-free survival; WBC, white blood cell.

(10 mg IV twice a day for 3-5 days, with a rapid taper) ⁽⁸¹⁾. A molecular test (*PML-RARA* fusion transcript by PCR) that detects molecular evidence of the t(15;17) provides a relatively sensitive and highly specific means to document minimal residual disease negativity and detect impending relapse ⁽⁸²⁾.

Once a diagnosis of APL is suspected, it is imperative that the patient be given ATRA, even before the diagnosis is confirmed. All-*trans*-retinoic acid is given at a dose of 45 mg/m²/d in divided doses. It serves to prevent coagulopathy and start induction therapy ⁽⁸³⁾.

Arsenic trioxide (ATO) was shown to be at least noninferior, and possibly superior, to ATRA and chemotherapy in low-/intermediate-risk APL. In the Italian-German APL 0406 trial, Lo-Coco et al showed that the CR rate was 100% in the ATRA+ATO arm versus 95% in the ATRA plus chemotherapy (IDA) arm, with a superior OS of 98.7% versus 91.1% (*P* = .02) ⁽⁸⁴⁾.

The regimens generally used for treatment of APL, according to risk category, are summarized in Tables 2-10, 2-11, and 2-12.

Ravandi et al evaluated outcomes of newly diagnosed APL patients treated with ATRA and ATO with or without GO without traditional cytotoxic chemotherapy ⁽⁸⁵⁾. The regimen is summarized in Table 2-13. They reported CR rates of 95% and 81%, respectively, for low-risk and high-risk patients. The estimated 3-year survival rate was 85%.

Hence, in the modern era of APL treatment, it is possible to have long-term cure for APL without the use of conventional chemotherapy, which is a tremendous achievement for modern-day oncology.

MINIMAL RESIDUAL DISEASE

Minimal residual disease (MRD) is defined as any measurable disease detectable above a certain level of detection, depending on the methodology applied. Minimal residual disease predicts a failure to maintain CR, and its detection is critical to assess the quality of response after induction therapy and to outline postremission therapy based on the individual risk of relapse. As mentioned in the section on APL, the detection of *PML-RARA* fusion transcript after achieving CR and its subsequent monitoring to detect early relapse has become the standard of care for patients with APL. Detection of MRD in non-APL AML is an upcoming field where guidelines and standard of care need to be defined. Several methods are being assessed to determine the best method for detection of MRD in patients with AML. There are several issues with the detection of MRD, including lack of a standardized methodology to measure MRD, inconsistency in MRD thresholds, and uncertainty of the ideal time for evaluation of MRD.

Konopleva et al reported that in patients with newly diagnosed AML who have abnormal cytogenetics at presentation, determination of cytogenetics in the marrow at day 21 of induction chemotherapy predicts RFS independent of the number of blasts ⁽⁸⁶⁾. Chen et al from MDACC demonstrated that persistence of cytogenetic abnormalities at the time of morphologic CR portends a worse outcome ⁽⁸⁷⁾. They looked at patients with abnormal cytogenetics at time of diagnosis who achieved a morphologic CR after induction.

Table 2-10 Treatment of High-Risk APL

Study	Induction	Consolidation	Maintenance
CALGB ⁽⁹⁸⁾	ATRA 45 mg/m ² PO every day until CR + Dauno 50 mg/m ² D3-6 + cytarabine 200 mg/m ² D3-9	ATO 0.15 mg/kg/d × 5 d/wk for 5 wk × 2 (C2 after 2-wk rest), then ATRA 45 mg/m ² PO D1-7 + Dauno 50 mg/m ² D1-3	ATRA 45 mg/m ² × 7 d every other week + MP 60 mg/m ² /d PO + MTX 20 mg/m ² weekly (1 year)

		ATRA 45 mg/m ² × 15 d + idarubicin 7 mg/m ² × 4 d, then ATRA 45 mg/m ² × 15 d + mitoxantrone 10 mg/m ² × 3 d, then ATRA 45 mg/m ² × 15 d + idarubicin 12 mg/m ² × 2 doses	

ATO, arsenic trioxide; ATRA, all-*trans*-retinoic acid; CALGB, Cancer and Leukemia Group B; CR, complete remission; D, day; Dauno, daunorubicin; IM, intramuscular; IT, intrathecal; MP, mercaptopurine; MTX, methotrexate; PO, oral; PETHEMA, Programa Español de Tratamientos en Hematología.

Twenty-eight percent of patients in CR had abnormal karyotype (ACCR) and the remaining 72% had normal cytogenetic CR (NCCR). Patients with ACCR had a shorter RFS and OS compared to patients with NCCR (6 months vs 21 months; $P < .001$; and 11 months vs 46 months; $P < .001$, respectively). The RFS and OS for patients with unfavorable cytogenetics at diagnosis who were NCCR were similar to those in patients with favorable/intermediate risk at diagnosis who were ACCR. The ACCR patients who underwent an allogeneic SCT had a significantly longer 3-year RFS (33% vs 9%; $P = .04$) and a 3-year OS (33% vs 8%; $P = .06$) than the patients who did not undergo an SCT. Interestingly, the RFS and OS achieved by patients with ACCR, who underwent an allogeneic SCT, was similar to the NCCR patients who did not undergo an SCT. This suggests a role for individualizing AML therapy based on cytogenetic MRD status.

Another method of quantitative detection of MRD in AML is real-time PCR (RT-PCR) (Table 2-14). Real-time PCR rapidly quantifies PCR products by reverse transcriptase fluorescent signals during exponential amplification. The sensitivity of molecular detection of fusion transcripts ranges from 1 leukemic cell in 1,000 to 100,000 normal cells, that is, 0.1% to 0.001%. The fusion transcripts most extensively used to monitor MRD in AML (in addition to *PML-RAR α* for APL) are *AML1-ETO*, *CBF β -MYH11*, and *MLL-AF9*, which are present in approximately one-third of non-APL AML cases⁽⁸⁸⁾. Various mutations, such as *FLT3*, *NPM1*, and

c-KIT, can also be assessed by RT-PCR to determine the residual disease status. Polymerase chain reaction analysis of *NPM1* mutations after therapy is prognostic and can be used to predict relapse. *NPM1* mutations are present in 30% of all AML patients and in 50% of patients with normal-karyotype AML. Chou et al looked at the role of MRD analysis of *NPM1* mutations by PCR and the impact on outcomes⁽⁸⁹⁾. One hundred ninety-four samples from 38 patients with de novo AML and *NPM1* mutations were analyzed over 10 years. The samples were taken 1 month after induction and 3 months after consolidation. Any rise in the mutant signals during follow-up was associated with a 3.2 times increased risk of relapse. Of the relapsed patients, the rise in the mutation levels predicted a relapse at a median of 4.9 months (range, 1-12.3 months) prior to a clinical relapse being seen. This analysis also showed that the degree of reduction in mutation levels affects outcomes and that there is a co-relation between MRD after consolidation and OS and RFS (but not after induction). The Wilms tumor 1 gene (*WT1*) is highly expressed in most acute leukemias, and its detection in bone marrow has been associated with the presence, persistence, or relapse of leukemia. Recently, investigators from Turin, Italy, systematically applied their best-performing *WT1* RT-PCR assay on 620 patient samples and demonstrated that application of a standardized *WT1* assay can indeed provide independent prognostic information in AML⁽⁹⁰⁾. Studies are ongoing to further elucidate the role of the *WT1*

Table 2-12 Treatment of APL with ATRA+ATO+GO

ATO, arsenic trioxide; ATRA, all-*trans*-retinoic acid; CR, complete remission; D, day; GO, gemtuzumab ozogamicin; IV, intravenous; PCR, polymerase chain reaction; PO, oral; WBC, white blood cell.

gene assay to risk stratify patients who might benefit from intensification of therapy to improve outcomes.

Leukemic cells express abnormal patterns of cellular markers, and these aberrant immunophenotypes can be identified by multiparameter flow cytometry.

Table 2-13 Monitoring of APL Therapy

• Document MR at end of consolidation
• Monitor PCR (BM or PB) every 3 mo \times 2 y
– High risk
– Age >60
– Long treatment delays during consolidation
• If PCR becomes positive from negative => confirm!
• If confirmed, intervene
• Try to use the same lab for PCR

BM, bone marrow; MR, molecular response; PB, peripheral blood; PCR, polymerase chain reaction.

Table 2-14 Advantages and Disadvantages of Real-Time Reverse Transcriptase Polymerase Chain Reaction

Advantages	Disadvantages
Very sensitive reactions	Applicable to a limited number of molecular targets – <i>PML-RARα</i> – CBF leukemias – <i>NPM1</i>
Mutations and translocations are commonly found in AML	CBF-AML may have persistence of qualitative assay positivity for years
	Can miss therapy-related AML
	Expensive
	Longer turnaround time

CBF, core-binding factor.

To yield a sensitivity of 0.01% (10^{-4}), at least 200,000 cells are needed per tube (at least 200,000 events are required to detect 20 aberrant blasts), and three to four tubes are run per patient; 0.1% is the commonly used threshold in most studies in the literature. An advantage of flow cytometry–based studies of MRD is that they can accurately quantify residual leukemic cells and can also distinguish aberrant blasts from normal myeloid precursors. An immunophenotypic fingerprint of the AML can be established for MRD analysis for follow-up. However, there are several advantages and disadvantages with this technique (Table 2-15).

Rubnitz et al reported outcomes with MRD-directed therapy in childhood AML (⁹¹). In this study, patients were randomized to receive HDAC-based induction versus LDAC-based induction. Minimal residual disease levels, on day 22 after induction, were used to allocate GO to determine the timing of the second induction. Minimal residual disease was determined, and GO was given to patients with poor early response, and high-risk patients were allocated to allogeneic SCT. This study showed that MRD was no different with high-dose chemotherapy versus low-dose chemotherapy at day 22 of induction 1. Minimal residual disease >1% on day 22 was a significant prognostic factor influencing OS and EFS in the high-risk patients but not in the standard-/favorable-risk patients. Patients with low-level MRD (0.1% to <1%) did as

well as the MRD-negative cohort. An Italian group analyzed the outcomes of adult AML patients based on MRD levels after induction and consolidation and reported that the MRD status at the end of consolidation was the most important predictor of prognosis. In the MRD-positive group, patients who underwent an allogeneic SCT had improved outcomes (⁹²).

In general, a lack of standardization among different laboratories, identification of thresholds, and time points during follow-up represent the major subjects of controversy for the routine implementation of MRD detection in non-APL AML at this time.

CONCLUSION

After a period of paucity in discoveries, new strategies are finally evolving that may help patients with AML. The biology of the disease is now better understood. Patients with CBF-AML have a high cure rate with HDAC. Patients with APL have benefited from newer treatment with ATRA and arsenical derivatives. Better definition of the complex process initiating and sustaining the leukemic process will lead to a better definition of targets for therapeutic intervention that may translate into improved cure rates. Specific attention must be given to prognostic factors that identify subsets of AML in which specific tailored therapies will be helpful.

Table 2-15 Advantages and Disadvantages of Flow Cytometry for Minimal Residual Disease Assessment

Advantages	Disadvantages
Widely applicable (90%-95% of cases)	Interpretation often challenging, requires experience
Relatively rapid turnaround time	Can be expensive
	Lack of standardization
	Leukemia-associated immunophenotypes (LAIPs) may not cover all leukemic blasts, partial overlap with normal
	Antigen shift resulting from selection/emergence of subclones
	- A complete change in LAIPs in about 20% of AML, with 80% having at least one LAIP similar to the original
	Posttherapy sample is hypocellular; not enough cells/events
	Use of a comprehensive panel of antibodies to establish baseline

Chronic Lymphocytic Leukemia and Associated Disorders

Nitin Jain
Carlos Bueso-Ramos
Susan O'Brien
William G. Wierda

INTRODUCTION

Chronic lymphocytic leukemia (CLL) is a clonal hematopoietic disorder involving expansion of CD5-positive B cells. Chemoimmunotherapy (CIT) has been the standard first-line treatment for patients with CLL (¹). In the last several years, major strides have been made in understanding the disease biology of CLL, and, fortunately, several of these discoveries are making their way into the clinic.

EPIDEMIOLOGY

Chronic lymphocytic leukemia is the most common leukemia in the Western Hemisphere, accounting for about 25% of all leukemias in the United States. The estimated number of new CLL cases for 2015 was 14,620, with 8,140 occurring in men and 6,480 in women. Chronic lymphocytic leukemia is uncommon in the Asian population and accounts for only 2.5% of all leukemias in Japan. The incidence is age-related, with an increase from 5.2 per 100,000 persons older than 50 years to 30.4 per 100,000 persons older than 80 years. Population studies have not identified specific occupational or environmental risk factors for developing CLL (²). The risk of CLL is not increased in Asians settled in Western countries, indicating that genetic factors play a part in CLL risk (³). Up to 15% to 20% of patients with CLL have a family member with CLL or a related lymphoproliferative disorder (⁴). Genome-wide association studies identified several single nucleotide polymorphisms associated with increased risk of CLL (^{5,6}).

BIOLOGY

Surface Antigen Phenotype

Chronic lymphocytic leukemia is a clonal B-cell lymphoid leukemia. Chronic lymphocytic leukemia cells morphologically resemble small mature lymphocytes arrested in an intermediate stage of the B-cell differentiation pathway. The hallmark of CLL cells is that they are monoclonal and express CD5, an antigen commonly found on T cells. CD5-positive B cells can be found in the mantle zone of lymphoid follicles, but they constitute a minor fraction of the B-cell population. CD19, CD20, and CD23 are B-cell markers expressed on CLL cells. Surface immunoglobulin, FMC7, CD22, CD11c, and CD79b are either weakly expressed or negative in CLL. Based on the antigen expression profile, CLL appears to arise from an “activated” B cell.

Somatic Hypermutation of Immunoglobulin Heavy-Chain Variable Gene

Normal B-cell development involves an antigen-independent phase and an antigen-dependent phase. During the antigen-independent phase, B cells undergo rearrangement of the variable (V), diversity (D), and joining (J) genes in the bone marrow. Somatic mutation of the heavy- and light-chain variable gene occurs after encounter with antigen in the germinal center. Assessment for somatic hypermutation of immunoglobulin heavy-chain variable gene (*IGHV*) defines two subsets of CLL. Approximately 50% of CLL cases have somatic

hypermutation (>2% deviation from germline sequence) of the *IGHV* gene and thus appear to arise from post-germinal B cells, whereas the subset of CLL lacking *IGHV* gene hypermutation ($\leq 2\%$ deviation from germline sequence) appears to arise from naive B cells (^{7,8}). The mutation status of CLL cells is fixed, and mutational status is not gained or lost through the course of disease. Several studies showed that unmutated *IGHV* is associated with worse clinical outcomes (⁹).

Because sequencing of the *IGHV* gene to identify the mutational status was labor intensive and not universally available, Damle et al first studied the correlation of *IGHV* mutation status with CD38 expression as a surrogate prognostic marker for *IGHV* mutation status (⁷). A significant association between CD38 expression and unmutated *IGHV* status was noted. Patients with $\geq 30\%$ CD38 expression had a median survival of 10 years, which was significantly shorter than the median survival not reached for patients with CD38 expression $< 30\%$ ($P = .0001$) (⁷). Gene expression profiling of mutated versus unmutated *IGHV* CLL cases showed zeta-associated protein 70 (*ZAP-70*) to be the most differentially expressed gene with higher expression in unmutated *IGHV* cases, providing another surrogate for *IGHV* mutation status (¹⁰). Higher expression of *ZAP-70* ($\geq 20\%$) was associated with worse clinical outcomes (^{10,11}).

Genomic Alterations

Using conventional chromosome banding techniques, cytogenetic abnormalities can be detected in up to 50% of CLL cases. These techniques are hampered by the low mitotic activity of CLL cells; B-cell mitogens may be used to enhance this activity. In addition, metaphases obtained for karyotyping may also arise from normal T cells in the sample, as indicated by sequential immunotyping followed by karyotypic analysis. Fluorescent in situ hybridization (FISH) performed on interphase cells using genomic DNA probes greatly enhanced the ability to detect molecular abnormalities in malignant cells. Fluorescent in situ hybridization demonstrated that molecular abnormalities occur in over 80% of CLL cases. 13q deletion is the most common genetic aberration found in CLL by FISH (55%), followed by 11q deletion (18%), 12q trisomy (16%), and 17p deletion (7%) (¹²). Prior to the use of FISH, trisomy 12 was the most frequently detected chromosomal abnormality in CLL by conventional cytogenetic methods (¹³). Structural abnormalities of 13q were often missed by Giemsa banding, presumably because of the small size of the deletion. The prognosis of CLL varies with the chromosomal abnormality. When divided into five prognostic categories—17p deletion, 11q deletion, 12q trisomy, no observed abnormalities,

and 13q deletion (as sole abnormality)—the survival times were 32, 79, 114, 111, and 133 months, respectively (¹²). Patients with 11q deletion tend to have more prominent lymphadenopathy. Patients with 17p and 11q deletion tend to have more advanced disease and respond poorly to conventional therapy (⁹). Clonal evolution can occur over time and with treatment; therefore, FISH assessment should be repeated when therapeutic intervention is being considered.

Whole exome sequencing of CLL cases has identified genes that are recurrently mutated and may contribute to the pathogenesis of the disease (^{14,15}). Recurrently mutated genes include *TP53*, *NOTCH1*, *SF3B1*, *MYD88*, *XPO1*, and *ATM*. Some of these mutations were correlated with clinical outcome (^{15,16}). *TP53* mutations are typically associated with del(17p). *ATM* and *SF3B1* mutations are typically associated with del(11q).

CLINICAL FEATURES

At diagnosis, most patients are older than 60 years, with more than 90% being over 50 years. The diagnosis of CLL is often incidental; routine blood count may reveal an elevated absolute lymphocyte count (ALC). In symptomatic patients, fatigue and infections may be presenting features. B symptoms (fever, weight loss, night sweat) can also occur but are uncommon at initial diagnosis. Exaggerated skin reaction to insect bites (Wells syndrome) is frequent in CLL. Leptomeningeal involvement is rare. Some patients may present with autoimmune hemolytic anemia or immune thrombocytopenia. Physical examination may reveal cervical, axillary, and/or inguinal lymphadenopathy. Splenomegaly and hepatomegaly are not uncommon.

LABORATORY FEATURES

Laboratory findings invariably show lymphocytosis. The ALC can range from $5 \times 10^9/L$ to $>500 \times 10^9/L$. Chronic lymphocytic leukemia cells resemble mature lymphocytes; they have dense chromatin as well as scant cytoplasm and lack nucleoli (Fig. 3-1). Preparation of the blood smear may damage these fragile lymphocytes and produce “smudge” cells. The bone marrow is typically hypercellular for age, and infiltration varies in terms of the percentage of marrow involved as well as in the pattern of involvement, which may be nodular, interstitial, or diffuse (Figs. 3-2A and B). Erythroid, myeloid, and megakaryocytic precursors may be normal or decreased. Anemia or thrombocytopenia may result from marrow infiltration or from immune destruction. Findings of microspherocytes in peripheral

FIGURE 3-1 Chronic lymphocytic leukemia. Peripheral blood smear showing mature-appearing lymphocytes. Note dense chromatin, scant cytoplasm, absence of nucleoli, and smudge cells.

FIGURE 3-3 Immune hemolytic anemia. Presence of micro-spherocytes (arrows) and nucleated red cells indicates immune destruction of red cells. Diagnosis is confirmed by demonstrating the presence of immunoglobulin G (IgG) and/or complement on red cells.

FIGURE 3-2 (A, B) Chronic lymphocytic leukemia. Bone marrow biopsies showing nodular, diffuse, and interstitial patterns of involvement.

blood smear (Fig. 3-3), reticulocytosis, and demonstration of immunoglobulin (Ig) G and/or complement on red cells support the diagnosis of immune hemolytic anemia. Pure red cell aplasia has been described in 1% to 6% of cases. Patients often develop hypogammaglobulinemia, which can progress in severity with advancing disease. Monoclonal gammopathy may also develop. Other laboratory abnormalities include elevated serum β_2 -microglobulin (β_2 -M); LDH is rarely elevated.

Up to 5% of otherwise normal individuals over the age 40 may harbor a population of monoclonal CD5⁺/CD19⁺/CD23⁺ B cells. These individuals are asymptomatic (absence of cytopenia and lymphadenopathy/organomegaly), and when the absolute monoclonal lymphocyte count is less than 5,000/ μ L and there is no palpable enlarged lymph node, they are characterized as having monoclonal B lymphocytosis (MBL) (¹⁷). Individuals with MBL should be monitored. It is estimated that the rate of progression from MBL to CLL is 1% to 2% per year.

DIAGNOSIS

In 2008, the International Workshop on Chronic Lymphocytic Leukemia (IWCLL) updated the recommendations on diagnosis and treatment of CLL (Table 3-1) (¹⁸). The diagnosis of CLL requires at least 5×10^9 clonal B lymphocytes/L in the peripheral blood, with less than 55% of the cells being atypical (prolymphocytes). A monoclonal B-cell count $\geq 5 \times 10^9$ /L was specified to distinguish CLL from

Table 3-1 Diagnostic Criteria for CLL

Parameter	NCI-IWCLL ^a
Diagnosis	
Lymphocytosis	≥5 × 10 ⁹ /L B lymphocytes in the peripheral blood
Clonality	Flow cytometry to confirm clonality
Duration of lymphocytosis	Not stated
Bone marrow lymphocytes (%)	Not necessary to make a diagnosis ^b

^aNational Cancer Institute–International Workshop on Chronic Lymphocytic Leukemia (¹⁹).
^bBone marrow aspirate and biopsy can be evaluated for factors contributing to cytopenias that may not be due to leukemia infiltration of the marrow.

small lymphocytic lymphoma in patients with palpable lymph nodes or splenomegaly. B-lymphocyte clonality should be demonstrated by using flow cytometry, which should also confirm expression of B-cell surface antigens (CD19, CD20, CD23), low-density surface immunoglobulin (M or D), and CD5. ZAP-70 (Fig. 3-4) expression in CLL cells has prognostic implication. Distinguishing CLL from mantle cell lymphoma (Figs. 3-5A and B) (see section “Differential Diagnosis”) and large granular leukemia (Fig. 3-6) is of utmost importance.

The presence of more than 55% of prolymphocytes would favor a diagnosis of prolymphocytic leukemia (PLL). Prolymphocytes (<55%) can be seen in peripheral blood or bone marrow of patients with CLL (Figs. 3-7A, B, and C).

FIGURE 3-4 ZAP-70 expression in chronic lymphocytic leukemia cells indicates poor prognosis. Immunohistochemistry (above) or flow cytometry can be used to detect ZAP-70 expression.

FIGURE 3-5 A. Mantle cell lymphoma (MCL) in leukemic phase. MCL cells (arrow) are larger than mature lymphocytes (center) with speckled chromatin; some show nuclear cleft. B. Nuclear cyclin D1 staining in mantle cells.

FIGURE 3-6 Large granular lymphocytes with cytoplasmic azurophilic granules.

Green: centromere 12
Red: D13S319

FIGURE 3-7 A. High-power view of a prolymphocyte juxtaposed with a mature-appearing lymphocyte. Note larger size, less condensed chromatin, and prominent nucleolus in prolymphocyte. B. Bone marrow smear from a 58-year-old man with a 3-year history of untreated chronic lymphocytic leukemia (CLL). There are small lymphocytes and larger prolymphocytoid lymphocytes with abundant lightly basophilic cytoplasm, fine chromatin, and variably prominent nucleoli. C. Interphase FISH. Almost all the lymphocytes show deletion of one locus of D13S319 (white arrow) (except two lymphocytes on slide 1, left low), and a large subset of CLL cells also showed trisomy 12 (+12). Interestingly, +12 is almost only seen in prolymphocytoid lymphocytes. The small lymphocytes with clumped chromatin and scant cytoplasm usually do not show +12.

DIFFERENTIAL DIAGNOSIS

Clinical, morphologic, immunophenotypic, and cytogenetic methods help to distinguish between CLL and other diseases such as mantle cell lymphoma, follicular lymphoma, T-cell PLL (T-PLL), hairy cell leukemia (HCL), marginal zone lymphoma, and Waldenström macroglobulinemia. Table 3-2 summarizes the immunophenotypic features of these disorders. Distinguishing CLL from mantle cell lymphoma is important because both can express CD5 (see Fig. 3-5A). Unlike CLL, mantle cell lymphoma cells are typically CD23 negative,

FMC-7 positive, and have strong surface immunoglobulin staining. Confirmation of mantle cell lymphoma can be made by detection of the t(11;14) translocation and/or positive nuclear cyclin D1 staining (see Fig. 3-5B).

STAGING

Staging systems for CLL include Rai and Binet staging (Table 3-3). The original Rai classification defined five stages from 0 to IV; this has been modified to three stages by defining Rai stage 0 as low risk, stages I and II

Table 3-2 Immunophenotypic Analysis in Chronic B-Cell Disorders

Disease	slg	CD5	CD10	CD20	CD22	CD23	CD79B	CD103	FMC7
CLL	Weak	++	–	+	–/+	++	–/+	–	–/+
B-PLL	Strong	–/+	–/+	++	+	–/+	++	–	++
HCL	Strong	–	–	++	++	–	+	+	++
SLVL	Strong	–/+	–	++	++	–/+	++	–	++
FL	Strong	–/+	++	++	++	–/+	++	–	++
MCL	Strong	++	–	++	++	–	++	–	++

B-PLL, prolymphocytic leukemia; CLL, chronic lymphocytic leukemia; FL, follicular lymphoma; HCL, hairy cell leukemia; MCL, mantle cell lymphoma; slg, surface immunoglobulin; SLVL, splenic lymphoma with villous lymphocytes.

as intermediate risk, and stages III and IV as high risk, with median survival times of >12.5, 7, and 1.5 years for each risk group, respectively. Similarly for Binet stages A, B, and C, median survival times are >10, 6, and 2 years, respectively. The diagnostic workup that is undertaken in CLL patients at initial presentation at the University of Texas MD Anderson Cancer Center (MDACC) is listed in [Table 3-4](#).

PROGNOSIS

Both CLL staging systems confer significant prognostic information; however, they are limited by their inability to identify which patient with early-stage disease will develop disease progression. An analysis of the French Cooperative Group trial of Binet stage A patients demonstrated that a subgroup of these stage A patients with

a hemoglobin ≥ 12 g/dL, a lymphocyte count $< 30 \times 10^9/L$, and $< 80\%$ lymphocytes in the bone marrow aspirate was less likely to progress than other stage A patients⁽¹⁹⁾. A lymphocyte doubling time of > 12 months, Rai stage 0 disease, nondiffuse bone marrow pattern, hemoglobin ≥ 13 g/dL, and ALC $< 30 \times 10^9/L$ similarly define a group of CLL with an excellent prognosis⁽²⁰⁾.

Serum factors have been identified as prognostic indicators in early-stage CLL. Patients with early-stage CLL with serum thymidine kinase (TK) levels > 7.0 U/L had a significantly shorter progression-free survival (PFS) compared to those with TK levels below that level. Elevated serum β_2 -M level is also an adverse prognostic feature that has been shown to correlate with clinical stage and disease progression. High serum LDH levels indicate a poor prognosis.

Fluorescent in situ hybridization, *IGHV* gene mutation status, ZAP-70 expression, and CD38

Table 3-3 Staging of CLL

Rai Stage	Modified Rai Stage	Description	Binet Stage	Description	Median Survival
0	Low risk	Lymphocytosis only	A	Hemoglobin ≥ 10 g/dL and platelets $\geq 100 \times 10^9/L$ and < 3 enlarged lymphoid-bearing areas	> 10 years
1	Intermediate risk	Lymphocytosis and lymphadenopathy	B	Hemoglobin ≥ 10 g/dL and platelets $\geq 100 \times 10^9/L$ and ≥ 3 enlarged lymphoid-bearing areas	5-7 years
2	Intermediate risk	Lymphocytosis and splenomegaly and/or hepatomegaly with/without lymphadenopathy			
3	High risk	Lymphocytosis and anemia (hemoglobin < 11 g/dL)	C	Hemoglobin < 10 g/dL or platelets $< 100 \times 10^9/L$ (irrespective of number of lymphoid-bearing areas)	2-3 years
4	High risk	Lymphocytosis and thrombocytopenia (platelets $< 100 \times 10^9/L$)			

Table 3-4 Initial Evaluation of Patients With CLL at MDACC

History and physical (close attention to lymph node areas, liver/spleen size)
Constitutional symptoms (fever, chills, weight loss, night sweats)
Assessment of performance status
CBC, electrolytes, BUN, creatinine, liver function tests, LDH, quantitative immunoglobulins, β_2 -microglobulin
Examination of peripheral blood smear
Bone marrow aspiration and biopsy (in patients with cytopenias or those in need of treatment)
Immunophenotyping of peripheral blood/bone marrow lymphocytes to establish diagnosis
Prognostic marker assessment Flow cytometry for CD38 Immunostaining/flow cytometry for ZAP-70 Interphase FISH (assessment of deletion 17p, deletion 11q, trisomy 12, deletion 13) <i>IGHV</i> mutation status
Imaging studies (only if presenting with significant adenopathy or needed treatment); many clinical trials are now incorporating CT scans as per new guidelines, but these are not standard of care outside of a clinical trial. CT scan or PET scan (PET scan preferred if there is a suspicion of Richter transformation)

BUN, blood urea nitrogen; CBC, complete blood count; CLL, chronic lymphocytic leukemia; CT, computed tomography; FISH, fluorescent in situ hybridization; LDH, lactate dehydrogenase; MDACC, MD Anderson Cancer Center; PET, positron emission tomography.

expression are well-established prognostic factors in CLL (described in earlier sections). A prognostic model integrating cytogenetic abnormalities identified by FISH with mutated *NOTCH1*, *SF3B1*, *BIRC3*, and *TP53* was proposed ⁽²¹⁾. The established prognostic factors in CLL indicating poorer outcome are listed in Table 3-5.

TREATMENT

Indications for Treatment

Unlike most leukemias, an unusual feature of CLL is that making the diagnosis is not necessarily an indication to initiate treatment. Early treatment of asymptomatic CLL with chemotherapy was not shown to prolong survival. In the current era of more effective CIT regimens and targeted therapies, this question will likely be investigated again. The National Cancer Institute (NCI)-IWCLL criteria for treatment of CLL are summarized in Table 3-6. The NCI-IWCLL criteria for response assessment of CLL are summarized in Table 3-7.

Table 3-5 Established Poor Prognostic Factors in CLL

Male gender
Advanced Rai or Binet staging
Cytogenetic abnormalities [del(17p), del(11q), complex cytogenetics]
Lymphocyte doubling time <12 months
Initial lymphocyte count $>50 \times 10^9/L$
Elevated serum TK
Elevated β_2 -microglobulin
Elevated serum-soluble CD23
Higher CD38 expression
Higher ZAP-70 expression
Diffuse pattern of marrow involvement
Unmutated <i>IGHV</i> gene
Gene mutations (<i>TP53</i> , <i>BIRC3</i> , <i>NOTCH1</i> , <i>SF3B1</i>)

TK, thymidine kinase.

Table 3-6 Indications for Treatment in CLL (NCI-IWCLL) ⁽¹⁸⁾

Active disease should be confirmed prior to initiating treatment.
1. Evidence of progressive marrow failure as manifest by the development or worsening of anemia and/or thrombocytopenia
2. Massive (ie, >6 cm below the left costal margin) or progressive or symptomatic splenomegaly
3. Massive nodes or clusters (ie, at least 10 cm in longest diameter) or progressive or symptomatic lymphadenopathy
4. Progressive lymphocytosis with an increase of $>50\%$ over a 2-month period or an anticipated doubling time of <6 months ^a
5. Autoimmune anemia and/or thrombocytopenia poorly responsive to corticosteroid therapy or other standard therapy
6. Constitutional symptoms, defined as any one or more of the following disease-related symptoms or signs: <ol style="list-style-type: none"> Unintentional weight loss $\geq 10\%$ within the previous 6 months Significant fatigue (ie, ECOG PS 2 or worse; cannot work or unable to perform usual activities) Fevers $>100.5^\circ F$ or $38.0^\circ C$ for ≥ 2 weeks without evidence of infection Night sweats for >1 month without evidence of infection

ECOG PS, Eastern Cooperative Oncology Group performance status; NCI-IWCLL, National Cancer Institute–International Workshop on Chronic Lymphocytic Leukemia.

^aIn patients with a lymphocyte count of $<30 \times 10^9/L$, lymphocyte doubling time should not be used as a single parameter to define treatment indication. Factors contributing to lymphocytosis or lymphadenopathy other than CLL (ie, infections) should be excluded.

Table 3-7 Definition of Response^a

Parameter	Complete Remission (CR)	Partial Remission (PR)	Progressive Disease (PD)
Group A			
Lymphadenopathy ^b	None >1.5 cm	Decrease ≥50%	Increase ≥50%
Hepatomegaly or splenomegaly ^b	Normal size	Decrease ≥50%	Increase ≥50%
Blood lymphocytes	<4 × 10 ⁹ /L	Decrease ≥50% from baseline	Increase ≥50% from baseline
Bone marrow	Normocellular, <30% lymphocytes, no B-lymphoid nodules Hypocellular marrow defines CRi	50% reduction in marrow infiltrate, or B-lymphoid nodules	
Group B			
Neutrophils	>1.5 × 10 ⁹ /L	>1.5 × 10 ⁹ /L or 50% improvement from baseline	
Platelet count	>100 × 10 ⁹ /L	>100 × 10 ⁹ /L or increase ≥50% over baseline	Decrease ≥50% over baseline secondary to CLL
Hemoglobin	>11 g/dL	>11 g/dL or increase ≥50% over baseline	Decrease of >2 g/dL from baseline secondary to CLL

Group A criteria define tumor load, group B criteria define marrow function.

CR: All of the criteria have to be met, and patients have to lack disease-related constitutional symptoms.

CRi: Patients meeting all the criteria of CR except count recovery (unrelated to disease activity). Patients with meeting all CR criteria but with hypocellular marrow are also CRi.

PR: At least two of the group A criteria plus one of the group B criteria have to be met. To define a PR, these parameters need to be documented for at least 2 months.

Nodular PR: Patients meeting all the criteria of CR except with residual marrow nodules. Immunohistochemistry should be performed to define whether these nodules are composed of primarily T cells, lymphocytes other than chronic lymphocytic leukemia (CLL) cells, or CLL cells.

Stable disease (SD): Absence of PD and failure to achieve at least a PR. Stable disease is considered equivalent to nonresponse.

PD: At least one of the above criteria of group A or group B has to be met.

^aNational Cancer Institute—International Workshop Group on CLL (¹⁸).

^bAs assessed by physical examination (imaging studies for clinical trials).

First-Line Treatment

Chemoimmunotherapy has been the standard first-line treatment for patients with CLL (¹).

Purine Analogues and Alkylating Agents

Alkylating agents such as chlorambucil or cyclophosphamide, either alone or in combination with corticosteroids, were the cornerstone of treatment of CLL for several decades. In 1988 to 1989, Grever et al and the MDACC group published the first results with fludarabine in patients with CLL (^{22, 23}). In the MDACC study, a 5-day schedule of fludarabine in previously treated patients with CLL produced a complete remission (CR) rate of 15% and an overall response rate (ORR) of 44%. Different fludarabine regimens including the addition of prednisone (²⁴), a 3-day schedule of fludarabine (²⁵), and a once-a-week schedule of fludarabine (²⁶) were studied at MDACC. The addition of prednisone to fludarabine did not improve response rates or survival; the incidence of opportunistic infections was increased. The response rate seen with the 3-day schedule of fludarabine was slightly less than that seen with the 5-day schedule but was associated

with less immunosuppression and lower morbidity. The once-a-week schedule had an inferior response rate. Fludarabine, when compared to chlorambucil, produced significantly higher response rates in previously untreated patients with CLL (Cancer and Leukemia Group B [CALGB] 9011 trial) (²⁷). In this study, 509 patients were randomized to receive fludarabine, chlorambucil, or both in combination. The combination arm was stopped early due to excessive infection-related toxicity. The fludarabine arm had significantly higher CR and ORR compared to patients treated with chlorambucil.

The German CLL Study Group (GCLLSG) CLL5 trial evaluated fludarabine versus chlorambucil as initial treatment for patients older than 65 years (²⁸). Although treatment with fludarabine was associated with superior ORR, there was no improvement in PFS or overall survival (OS). The French Cooperative Group on CLL randomized 938 previously untreated patients to one of three treatment regimens: fludarabine, CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone), or CAP (cyclophosphamide, doxorubicin, prednisone) (²⁹). Higher ORR and longer time to progression were seen with fludarabine. Fludarabine in

combination with cyclophosphamide (FC) was shown to be an effective regimen in CLL. Three large randomized trials (German CLL4 trial [30], US Intergroup E2997 trial [31], and UK LRF CLL4 trial [32]) evaluated the efficacy of FC versus fludarabine monotherapy in treatment-naïve CLL patients and reported superior PFS with the FC combination compared to fludarabine or chlorambucil monotherapy. E2997 was a phase III randomized trial comparing FC versus fludarabine monotherapy in patients with treatment-naïve CLL (31). A total of 278 patients were randomly assigned. Fludarabine/cyclophosphamide was associated with a higher CR (23.4% vs 4.6%; $P < .001$) and higher ORR (74.3% vs 59.5%; $P = .013$) compared to fludarabine monotherapy. The PFS was significantly improved for patients treated with FC compared to fludarabine alone (31.6 vs 19.2 months; $P < .0001$).

Bendamustine is an alkylating agent that has structural similarities to a purine analog. It consists of both a nitrogen mustard core and purine-like side group. Bendamustine has little cross-resistance with other alkylating agents. A pivotal phase III study comparing bendamustine to chlorambucil in patients with previously untreated CLL led to its approval by the US Food and Drug Administration (FDA) (33). A total of 319 patients were randomly assigned. Bendamustine led to a significantly higher ORR (68%) compared to chlorambucil (31%; $P < .0001$). Patients in the bendamustine arm, compared with the chlorambucil arm, had a higher CR rate (31% vs 2%) and longer PFS (21.6 vs 8.3 months; $P < .0001$).

Cladribine (2-chlorodeoxyadenosine; 2-CDA) and pentostatin have activity in treating CLL. The Polish Adult Leukemia Group (PALG)-CLL2 trial compared cladribine monotherapy, cladribine plus cyclophosphamide, and cladribine, cyclophosphamide, and mitoxantrone as initial therapy for patients with CLL. Although there was a higher CR rate in the mitoxantrone arm, there was no difference in PFS or OS among the three arms (34). The PALG-CLL3 phase III trial reported equivalent efficacy of fludarabine/cyclophosphamide versus cladribine/cyclophosphamide in patients with treatment-naïve CLL (35).

Monoclonal Antibodies

Rituximab

CD20 is a B-cell-specific surface antigen that is expressed on 95% of B cells. It is tightly bound to the cell surface and is not shed or internalized upon antibody binding. Rituximab is a chimeric antibody that targets the CD20 antigen. Rituximab can mediate cell lysis by various mechanisms, including antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and direct induction of apoptosis. Standard-dose rituximab monotherapy has

limited activity in treating patients with CLL. O'Brien et al conducted a dose-escalation study with rituximab; patients received an initial dose of 375 mg/m², and the dose was then escalated in cohorts to a maximum of 2,250 mg/m² (36). The response rate was 36% in patients with CLL, and the response correlated with the dose: 22% for patients treated at 500 to 825 mg/m², 43% for those treated at 1,000 to 1,500 mg/m², and 75% for those treated at the highest dose of 2,250 mg/m². Another dose-intensification strategy with administration of rituximab 375 mg/m² three times a week for 4 weeks yielded an ORR of 45% in patients with CLL (37).

Chemoimmunotherapy

A phase II trial (CALGB 9712 study) of sequential versus concurrent administration of fludarabine and rituximab in previously untreated patients with CLL was reported (38). Patients were randomized to receive either six monthly courses of fludarabine concurrently with rituximab followed 2 months later by four weekly doses of rituximab as consolidation or fludarabine alone for 6 months followed 2 months later by the same rituximab consolidation therapy. A total of 104 patients were randomized to the concurrent or sequential regimens. The ORR in the sequential arm was 77%, and the CR rate was 28%. The ORR in the concurrent arm was 90%, and the CR rate was 47%.

A CIT protocol developed at MDACC demonstrated the efficacy of combining rituximab with fludarabine and cyclophosphamide (39,40). The regimen was as follows: fludarabine 25 mg/m² per day for 3 days, cyclophosphamide 250 mg/m² per day for 3 days, and rituximab 375 to 500 mg/m² on day 1 (FCR regimen). This was a single-arm study of FCR as initial therapy in 300 patients with progressive or advanced CLL. At a median follow-up of 6 years, the ORR was 95% (CR, 72%; nodular partial remission [PR], 10%; PR, 13%). The 6-year OS and failure-free survival rates were 77% and 51%, respectively. The median time to progression was 80 months. Of note, patients who attained a CR with negative flow cytometry had a superior time to progression (85 vs 49 months) and OS (84% vs 65% at 6 years).

The GCLLSG group conducted a phase III trial to evaluate the efficacy of FCR versus FC in first-line treatment of patients with advanced CLL (CLL8 trial) (9). A total of 817 patients were randomized to receive six courses of either FC (409 patients) or FCR (408 patients). The median age was 61 years (range, 30-81 years). They reported a significantly higher CR rate (44% vs 22%; $P < .0001$), ORR (90% vs 80%; $P < .0001$), PFS (median PFS, 52 vs 33 months; $P < .0001$), and OS (3-year OS, 87% vs 83%; $P = .012$) with the addition of rituximab. Treatment with FCR was associated with a higher incidence of grade 3 or 4 neutropenia (33.7%

vs 21%; $P < .0001$); however, there was no difference in the incidence of grade 3 or 4 infections. This trial established the role of anti-CD20 monoclonal antibody (mAb) in the first-line therapy of CLL.

Bendamustine in combination with rituximab has also been evaluated as first-line treatment for patients with CLL. Fischer et al reported on the outcomes of 117 patients with treatment-naïve CLL who received bendamustine and rituximab (BR) ⁽⁴¹⁾. Eligibility criteria included creatinine clearance >30 mL/min. The ORR was 88% with a CR rate of 23%. The median PFS was 34 months. Notably, one-third of the patients had a creatinine clearance ≤ 70 mL/min (these patients are typically excluded from the FCR trials), and these patients did equally as well as patients with a creatinine clearance >70 mL/min.

The GCLLSG recently reported results of the randomized phase III study of FCR versus BR as first-line therapy for patients with CLL (CLL10 trial) ⁽⁴²⁾. This trial included patients with CLL [non-del(17p)] and good physical status (Cumulative Illness Rating Scale [CIRS] score ≤ 6 and creatinine clearance ≥ 70 mL/min). A total of 282 patients received FCR, and 279 patients received BR. The FCR arm had a significantly higher CR/CR with incomplete count recovery (CRi) rate (39.7 vs 30.8; $P = .03$) and significantly improved PFS (median PFS, 55.2 vs 41.7 months; $P < .001$). Overall survival was not different between the two groups. Not unexpectedly, patients on the FCR arm experienced more grade 3 or 4 neutropenia (84.2% vs 59%; $P < .001$), more thrombocytopenia (21.5% vs 14.4%; $P = .03$), and increased risk of grade 3 or 4 infections (39.1% vs 26.8%; $P < .001$). However, the treatment-related mortality was similar in the two arms. For patients >65 years of age, there was no improvement

in PFS noted with FCR compared to BR; however, there was an increased risk of infections in the older patients. Based on these data, FCR is the standard first-line CIT regimen for patients with CLL who are ≤ 65 years old. However, for patients who are older than 65 years and deemed fit to receive CIT, BR is the preferred first-line therapy. It is important to note that for patients with moderate renal dysfunction (creatinine clearance, 30-70 mL/min), FCR therapy can lead to significant cytopenias necessitating dose reductions or treatment discontinuations, and therefore, BR may be a better alternative in this group of patients. A list of published CIT trials in the first-line setting in patients with CLL is provided in [Table 3-8](#).

Several studies have been conducted with the intent of modifying the FCR regimen by dose-intensifying rituximab ⁽⁴³⁾, adding mitoxantrone ⁽⁴⁴⁾, adding alemtuzumab ⁽⁴⁵⁾, adding granulocyte-macrophage colony-stimulating factor ⁽⁴⁶⁾, or using lower doses of FCR (FCR-Lite) ^(47, 48), but these studies have not shown superior results as compared to those seen with the standard FCR regimen.

Ofatumumab

Ofatumumab is a fully human IgG1 mAb that binds to a different epitope of CD20 than rituximab. Ofatumumab has higher CDC compared with rituximab ⁽⁴⁹⁾. Wierda et al reported a pivotal trial of ofatumumab monotherapy (weekly for 8 weeks, followed by four monthly infusions) in patients with fludarabine- and alemtuzumab-refractory CLL or fludarabine-refractory CLL with bulky lymph nodes ⁽⁵⁰⁾. In a recent update of this study, the ORR was reported as 49% and 43%, respectively. The median PFS was 4.6 to 5.5 months, and the median OS was 13.9 to 17.4 months. Based

Table 3-8 First-Line Chemoimmunotherapy Trials for CLL

Regimen	Trial	No. of Patients	Median Age (years)	CR (%)	ORR (%)	PFS (months)
FCR	MDACC ^(39, 40)	300	57	72	95	80
	CLL8 trial (FCR arm) ⁽⁹⁾	408	61	44	90	52
	CLL10 trial (FCR arm) ⁽⁴²⁾	282	61	40	95	55
	FCR-Lite ^(47, 48)	63	58	73	94	70
BR	GCLLSG phase II ⁽⁴¹⁾	117	64	23	88	34
	CLL10 trial (BR arm) ⁽⁴²⁾	279	62	31	96	42
FR	CALGB 9712 ⁽³⁸⁾	104	63	47	84	42
PCR	Kay	64	63	41	91	33
FCO	Wierda	61	56	41	75	70% (1 yr)
PCO	Shanafelt	48	65	46	96	NR

BR, bendamustine, rituximab; CALGB, Cancer and Leukemia Group B; CR, complete response; FCO, fludarabine, cyclophosphamide, ofatumumab; FCR, fludarabine, cyclophosphamide, rituximab; FR, fludarabine, rituximab; GCLLSG, German Chronic Lymphocytic Leukemia Study Group; MDACC, MD Anderson Cancer Center; NR, not reported; ORR, overall response rate; PCO, pentostatin, cyclophosphamide, ofatumumab; PCR, pentostatin, cyclophosphamide, rituximab; PFS, progression-free survival.

on these data, ofatumumab was approved for patients with CLL refractory to fludarabine and alemtuzumab. Ofatumumab has also been combined with chlorambucil as first-line therapy in patients who were deemed ineligible for FCR-based regimens (COMPLEMENT-1 trial) ⁽⁵¹⁾. A total of 447 patients were randomized to receive chlorambucil +/- ofatumumab. The chlorambucil/ofatumumab combination, compared with chlorambucil alone, significantly improved ORR (82% vs 69%; $P < .001$) and PFS (median, 22.4 vs 13.1 months; $P < .001$) ⁽⁵¹⁾. Based on these results, the combination of ofatumumab and chlorambucil was approved for the first-line treatment of patients with CLL for whom fludarabine-based therapy is considered inappropriate.

Obinutuzumab

Obinutuzumab is a humanized type II CD20 mAb with a glycoengineered Fc domain that leads to enhanced ADCC compared with rituximab. This type II CD20 mAb is more effective at direct induction of CLL cell apoptosis, which leads to more effective B-cell depletion than rituximab. In the GCLLSG CLL11 trial, previously untreated patients with CLL with coexisting conditions (CIRS score >6 and/or creatinine clearance 30-69 mL/min) were randomly assigned to receive chlorambucil monotherapy, chlorambucil plus rituximab, or chlorambucil plus obinutuzumab ^(52, 53). A total of 781 patients were enrolled. The median age was 73 years. Treatment with obinutuzumab-chlorambucil, compared to rituximab-chlorambucil, resulted in a higher ORR of 78.4% (CR 20.7% + PR 57.7%) versus 65.1% (CR 7% + PR 58.1%; $P < .001$). Progression-free survival was significantly longer with obinutuzumab-chlorambucil compared to that seen with rituximab-chlorambucil (median PFS, 29.2 vs 15.4 months; $P < .001$) ^(52, 53). Infusion-related reactions and neutropenia were more common in the obinutuzumab-chlorambucil arm, but the risk of infection was not increased. Obinutuzumab-chlorambucil was superior to chlorambucil monotherapy for both PFS and OS. This trial established the combination of chlorambucil with a CD20 mAb as a standard of care for first-line therapy in older patients with CLL who have comorbidities. Based on the CLL11 trial, the FDA approved obinutuzumab in combination with chlorambucil for patients with previously untreated CLL.

Alemtuzumab

CD52 is a surface antigen abundantly expressed on CLL cells and normal B and T lymphocytes. Alemtuzumab is a humanized mAb targeting CD52. In the pivotal trial of alemtuzumab, 93 patients, all of whom were refractory to fludarabine, received alemtuzumab ⁽⁵⁴⁾. Alemtuzumab was given intravenously three times weekly for a maximum of 12 weeks. The ORR was 33% (CR, 2%). Response rates were lower

among patients with bulky disease. This trial led to FDA approval of this agent for fludarabine-refractory patients with CLL. Subcutaneous administration of alemtuzumab has similar efficacy in CLL as the intravenous administration, unlike in T-PLL ⁽⁵⁵⁾. Hillmen et al conducted a phase III randomized trial (CAM307 trial) to evaluate the efficacy and safety of intravenous alemtuzumab compared with chlorambucil in the first-line treatment of patients with CLL ⁽⁵⁶⁾. In this trial, 297 patients were randomized, 149 to alemtuzumab and 148 to chlorambucil. Alemtuzumab was found to produce a higher ORR (83% vs 55%; $P < .0001$) and CR rate (24% vs 2%; $P < .0001$) than chlorambucil. It led to superior PFS, with a 42% reduction in risk of progression or death (hazard ratio [HR] = 0.58; $P = .0001$). In addition, the elimination of minimal residual disease (MRD) occurred in 11 of 36 patients treated with alemtuzumab who attained CR compared to none of the patients treated with chlorambucil. Alemtuzumab was well tolerated but did lead to a higher risk of cytomegalovirus (CMV) infection. Because alemtuzumab acts via a p53 independent pathway, it was originally investigated as a promising strategy for patients with del(17p). However, somewhat disappointingly, patients with 17p deletion in the CAM307 trial, although faring better with alemtuzumab than chlorambucil, had a median PFS of only 10.8 months with alemtuzumab. In an attempt to improve upon the efficacy of FCR, a combination of alemtuzumab and FCR (CFAR) has been reported, both in the first-line and in the relapsed setting ^(45, 57). In the first-line CFAR trial, patients <70 years old with serum β_2 -M ≥ 4 mg/L were enrolled. Sixty patients were treated. The ORR was 92%, with a CR rate of 70%. The time-to-event outcomes were comparable to the high-risk FCR-treated patients.

Two recent studies evaluated the combination of alemtuzumab and corticosteroids. In the UK CLL206 trial, the use of alemtuzumab with high-dose pulse methylprednisolone as first-line treatment for patients with del(17p) resulted in a high ORR of 88% with an impressive CR rate of 65%, but the median PFS was only 18.3 months ⁽⁵⁸⁾. The French/German CLL20 trial combined alemtuzumab with dexamethasone followed by consolidation either with alemtuzumab or with an allogeneic stem-cell transplantation (allo-SCT) ⁽⁵⁹⁾. Forty-two patients with del(17p) received first-line therapy with alemtuzumab and dexamethasone in this trial, with an ORR of 97% and a median PFS of 32.8 months. Consolidation with allo-SCT may have contributed to the improved outcomes. However, due to the introduction of novel targeted therapies, potential toxicities with alemtuzumab such as CMV reactivation, and the withdrawal of the drug from the commercial market, alemtuzumab has a limited role in the management of patients with CLL.

Patient Stratification for First-Line Treatment

Based on age, comorbidities, and FISH status, patients can be categorized into several groups:

- Intensive CIT eligible [non-del(17p)]: These are generally patients less than 65 years of age without significant comorbidities. Patients 65 to 70 years of age with good performance status can also be considered in this treatment group. The FCR regimen is the preferred first-line treatment option for these patients. The BR regimen is a reasonable first choice for patients age 65 years or older. For patients with renal impairment (creatinine clearance between 30 and 70 mL/min), BR is preferred over FCR.
- Intensive CIT ineligible [non-del(17p)]: These are generally patients over the age of 65 years or patients with comorbidities. For this group of patients, the combination of chlorambucil and obinutuzumab is the preferred treatment choice. The combination of chlorambucil with ofatumumab is another potential treatment option.
- Patients with del(17p): Patients with del(17p) or *TP53* gene mutation have poor outcomes with conventional CIT regimens such as FCR (^{9, 40}). For patients with del(17p), ibrutinib, a Bruton tyrosine kinase (BTK) inhibitor, is the preferred first-line therapy, irrespective of the patient age (see the “Novel Targeted Therapies” section for details).
- Frail patients with significant comorbidities: The median age at the time of first treatment for CLL is around 76 to 77 years. Comorbid conditions and poor performance status can limit the ability of patients in this age group to receive CIT. For such patients, CD20 mAb therapy alone should be considered.

Minimal Residual Disease

Bottcher et al evaluated MRD by four-color flow-cytometry (sensitivity of at least 10^{-4}) in patients enrolled on the CLL8 trial (⁶⁰). Minimal residual disease levels were characterized as low ($<10^{-4}$), intermediate ($\geq 10^{-4}$ to $<10^{-2}$), or high ($\geq 10^{-2}$). After completion of all therapy, there was a significantly higher proportion of patients with low-level MRD (MRD negative per IWCLL) in the FCR arm compared to the FC arm (peripheral blood: 63% vs 35%; $P < .0001$; bone marrow: 44% vs 28%; $P = .0007$). Achievement of MRD-negative remission was significantly associated with a longer PFS, and in a multivariable model, MRD remained predictive for PFS and OS. The MDACC group reported outcomes for MRD assessment in the bone marrow after first-line FCR therapy (⁶¹). At the final response assessment, 43% of patients were MRD negative. In a multivariable model, mutated *IGHV* gene and trisomy 12 were independently associated

with achievement of MRD-negative remission. Evaluating MRD at the end of treatment is now being incorporated as an endpoint in most clinical trials.

Novel Targeted Therapies

These include B-cell receptor (BCR) inhibitors such as BTK inhibitors, phosphoinositide 3-kinase kinase (PI3K) inhibitors, and spleen tyrosine kinase (Syk) inhibitors. Targeting Bcl-2, an antiapoptotic protein that is over-expressed in CLL cells, with the small-molecule inhibitor venetoclax represents another important novel strategy. Several studies were done with the immunomodulatory drug lenalidomide in patients with CLL. Immunotherapy with genetically modified T cells (chimeric antigen receptor [CAR]) represents another novel approach to target CLL cells. Preclinical data support the use of checkpoint inhibitors in patients with CLL (⁶²), and clinical trials with agents targeting PD-1/PD-L1 are under way.

B-Cell Signaling Pathway Inhibitors

Chronic lymphocytic leukemia cells receive growth and survival signals from the microenvironment of bone marrow, lymph nodes, and spleen. Bruton tyrosine kinase is a central molecule in signal transduction for the BCR as well as CD19, CD38, CD40, CXCR4 chemokine receptor, tumor necrosis factor receptors, and toll-like receptors (TLRs). Other important signal transduction molecules include PI3K and Syk.

BTK Inhibitors

Bruton tyrosine kinase is a nonreceptor tyrosine kinase of the Tec kinase family and plays a crucial role in BCR signaling. Ibrutinib is an oral, selective, and irreversible inhibitor of BTK. It forms a covalent bond with the cysteine-481 of BTK. Byrd et al reported outcomes of 101 patients with relapsed or refractory CLL who received ibrutinib monotherapy (⁶³). The median age was 64 years (range, 37-82 years). Thirty-four percent of the patients had del(17p), and 78% had unmutated *IGHV*. Fifty-nine percent of the patients had received four or more prior therapies. The ORR was 90%, with 7% CR, 65% PR, and 9% PR with lymphocytosis (PR-L). The estimated PFS at 30 months was 69%. The median PFS times for patients with del(17p) and del(11q) were 28 and 38.7 months, respectively, and were inferior to the PFS times of patients without del(17p) or del(11q). The most common toxicity was diarrhea, occurring in 55% of patients, the majority of whom had grade 1 or 2 diarrhea. Notable grade ≥ 3 adverse events were hypertension (20%), pneumonia (25%), neutropenia (18%), thrombocytopenia (10%), bleeding (8%), and atrial fibrillation (6%). In a randomized phase III trial (RESONATE trial), patients with

relapsed or refractory CLL were randomized to ibrutinib ($n = 195$) or ofatumumab ($n = 196$). The ibrutinib arm had a much higher ORR and superior PFS and OS compared to the ofatumumab arm ⁽⁶⁴⁾. Based on this trial, ibrutinib (420 mg orally once daily) was FDA approved for patients with relapsed/refractory CLL and for patients with del(17p). There are limited data with ibrutinib in the first-line setting. O'Brien et al reported on the outcomes of 31 patients with CLL who received ibrutinib monotherapy in the first-line setting ⁽⁶⁵⁾. The median age was 71 years (range, 65-84 years). After a median follow-up of 35 months, an ORR of 84% was noted, with 23% attaining CR ⁽⁶⁶⁾. The 30-month PFS and OS rates were 96% and 97%, respectively.

It is important to note that most patients will develop lymphocytosis upon initiating ibrutinib. This is expected with ibrutinib and other BCR inhibitors, and it generally resolves over the course of 6 to 9 months with continued treatment. Development of lymphocytosis does not appear to be detrimental to the long-term clinical outcomes.

Mechanisms of ibrutinib resistance remain an area of active research. Several of the patients who progressed on ibrutinib were found to have mutation of *BTK* at cysteine-481 (C481S) and gain-of-function mutations in *PLC γ 2*, a signaling molecule downstream of BTK ⁽⁶⁷⁾. Several other BTK inhibitors are in clinical development, including ACP-196 and ONO-4059.

PI3K Inhibitors

PI3K- δ is a critical kinase for activation, proliferation, and survival of B cells and is hyperactive in many B-cell malignancies, including CLL. Idelalisib is a potent, selective, reversible inhibitor of PI3K- δ . A phase I trial of idelalisib was conducted in relapsed and refractory patients with CLL ⁽⁶⁸⁾. A total of 54 patients were enrolled with a median age of 62.5 years (range, 37-82 years). Twenty-four percent of the patients had del(17p) or *TP53* mutation, and 91% had unmutated *IGHV*. The median number of prior therapies was five. Patients were treated at one of six dose levels of oral idelalisib (range, 50-350 mg once or twice daily). The ORR was 72% (39% PR, 33% PR-L). The median PFS was 15.8 months. The most commonly observed grade ≥ 3 adverse events were pneumonia (20%), neutropenic fever (11%), and diarrhea (6%). Transaminitis of any grade was observed in 15 patients (28%); only one patient experienced a grade ≥ 3 transaminitis. A phase III clinical trial evaluated the activity of idelalisib/rituximab versus rituximab/placebo in patients with relapsed/refractory CLL in whom rituximab monotherapy would be considered appropriate (not able to receive cytotoxic agents for one or more of the following reasons: severe neutropenia or thrombocytopenia caused by cumulative myelotoxicity from previous therapies, creatinine clearance < 60 mL/min, or

a CIRS score of > 6) ⁽⁶⁹⁾. A total of 220 patients were enrolled. Idelalisib 150 mg was dosed twice daily continuously in 110 patients. Rituximab was administered to all patients at 375 mg/m² for the first dose and then at 500 mg/m² every 2 weeks for four doses and then every 4 weeks for three doses (eight total doses). This trial demonstrated superior efficacy for combined idelalisib and rituximab over rituximab and placebo, with an HR for PFS of 0.15 ($P < .001$) and HR for OS of 0.28 ($P = .02$). Pneumonitis was seen in 4% of the patients treated on the idelalisib/rituximab arm. This trial led to the FDA approval of the combination of idelalisib and rituximab for patients with relapsed/refractory CLL in whom rituximab monotherapy would be considered appropriate.

There are limited data in the first-line setting with idelalisib. In a recent report, idelalisib monotherapy (150 mg twice a day) was given as first-line therapy to patients ≥ 65 years with CLL ⁽⁷⁰⁾. A total of 37 patients were treated. Fourteen percent of the patients had del(17p). In the 27 evaluable patients, an ORR of 81% (all PR/PR-L) was noted. Pneumonitis was seen in two patients. The combination of idelalisib and rituximab has also been reported in the first-line setting for patients ≥ 65 years old with CLL ⁽⁷¹⁾. A total of 64 patients were enrolled. The ORR was 97%, with a CR rate of 19%. However, toxicities were common with this regimen; the important grade ≥ 3 adverse events included diarrhea/colitis (42%), pneumonia (19%), rash (13%), and transaminitis (23%). Colitis is a late event, with a median time to onset of around 9 months. Toxicities observed with idelalisib may be immune-mediated. Besides idelalisib, several other PI3K inhibitors are in clinical development in CLL, including duvelisib (IPI-145) (PI3K- γ and - δ inhibitor) and TGR-1202 (PI3K- δ inhibitor).

BCL-2 Inhibitors

CLL cells express high levels of antiapoptotic proteins of the Bcl-2 family, rendering them long-lived and resistant to senescence and death. Navitoclax (ABT-263) is an orally administered small-molecule inhibitor of Bcl-2, Bcl-w, and Bcl-xL. A phase I/II trial of orally administered navitoclax reported antitumor activity in patients with CLL; however, dose-limiting toxicity was thrombocytopenia ⁽⁷²⁾. Thrombocytopenia was secondary to the accelerated platelet senescence from inhibition of Bcl-xL in the platelets. Venetoclax (ABT-199) was designed as a molecule with greater affinity for Bcl-2 and reduced affinity for Bcl-xL ⁽⁷³⁾. Preliminary reports suggested monotherapy activity of venetoclax in patients with relapsed/refractory CLL with an ORR of 77% and CR/CRi rate of 23% ⁽⁷⁴⁾. Notably, the CR rate is higher than that seen in BCR inhibitors in relapsed or refractory CLL.

Lenalidomide

Lenalidomide is an immunomodulatory drug with multiple effects on the tumor microenvironment and immune system, including downregulation of immune checkpoint PD-1 on T cells (⁷⁵). Lenalidomide monotherapy was initially studied in relapsed or refractory CLL given either as continuous or interrupted (21 of 28 days) administration of up to 25 mg daily; the reported ORR was 32% to 47%, with 7% to 9% achieving CR, including patients who achieved MRD-negative remission (^{76,77}). Importantly, the responses were independent of the high-risk features including del(17p) and del(11q). Based on these encouraging results, the MDACC group explored lenalidomide monotherapy as first-line therapy for patients with CLL (^{78,79}). Treatment consisted of continuous lenalidomide 5 mg daily. The dose of lenalidomide could be escalated by 5 mg per cycle to the maximum daily dose of 25 mg. A total of 60 patients were enrolled. The ORR was 65%, with 10% CR rate. The median time to best response was 25 months. The estimated 2-year PFS was 60%. Tumor flare, noted in 52% of the patients, was associated with an improved PFS. The MDACC group reported results of the combination of lenalidomide and rituximab, both in the first-line and relapsed setting for patients with CLL (⁸⁰). In the first-line setting, treatment consisted of rituximab 375 mg/m² given weekly for 4 weeks then monthly during months 3 to 12 and continuous lenalidomide 10 mg daily from day 9 onward. Forty-eight patients were evaluable. The ORR was 83%, with a CR rate of 15%. Improvement in immunoglobulin levels and T-cell function was noted after lenalidomide treatment, suggesting immune restoration (⁷⁵). Future studies, likely in combination with targeted agents, will further clarify the role of lenalidomide in the treatment of CLL.

Chimeric Antigen Receptor T-Cell Therapy

Chimeric antigen receptors are engineered immune receptors introduced ex vivo into T cells, usually autologous, that redirect these cells to react against CLL cells. The CAR is a recombinant protein composed of an antigen-binding domain derived from single-chain immunoglobulin variable genes and intracellular signaling domains derived from CD3 ζ and costimulatory domains derived from CD28 and/or CD137. The transduced T cells are infused into the patient, where they bind to the target antigen and induce T-cell activation and proliferation, cytokine production, and killing of cells expressing the target antigen. CD19 is the most common target of the current CAR T-cell trials, although other targets are being explored as well. Early clinical data are promising, and long-term outcomes are awaited (^{81,82}).

Stem-Cell Transplantation

Because CLL is a disease of older adults, reduced-intensity conditioning (RIC) allo-SCT is the most common type of transplantation offered to patients with CLL. Reduced-intensity conditioning allo-SCT in CLL leads to 5-year event-free survival and OS rates of 35% to 45% and 50% to 60%, respectively (⁸³). Khouri et al reviewed outcomes of 86 patients with CLL who underwent RIC allo-SCT at MDACC (⁸⁴). The median age was 58 years. Eighty-three of the 86 patients experienced donor cell engraftment. Overall, the estimated 5-year PFS and OS rates were 36% and 51%, respectively. Notably, immune manipulation by withdrawal of immunosuppression or donor lymphocyte infusions enhanced clinical responses, indicating that CLL is a disease sensitive to immune manipulation. With the introduction of novel targeted therapies, the indications for an allo-SCT in patients with CLL need to be revisited. Allogeneic stem-cell transplantation will likely continue to remain an important strategy for selected group of patients, such as those with high-risk CLL [del(17p) or del(11q) or *TP53* mutation] who have experienced relapse with or are refractory to novel agents.

Supportive Care

Patients with CLL can have a host of complications ranging from immune cytopenias to infectious issues. Supportive care maneuvers are delineated in [Table 3-9](#).

Autoimmune Complications of Chronic Lymphocytic Leukemia

Autoimmune hemolytic anemia (AIHA), autoimmune thrombocytopenia (ITP), and pure red cell aplasia

Table 3-9 Supportive Care for Patients With CLL

Situation	Treatment Regimen
Antibiotic prophylaxis	Acyclovir/valacyclovir for herpes virus Trimethoprim/sulfamethoxazole for PCP If getting alemtuzumab: valganciclovir during and 2 months after treatment
Blood transfusions	Blood products should be irradiated (prevents graft-versus-host disease)
Recurrent infections	Antibiotics, antifungals, antiviral agents If IgG <500 mg/dL, and recurrent severe infections, start IVIG every month (0.5 g/kg)

IgG, immunoglobulin G; IVIG, intravenous immunoglobulin; PCP, *Pneumocystis carinii* pneumonia.

develop in some patients with CLL. The incidence of AIHA is 4% to 11% and that of ITP is 2% to 3%⁽⁸⁵⁾. Pure red cell aplasia is least common. The autoantibodies in CLL are typically polyclonal and usually IgG, indicating that they are not produced by the leukemic clone. The severity of the autoimmune complications does not necessarily correlate with the severity of CLL, and such events may develop in patients with early stages of the disease. Prednisone is the usual treatment for AIHA and ITP, with a high likelihood of response. However, the majority of patients relapse when treatment is stopped. Intravenous immunoglobulin produces response in 40% of patients, but these responses tend to be transient. CD20 mAb, particularly rituximab, has also been used to treat autoimmune complications of CLL, either as monotherapy or in combination with cyclophosphamide and dexamethasone (RCD regimen)⁽⁸⁶⁾. Cyclosporine is another option for treatment of immune-mediated cytopenias and can produce responses even in patients with steroid-refractory immune cytopenias⁽⁸⁷⁾. Splenectomy is reserved for refractory cases.

Hypogammaglobulinemia

Hypogammaglobulinemia is a frequent complication of CLL. The most common cause of morbidity in patients with CLL is infection, in part due to hypogammaglobulinemia. A randomized study evaluated the use of intravenous immunoglobulin (IVIG) versus placebo in patients with CLL and showed significant reduction in bacterial infections, but no difference in the number of life-threatening infections or nonbacterial infections⁽⁸⁸⁾. Replacement therapy with IVIG is indicated for patients with hypogammaglobulinemia and severe repeated infections.

TRANSFORMATION

Richter Syndrome

The term Richter syndrome (RS) refers to the development of aggressive large-cell lymphoma during the course of CLL. Rarely, disease transformation to Hodgkin lymphoma is seen. Richter syndrome is seen in approximately 5% of patients with CLL. Richter syndrome is usually associated with worsening systemic symptoms, including B symptoms, elevated LDH, rapid tumor growth, and/or extranodal involvement. Diagnosis requires tissue biopsy. Positron emission tomography scans help identify sites to direct tissue biopsy, and every attempt should be made to biopsy the site with the maximum standardized uptake value⁽⁸⁹⁾. In 80% of patients, the diffuse large B-cell lymphoma (DLBCL) is clonally related to the original

CLL, which is a marker of poor prognosis (median survival, approximately 1 year). In the other 20% of patients, the DLBCL is clonally unrelated to the original CLL, possibly representing a new neoplasm, and the prognosis is similar to de novo DLBCL (median survival, approximately 5 years). Risk factors associated with development of RS in a patient with CLL include lymph node size of >3 cm, number of prior therapies, advanced Rai stage (III-IV), del(17p), del(11q), unmutated *IGHV* gene, short telomere length (<5,000 bp), stereotyped B-cell receptors, and expression of CD38, CD49d, or ZAP-70⁽⁹⁰⁾. Presence of *NOTCH1* mutation is also associated with increased risk of RS. *TP53* mutation is commonly acquired at the time of CLL transformation⁽⁹⁰⁾. Other common genetic abnormalities seen in patients with RS include activation of *C-MYC* and inactivation of *CDKN2A*, indicating possible cell cycle deregulation, and *NOTCH1* mutations (commonly in conjunction with trisomy 12)^(91,92). The traditional treatment strategy has been intensive CIT such as OFAR (oxaliplatin, fludarabine, cytarabine, and rituximab), Hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone), and rituximab plus CHOP⁽⁹³⁾. Allogeneic stem-cell transplantation remains the only potentially curative option for patients with RS.

Prolymphocytic Transformation

The NCI-IWCLL criteria allow a diagnosis of CLL to be made in the presence of ≤55% prolymphocytes. The presence of >55% prolymphocytes indicates prolymphocytic transformation. Prolymphocytic leukemia is characterized by a high number of circulating prolymphocytes, splenomegaly, minimal lymphadenopathy, and a median survival of less than 3 years.

HAIRY CELL LEUKEMIA

Hairy cell leukemia is an uncommon B-cell lymphoproliferative disorder affecting adults and represents 2% of all leukemia. There is a marked male preponderance. Most patients have cytopenias; splenomegaly is also frequent at presentation. Hairy cells can be seen in peripheral blood, but their numbers vary. Hairy cells are twice as large as normal lymphocytes, with the nuclei showing a loose chromatin pattern and villus-like cytoplasmic projections (Fig. 3-8) (best viewed under phase-contrast microscopy). Hairy cells typically show positive staining for tartrate-resistant acid phosphatase (TRAP) (Fig. 3-9). Hairy cells infiltrate the bone marrow in an interstitial or focal pattern, with clear zones between cells (“fried-egg” appearance) (Fig. 3-10). Marrow reticulin is increased, and aspirates may result in “dry tap.”

FIGURE 3-8 Hairy cell in peripheral blood with cytoplasmic projections.

FIGURE 3-9 Hairy cell staining for tartrate-resistant acid phosphatase (left). Note the absence of orange-brown staining in a neutrophil.

FIGURE 3-10 Bone marrow involvement by hairy cell leukemia showing "fried-egg" appearance (hematoxylin and eosin stain).

Immunophenotypic analysis of hairy cells shows the presence of CD19, CD20, CD22, CD25, and CD103; in contrast to CLL, hairy cells are negative for CD5 and CD23. Hairy cells also stain strongly for surface immunoglobulin and FMC-7. The *BRAF V600E* mutation was recently found to be present in all patients with HCL (⁹⁴). This may have implications for both diagnosis and treatment of HCL, and vemurafenib, a BRAF inhibitor, is currently in clinical trials as therapy for relapsed or refractory HCL.

Treatment decisions are usually based on the degree of cytopenia and accompanying complications (eg, bleeding, infections, anemia). Pentostatin and cladribine (2-CDA) are the nucleoside analogs that are the mainstay of treatment of HCL. Pentostatin is administered at 4 mg/m² every 2 weeks until maximum response, and 2-CDA is given at 0.1 mg/kg/d as a continuous intravenous (IV) infusion for 7 days, or the same total dose can be administered as a 2-hour infusion over 5 days. Because 2-CDA offers a more convenient schedule (single course of therapy) and produces remission rates comparable to those achieved with pentostatin, 2-CDA is more frequently used. Estey et al reported a CR rate of 78% with 2-CDA in patients who had newly diagnosed or previously treated HCL (⁹⁵). One trial evaluated a strategy to improve the initial response to nucleoside analog therapy by adding additional doses of rituximab. Patients received 2-CDA (5.6 mg/m² intravenously over 2 hours per day for 5 consecutive days) followed approximately 4 weeks later with rituximab (375 mg/m² intravenously weekly for eight doses) (⁹⁶). A CR rate of 100% was reported, and after a median follow-up period of 25 months, the median CR duration, PFS, and OS had not been reached. The majority of relapsed patients achieve second remission when retreated with pentostatin or 2-CDA. The choice of agent may depend on the duration of the first remission: if <3 years, use an alternate agent; if >5 years, use the same agent. Splenectomy, although performed infrequently, can induce hematologic remission. The use of interferon- α is currently limited to patients unresponsive to nucleoside analogs. Rituximab can play a role in patients with relapsed or primary refractory HCL after purine analogs. A percentage of patients may relapse with 2-CDA-resistant disease. In addition, 10% to 20% of patients have a variant form of HCL with high numbers of circulating hairy cells and a poor response to nucleoside analogues. Classic and variant hairy cells strongly express CD22. Recombinant immunotoxin, BL22, has been used in the treatment of chemotherapy-resistant HCL. Moxetumomab pasudotox (HA22 or CAT-8015) is derived from BL22, selected for high-affinity for CD22, and is in clinical trials in patients with HCL.

PROLYMPHOCYTIC LEUKEMIA

Prolymphocytic leukemia is characterized by splenomegaly, a high number of circulating prolymphocytes, minimal lymphadenopathy, and a median survival of less than 3 years. Prolymphocytes are larger and less homogeneous than CLL cells; they have abundant clear cytoplasm, clumped chromatin, and a prominent nucleolus (see Figs. 3-7A, B and C). Prolymphocytes can be of either B- or T-cell type. B-cell PLL cells usually do not express CD5 but stain strongly for surface immunoglobulin and FMC-7 (see Table 3-2). T-cell PLL demonstrates postthymic T-cell nature (TdT⁺, CD1a⁺, CD5⁺, CD2⁺, CD7⁺). A majority of the cases express CD4⁺ and are CD8⁻. Chromosomal abnormalities of chromosome 14 are present in >75% of patients. TCL-1 is commonly overexpressed and detectable by immunohistochemistry.

For T-PLL, alemtuzumab IV is the treatment of choice. Dearden et al reported superior results in the first-line setting with IV alemtuzumab compared to subcutaneous alemtuzumab⁽⁹⁷⁾. With IV alemtuzumab, an ORR of 91% and CR rate of 81% were reported. Allogeneic stem-cell transplantation is the preferred consolidation regimen. Pentostatin should be considered for patients with poor response to alemtuzumab or relapsed disease. Retreatment with alemtuzumab is a reasonable option if the duration of the first remission was >12 months.

LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Large granular lymphocytes (LGLs) are larger than normal lymphocytes and contain azurophilic granules in their cytoplasm (see Fig. 3-6). They normally comprise 10% to 15% of peripheral blood mononuclear cells. Clonal expansion of LGLs can arise from either of the normal cellular counterparts and so may have a natural killer (NK)- or T-cell phenotype; the T-cell phenotype composes 80% of LGL leukemias. T-cell LGL cells have a CD3⁺/CD57⁺/CD56⁻ immunophenotype, and NK-cell LGL cells are CD3⁺/CD56⁺/CD57⁻⁽⁹⁸⁾. T-cell receptor gene rearrangement studies can help establish the clonality. More recently, around 40% of NK- and T-cell LGL leukemia patients were noted to have mutations in the *STAT3* gene⁽⁹⁹⁾. Mutations in *STAT5b* were noted in a smaller subset (2%) of patients⁽¹⁰⁰⁾. The clinical presentation of LGL leukemia is usually indolent. Cytopenias including neutropenia with accompanying infections, thrombocytopenia, and anemia are common. A small percentage of LGL leukemia patients develop a more aggressive course; these cases tend to have an NK-cell phenotype. Several therapies, including low-dose methotrexate, oral cyclosporine, and oral

cyclophosphamide with or without oral prednisone, have all been effective.

Hagop M. Kantarjian

INTRODUCTION

Chronic myeloid leukemia (CML) is a myeloproliferative disorder of pluripotent hematopoietic stem cells, characterized by the molecular *BCR-ABL1* rearrangement, which drives a proliferative and survival advantage of the leukemic clone. About 30% to 50% of patients with CML are asymptomatic at diagnosis and are incidentally diagnosed during routine examination. Patients may also present with characteristic clinical findings secondary to large numbers of myeloid circulating progenitors, leading to splenomegaly, leukocytosis, or even isolated thrombocytosis. The landscape of CML has had a dramatic course, with a host of findings that have elucidated the biology and molecular pathology of the disease. The understanding of the molecular events led to the creation of the first targeted therapy—imatinib mesylate. Its impact on therapy and survival propelled CML as a model for modern molecular medicine in the fast-developing era of personalized targeted therapy.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of CML is 1 to 2 cases per 100,000 adults with a slight male predominance and rising incidence with age, accounting for approximately 15% of newly diagnosed cases of leukemia in adults (¹). Chronic myeloid leukemia is uncommon in children, with a median age at diagnosis of 67 years. There are no known hereditary, geographic, familial, or ethnic associations. No chemical or infectious associations have

been established, although an increased risk has been linked with exposure to ionizing radiation (²).

In 2014, in the United States, an estimated 6,000 cases of CML were diagnosed. Since 2000, the year of introduction of imatinib, the annual mortality in CML has decreased from 10% to 20% to 1% to 2%. Consequently, the prevalence of CML in the United States, which was estimated at about 25,000 to 30,000 cases in 2000, has increased to an estimated 80,000 to 100,000+ cases in 2015 and will reach a plateau of about 180,000 cases by 2030 (³). The overall survival (OS) of patients over the recent decade has greatly improved. The exact mechanism of initiation of the defining molecular event in CML—Philadelphia (Ph) chromosome translocation—remains elusive.

BIOLOGY OF CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia is defined by a unique cytogenetic and/or molecular abnormality—the Ph chromosome—originating in a pluripotent stem cell, with a balanced translocation between the long arms of chromosomes 9 and 22, $t(9,22)(q34,q11.2)$ (⁴). Detectable by routine cytogenetics or by fluorescent in situ hybridization (FISH), the Ph chromosome is noted in 90% to 95% of patients with the clinical and laboratory features of CML. In the remaining 5% to 10% of patients, the molecular *BCR-ABL1* rearrangement can be recognized with high-sensitivity reverse transcriptase polymerase chain reaction (RT-PCR). All remaining cases with unknown biology deemed as true

Table 4-1 Criteria for Accelerated Phase According to MDACC, IBMTR, and WHO

	MDACC	IBMTR	WHO
Blasts	≥15%	≥10%	10-19 ^a
Blasts+Pros	≥30%	≥20%	NA
Basophils	≥20%	≥20% ^b	≥20%
Platelets ($\times 10^9/L$)	<100	Unresponsive \uparrow , persistent \downarrow	<100 or >1000 unresponsive
Cytogenetics	CE	CE	CE not at diagnosis
WBC	NA	Difficult to control, or doubling <5 days	NA
Anemia	NA	Unresponsive	NA
Splenomegaly	NA	Increasing	NA
Other	NA	Chloromas, myelofibrosis	Megakaryocyte proliferation, fibrosis

CE, clonal evolution; IBMTR, International Bone Marrow Transplant Registry; MDACC, University of Texas MD Anderson Cancer Center; NA, not applicable; Pros, promonocytes; WHO, World Health Organization.

^aBlast phase ≥20% blasts (≥30% for MDACC and IBMTR).

^bBasophils + eosinophils.

Ph-negative CML or atypical CML carry a poor prognosis. The Ph chromosome joins the proto-oncogene *c-abl* from chromosome 9 to the breakpoint cluster region (*BCR*) gene in chromosome 22, generating a novel fusion *BCR-ABL1* oncogene. Depending on the breakpoint region in *BCR*, several variants including those of 190, 210 (most common; 95% of Ph-positive cases), or 230 kDa molecular weight can be formed. The translation product is a chimeric protein with constitutively active tyrosine kinase activity that activates multiple downstream pathways, including PI3 kinase, NF- κ B, JAK/STAT, RAS, RAF, ERK, MYC, and JNK.

Following the 2005 discovery of the *JAK2* V617F mutation as the molecular abnormality common to polycythemia vera, essential thrombocytosis, and idiopathic myelofibrosis, CML has been segregated into a separate group of myeloproliferative neoplasms categorized as *BCR-ABL1* positive/*JAK2* V617F negative.

Roughly 10% to 15% of patients, typically at a more advanced stage of disease, experience clonal evolution with additional chromosomal aberrations including trisomy 8, monosomy 7, isochromosome 17, a double Ph chromosome, or additional loss of material from 22q. Clonal evolution is considered a criterion of accelerated phase, particularly when it occurs during the course of the disease. Corresponding molecular alterations that follow these changes include deregulation of *p53*, *RB1*, *C-MYC*, and *AML-EVI1*.

stepwise progression of disease in terms of aggressiveness from CP to BP, the natural course of the disease may not progress from one to the other, nor will disease always include all three. The vast majority of patients are diagnosed as asymptomatic in the CP. Splenomegaly is the most consistent presenting sign, detected in 50% to 60% of cases. Previously defined criteria indicating progression from CP to AP include 15% or more blasts, 30% or more blasts plus promyelocytes, 20% or more basophils, platelets $<100 \times 10^9/L$ unrelated to therapy, or cytogenetic clonal evolution (⁵). Other criteria have been proposed (Table 4-1). Compared to CP, median survival in AP is significantly shorter, although a significant improvement in survival has been observed with the availability of tyrosine kinase inhibitors (TKIs), particularly among early responders (⁶).

Most patients evolve into AP prior to BP, but 20% progress to BP without AP warning signals. Blast phase is considered an acute leukemia. It is defined by the presence of at least 30% blasts in the peripheral blood or bone marrow or the presence of extramedullary disease (chloroma or granulocytic sarcoma). Half of the patients in BP carry a myeloid phenotype, whereas the other half is split evenly between lymphoid and undifferentiated (⁷). Median survival in BP CML remains poor; a combination of TKI with chemotherapy followed by allogeneic stem-cell transplantation is recommended.

CLINICAL FEATURES AND NATURAL HISTORY

There are three separate phases of CML: chronic phase (CP), intermediate or accelerated phase (AP), and terminal or blast phase (BP). Even though all three represent a

DIAGNOSIS AND CLINICAL WORKUP

Initial evaluation aims to elicit signs and/or symptoms of disease, whereas physical examination evaluates for any presence of organomegaly or extramedullary

hematopoiesis. Diagnosing typical CML requires documentation of the Ph chromosome abnormality by routine cytogenetic evaluation (karyotype), FISH, or molecular studies (RT-PCR) (⁶). Bone marrow aspiration and biopsy are required, because they will not only confirm the diagnosis (eg, cytogenetic analysis), but also provide information needed for staging and classification. Although FISH, which relies on colocalization of large genomic probes specific to the *BCR* and *ABL* genes, or RT-PCR from peripheral blood can both confirm the presence of the Ph chromosome or the *BCR-ABL1* rearrangement, only bone marrow cytogenetics can reveal additional chromosomal abnormalities that are important in the initial diagnosis and staging.

True Ph- and *BCR-ABL1*-negative patients are considered to have Ph-negative CML or chronic myelomonocytic leukemia. In a few instances, a patient may be diagnosed with Ph-positive acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL). It may be impossible to determine whether these cases represent de novo Ph-positive acute leukemias or a BP of a previously unrecognized CML.

LABORATORY FEATURES

The most common laboratory finding in CP CML is leukocytosis, with myeloid cells in all stages of maturation seen in the peripheral blood. Frequently, there is an increase of basophils and eosinophils. The bone marrow is markedly hypercellular, with the myeloid-to-erythroid ratio significantly increased (Figs. 4-1 to 4-5) (⁹).

FIGURE 4-1 Chronic myeloid leukemia, chronic phase. The bone marrow biopsy is 100% cellular with granulocytic and megakaryocytic hyperplasia.

FIGURE 4-2 Chronic myeloid leukemia, chronic phase. Myeloid progenitors with increased immature cells in a hypercellular bone marrow.

FIGURE 4-3 Chronic myeloid leukemia in accelerated phase. Aspirate smear shows increased blasts and basophils.

FIGURE 4-4 Chronic myeloid leukemia, accelerated phase. Bone marrow biopsy section demonstrate foci of blasts.

FIGURE 4-5 Chronic myeloid leukemia in blast phase. The majority of evaluable white cells are immature (blasts).

A marrow aspiration and chromosomal analysis are needed to identify any variances in marrow blasts or basophils and to identify the Ph chromosome and possible cytogenetic clonal evolution (Fig. 4-6). Fluorescent in situ hybridization and PCR should be done at diagnosis in all patients. FISH may identify the presence of the *BCR-ABL1* rearrangement, even when the Ph chromosome is not found by conventional cytogenetic analysis. Furthermore, FISH can be performed

FIGURE 4-7 Fluorescent in situ hybridization (in metaphase in left panel; in interphase in right panel) image showing the *BCR-ABL* rearrangement.

on peripheral blood interphase cells (Fig. 4-7). Reverse transcriptase PCR testing amplifies the region around the splice junction between *BCR* and *ABL* and is highly sensitive for detecting CML, identifying the initial type of *BCR-ABL1* transcript (important for follow-up), and especially quantifying minimal residual disease (MRD). In general, simultaneous peripheral blood and marrow quantitative PCRs have a high level of concordance, although false-positive and false-negative results can

FIGURE 4-6 Karyotype from a patient with blast-phase chronic myeloid leukemia demonstrating clonal evolution. Reciprocal translocation involving chromosomes 9 and 22 has occurred. Additional chromosomal abnormalities are present indicating clonal evolution.

Table 4-2 Monitoring of CML Patients

Status	Diagnostic Testing
At diagnosis	• Bone marrow evaluation with cytogenetics and RT-PCR
During therapy	• Cytogenetics at 3, 6, and 12 months of therapy, then every 6-12 months. Once the patient achieves a stable CCyR, every 12-36 months or closer if the transcript level changes significantly
	• FISH if insufficient metaphases or to monitor cytogenetic response in between bone marrows
	• After achieving durable CCyR, quantitative RT-PCR every 3-6 months for the first year, then every 6 months for patients in MMR
	• ABL kinase domain mutation screening for any of the following patients: failing to achieve CHR at 3 months, PCyR at 6 months and CCyR at 12 months; hematologic or cytogenetic relapse; sustained 1-log increase in <i>BCR-ABL1</i> transcript ratio; progression to AP or BP

AP, accelerated phase; BP, blast phase; CCyR, complete cytogenetic response; CHR, complete hematologic response; CML, chronic myeloid leukemia; FISH, fluorescent in situ hybridization; MMR, major molecular response; PCyR, partial cytogenetic response; RT-PCR, reverse transcriptase polymerase chain reaction.

be seen (false-negative results due to poor-quality material or failure of the reaction; false-positive results due to contamination). Quantitative PCR assesses the amount of *BCR-ABL1* transcripts and is universally performed. Table 4-2 presents a summary of the proposed evaluation at diagnosis and during follow-up for patients with CML.

PROGNOSIS

As the newer generation agents became available, the prognostic significance of certain clinical characteristics changed. Achieving a complete cytogenetic response (CCyR) is the most important prognostic factor for long-term survival⁽¹⁰⁾. It has become evident that achieving a cytogenetic response, particularly during the first 3 to 6 months of therapy, translates into the best probability of long-term outcome.

RESPONSE AND EVALUATION OF MINIMAL RESIDUAL DISEASE

Response to therapy is initially judged by measurement of hematologic response criteria. A complete hematologic response (CHR) is defined as normalization of

Table 4-3 Response Criteria in CML

Hematologic remission	
Complete	Normalization of peripheral counts and differential, and disappearance of all signs and symptoms of CML including splenomegaly
Cytogenetic remission ^a	
Complete	0% Ph-positive metaphases
Partial	1%-35% Ph-positive metaphases
Minor	36%-95% Ph-positive metaphases
None	>95% Ph-positive metaphases
(Complete and partial remissions together constitute major cytogenetic remissions, ie, 0%-34% Ph-positive metaphases)	
Molecular remission ^b	
Complete	Undetectable <i>BCR-ABL</i> transcripts ^c
Major	<i>BCR-ABL/ABL</i> ratio of <0.1% (International Scale)

^aCytogenetic response is based on a routine karyotype analyzing at least 20 metaphases.

^bMolecular responses is based on quantitative polymerase chain reaction (PCR; usually real-time PCR).

^cPCR with a sensitivity of at least 4.5-log.

white blood cell (WBC) counts to $<10 \times 10^9/L$ with a normal differential, platelet count $<450 \times 10^9/L$, and disappearance of splenomegaly and other symptoms of CML. Patients who achieve a CHR are further classified according to the type of cytogenetic response attained (Table 4-3).

Cytogenetic responses are divided into complete, partial, and minor. Complete cytogenetic response corresponds to 0% of all metaphases remaining Ph positive; partial cytogenetic response is defined as 1% to 35% of metaphases being Ph positive; and minor cytogenetic response is defined as 35% to 95% Ph-positive metaphases. An analysis involving review of at least 20 metaphases is necessary to evaluate a cytogenetic response. Although FISH results correlate well with the karyotypic evaluation, cytogenetic response criteria have not been validated with FISH.

Molecular response is assessed by quantitative PCR (usually RT-PCR) in the peripheral blood or bone marrow⁽¹¹⁾. A major molecular response (MMR) is considered when the *BCR-ABL1/ABL1* ratio is $\leq 0.1\%$ on the international scale (IS). A complete molecular response (CMR) represents achievement of undetectable transcripts of *BCR-ABL1* in an assay with a sensitivity of at least 4.5 logs. For correlative purposes, *BCR-ABL1* transcript levels (IS) of $\leq 1\%$ are equivalent to a CCyR; levels of $\leq 10\%$ are equivalent to a partial cytogenetic response.

THERAPY

Three commercially available TKIs are approved for the frontline treatment of CML: imatinib, dasatinib, and nilotinib. Available guidelines support all three as viable frontline options for the initial management of CP CML.

Imatinib Mesylate

Prior to the development of targeted therapy, CML was treated with busulfan or hydroxyurea for many years, with a poor prognosis and inability to delay disease progression. The introduction of interferon- α (IFN- α) improved survival in CML and resulted in CCyRs in 5% to 25% of patients with CP CML.

Imatinib mesylate (STI-571 or Gleevec) is a selective and potent competitive inhibitor of the adenosine triphosphate (ATP)-binding site of the Bcr-Abl oncoprotein, as well as c-kit, PDGFR α and PDGFR β , and abl-related gene (ARG) (¹²). It is taken orally with 98% bioavailability and a half-life of 13 to 16 hours. It was first used in CML patients who developed resistance or intolerance to IFN- α and resulted in a CCyR of 60% and an estimated 5-year OS of 76% (¹³).

Based on these results, the large International Randomized Study of Interferon and STI571 (IRIS) trial evaluated imatinib versus IFN- α and low-dose cytarabine as frontline therapy in patients with newly diagnosed CP CML. Patients were randomized to receive imatinib 400 mg/d or IFN- α plus low-dose subcutaneous cytarabine, which was standard of care at the time (¹⁰). After a median follow-up of 19 months, planned outcome analyses were significantly better in almost all categories for patients receiving imatinib. The rates of CCyR (74% vs 9%; $P < .001$) and freedom from progression to AP or BP at 12 months (99% vs 93%; $P < .001$) were improved. There was a high crossover rate to imatinib. The responses to imatinib were durable, as outlined in an 8-year follow-up of the original study (¹⁴). Estimated event-free survival was 81%, and OS was 93% when only CML-related deaths were considered. With an annual mortality of 2%, the estimated median survival of a newly diagnosed patient with CML may be in the range of 20 to 30 years.

Imatinib Dose

A phase I imatinib study in patients who had failed prior IFN- α therapy established a clear relationship between dose and response (¹⁵). No significant responses were observed at doses <300 mg daily. An arbitrary dose of 400 mg daily for CP was selected in phase II studies, despite the lack of dose-limiting toxicity at doses up to 1,000 mg daily (maximum-tolerated dose was not defined). The Rationale and

Insight for Gleevec High-Dose Therapy (RIGHT) trial studied imatinib 400 mg twice a day as initial therapy in 115 patients with newly diagnosed CML (¹⁶). The rate of CCyR was 85% at 12 months and 83% at 18 months, with corresponding rates of MMR of 54% at 12 months and 63% at 18 months.

These results led to a randomized phase III open-label study, the Tyrosine Kinase Inhibitor Optimization and Selectivity Trial (TOPS), comparing 400 and 800 mg of imatinib in 476 patients. The trial showed significant superiority for the 800-mg dose in terms of MMR rate at 3 months (3% vs 12%), 6 months (17% vs 34%), and 9 months (33% vs 45%) but not at 12 months (40% vs 46%) (¹⁷). A final update of the trial showed no significant difference in MMR rates at 24 months (52% vs 50%) (¹⁸). Another European study also reported no benefit with imatinib 800 mg compared to 400 mg in high-risk CML (CCyR rates were 64% and 58% and MMR rates were 40% and 33%, respectively) (¹⁹).

The French SPIRIT study evaluated the impact of adding IFN or cytarabine in a randomized study where 636 patients with untreated CP CML received one of the following: imatinib 400 mg daily alone, imatinib 400 mg daily with cytarabine (20 mg/m²/d on days 15-28 of each 28-day cycle) or pegylated IFN- α -2a (90 μ g weekly), or imatinib 600 mg daily alone (²⁰). The rates of cytogenetic response at 12 months were similar among the four groups, whereas the rate of molecular response (a decrease in the ratio of *BCR-ABL1/ABL1* of $\leq 0.01\%$) was significantly higher in patients receiving imatinib and pegylated IFN- α -2a compared with imatinib 400 mg alone arm (30% vs 14%, respectively; $P = .001$). This rate was also significantly higher in patients treated for more than 12 months compared to treatment lasting ≤ 12 months. However, this high rate of early and deep responses did not translate into long-term improvement due to the poor tolerance of pegylated IFN.

Imatinib 400 mg daily is the regimen of choice for newly diagnosed patients with CP CML, with an emphasis on maintaining adequate dose intensity with minimal treatment interruptions or dose reductions for the best outcome.

Management of Toxicity

Imatinib is well tolerated, although adverse events not requiring treatment interruptions or decrease in dosing may occur in 30% to 40% of patients. A list of some of the most frequently encountered side effects and suggestions for management are included in Table 4-4. Any grade 3 or 4 toxicities related to imatinib require treatment interruption and resumption upon resolution of toxicity or its decrease to grade 1 or less. Subsequent dose should be reduced if recurring or

Table 4-4 Recommended Management of the Most Common Adverse Events Associated With Imatinib

Adverse Events	Management
Nausea/vomiting	Take with food, fluids
	Antiemetics
Diarrhea	Loperamide
	Diphenoxylate atropine
Peripheral edema	Diuretics
Periorbital edema	Steroid-containing cream
Skin rash	Avoid sun exposure
	Topical steroids
	Systemic steroids
	(Early intervention important)
Muscle cramps	Tonic water or quinine
	Electrolyte replacement as needed
	Calcium gluconate
Arthralgia, bone pain	Nonsteroidal anti-inflammatory agents
Elevated transaminases (uncommon)	Hold therapy and monitor closely
	Dose reduction upon resolution
Myelosuppression	
Anemia	Treatment interruption/dose reduction usually not indicated
	Erythropoietin or darbepoetin
Neutropenia	Hold therapy if grade ≥ 3 (ie, ANC $<1 \times 10^9/L$)
	Restart at lower dose if recovery takes >2 weeks
	Consider G-CSF if recurrent/persistent, or sepsis
Thrombocytopenia	Hold therapy if grade ≥ 3 (ie, platelets $<50 \times 10^9/L$)
	Restart at lower dose if recovery takes >2 weeks
	Consider IL-11 10 $\mu g/kg$ 3-7 days/week

ANC, absolute neutrophil count; G-CSF, granulocyte colony-stimulating factor; IL-10, interleukin-10.

long-lasting adverse effects are encountered, keeping in mind that doses below 300 mg daily are not recommended due to lack of adequate activity. Only 2% to 3% of patients exhibit true intolerance to imatinib and require permanent discontinuation. Early recognition and intervention targeting toxicities greatly reduce the need for unnecessary treatment interruptions and dose reductions.

Myelosuppression is common and frequently seen within the first 2 to 3 months of therapy. It is generally self-limited, and dose interruptions are not recommended unless grade 3 neutropenia or thrombocytopenia (ie, neutrophils $<1 \times 10^9/L$, platelets $<50 \times 10^9/L$) develops. Anemia alone usually does not require interruptions or dose adjustments. Treatment is restarted when counts recover above specified thresholds. Following treatment interruption, WBC should be monitored at least once weekly, and if recovery occurs within 2 weeks, treatment would be resumed with the same dose at which myelosuppression occurred. If recovery takes longer than 2 weeks, the dose could be reduced in increments (eg, from 800 to 600 mg, from 600 to 400 mg, or from 400 to 300 mg). Hematopoietic growth factors may be beneficial with recurrent or prolonged myelosuppression (eg, erythropoietin or darbepoetin and filgrastim).

Dasatinib

Dasatinib (Sprycel) is an oral second-generation TKI that is a piperazinyl derivative. It has an excellent oral bioavailability and is 350 times more potent in vitro than imatinib^(21, 22) (in vitro sensitivity of different *BCR-ABL1* mutants to different TKIs is presented in Table 4-5)⁽²³⁾. Dasatinib exhibits significant activity against most imatinib-resistant *BCR-ABL1* mutations, with the exception of T315I, as well as a few others, including V299L and F317L⁽²⁴⁾. In contrast to imatinib, dasatinib binds to both the active and inactive conformations of *BCR-ABL1* and also inhibits the Src family of kinases, which may be important in suppressing critical cell signaling pathways⁽²⁵⁾.

Following evaluation in the salvage setting after imatinib failure, dasatinib was assessed in the front-line setting. The DASISION trial was a phase III randomized study that compared imatinib 400 mg once daily to dasatinib 100 mg once daily in 519 patients with newly diagnosed CP CML⁽²⁶⁾. The primary end point was confirmed CCyR at 12 months. The dasatinib arm resulted in higher confirmed CCyR at 12 months (77% vs 66%; $P = .007$). The rates of molecular response were significantly higher with dasatinib (MMR, 76% vs 64%, $P = .002$; molecular response with a 4.5-log reduction in *BCR-ABL* transcripts from baseline [MR^{4.5}], 42% and 33%, $P = .025$). Dasatinib induced deeper responses at early time points (3, 6, or 12 months) compared to imatinib. The rate of transformation to AP or BP was lower in patients treated with dasatinib (4.6% and 7.3%, respectively). There was no progression-free survival (PFS) or OS difference at 5 years. Relevant toxicities included pleural effusion rate of 29% with dasatinib (mostly grade 1 or 2; 15 patients discontinued dasatinib due to pleural effusion). Arterial ischemic events were slightly higher

with dasatinib (5% vs 2%, respectively). Pulmonary hypertension was reported in 14 dasatinib-treated patients, with 6 discontinuing the drug. Comparison of the phase III trials in the frontline treatment of CP CML with imatinib, dasatinib, and nilotinib is outlined in Table 4-6.

A randomized phase II trial compared dasatinib 100 mg daily with imatinib 400 mg daily in 253 patients with newly diagnosed CP CML. Higher rates of CCyR (84% vs 69%) and 12-month MMR (59% vs 44%; $P = .059$) were reported in patients receiving dasatinib. No difference in PFS or OS was reported. Grade 3 and 4 toxicities were most commonly hematologic,

including thrombocytopenia, which was more common with dasatinib (18% vs 8%) (²⁷).

The results of the SPIRIT-2 trial were recently reported (²⁸). More than 800 patients with newly diagnosed CML were treated in a phase III trial and were randomized to either dasatinib 100 mg daily or imatinib 400 mg daily (²⁸). The 12-month CCyR and MMR rates were higher with dasatinib (CCyR: 51% vs 40%, $P = .002$; MMR: 58% vs 43%, $P < .001$). Among 40 patients who discontinued therapy due to sub-optimal response, only three patients (1%) received dasatinib. The PFS and OS were not significantly different. The rate of grade 3 or 4 thrombocytopenia was

Table 4-6 Comparison of the Phase III Trials in the Frontline Treatment of CP CML

Trial	Treatment	CCyR (%)	MMR (%)	<i>BCR-ABL</i> <10% at 3 Months (%)	EFS/PFS (%)	OS (%)	Longest Follow-Up (years)

CCyR, complete cytogenetic response; CP CML, chronic phase chronic myelogenous leukemia; EFS/PFS, event-free survival/progression-free survival; MMR, major molecular response; NR, not reported; OS, overall survival.

higher with dasatinib (13% vs 4%). Pleural effusions were observed in 78 patients (19%) treated with dasatinib (13 required drainage). The rate of cardiovascular events was slightly higher with dasatinib (2% vs 0.5%).

Dasatinib is otherwise well tolerated. Myelosuppression occurs frequently, with grade 3 or 4 neutropenia or thrombocytopenia in 20% of patients. The most common nonhematologic grade 3 or 4 toxicities at the same dose were pleural effusion (9%), dyspnea (6%), bleeding (4%), diarrhea (3%), and fatigue (3%).

Nilotinib

Nilotinib (Tasigna) is a structural analog of imatinib with 50 times more potent affinity for the ATP-binding site *in vitro*⁽²⁹⁾ and more selective activity against unmutated and most mutated forms of *BCR-ABL1*^(29,30). It is approved at a dose of 400 mg twice daily for patients with CP or AP CML who have resistance or intolerance to imatinib.

After approval for patients who failed imatinib therapy, nilotinib was evaluated in newly diagnosed CML in CP. The ENESTnd study was a randomized phase III trial comparing two different dose schedules of nilotinib (300 and 400 mg twice daily) to imatinib 400 mg once daily as initial therapy for patients with early CP CML⁽³¹⁾. The primary end point was the rate of MMR at 12 months, which was higher with both doses of nilotinib compared to imatinib (44% and 43% vs 22%; $P < .001$). The rate of transformation to AP or BP by 12 months of therapy was significantly lower with nilotinib (<1%) compared to imatinib (4%). The adverse effect profiles showed a higher rate of

cardiovascular events with nilotinib (10% with nilotinib 300 mg twice a day; 16% with nilotinib 400 mg twice a day; and 2% with imatinib). The 6-year follow-up continues to demonstrate higher rates of early and deeper sustained molecular response with nilotinib, a reduced risk of progression to AP and BP, and an acceptable safety profile⁽³²⁾. Nilotinib is well tolerated, with grade 3 or 4 myelosuppression as the most common adverse event (neutropenia or thrombocytopenia observed in 10%-20% of patients). Nonhematologic toxicity includes liver function abnormalities in 10% to 15% of patients and asymptomatic elevation of lipase and amylase in 10% to 15% of patients. Vascular adverse events were reported at an cumulative rate of 10% over 6 years. Rare cases (<1%) of pancreatitis have been reported. Nilotinib has the potential for QTc prolongation, and a baseline electrocardiogram is required prior to the start of therapy. Diabetes may be exacerbated with nilotinib.

Selecting a Frontline Therapy

With multiple TKIs available for newly diagnosed CP CML, there are several considerations when choosing a starting agent, such as efficacy, patient status (eg, age; comorbidities; history of diabetes, hypertension, pancreatitis, chronic lung disease, pulmonary hypertension, cardiac history), and treatment value. The high prices of TKIs are of concern, given that patients can now remain on TKIs and expect to live normal lives⁽³³⁾. The prices for the second-generation dasatinib and nilotinib are comparable, both costing more

than \$100,000 annually. Once imatinib becomes available as a generic drug, the choice of TKIs in relation to value (benefit-to-price) needs to be considered, particularly in patients with low-risk disease.

For patients with baseline cardiopulmonary comorbidities such as chronic obstructive pulmonary disease, congestive heart failure, or uncontrolled hypertension or pulmonary arterial hypertension, a TKI other than dasatinib may be favored, given the risk of pleural effusions. Dasatinib also impairs platelet function, and patients on concomitant anticoagulants may be at an increased risk for hemorrhagic complications⁽³⁴⁾.

Nilotinib has been linked with hyperglycemia and QT interval prolongation, and should be used with caution in uncontrolled diabetics and in patients with baseline QT prolongation (routine monitoring of the QT interval is essential). Potassium and magnesium should be repleted to optimal serum levels prior to starting nilotinib, and the drug should be taken on an empty stomach twice daily. Recently, nilotinib has been associated with a low but significant incidence of peripheral artery disease, cerebrovascular accidents, and cardiovascular syndromes⁽³⁵⁾. Therefore, it is reasonable to choose other TKIs for patients with cardiovascular morbidities. Nilotinib rarely causes pancreatitis and should be avoided in patients with prior history of pancreatic inflammations. Imatinib is associated with the development of peripheral edema as one of its major side effects. Among patients with significant baseline peripheral edema, nilotinib or dasatinib may be favored as first options; close monitoring and intermittent use of loop diuretics might mitigate the effects of fluid retention.

MONITORING PATIENTS

Monitoring involves routine blood counts with differentials, cytogenetics, and molecular testing for *BCR-ABL1* transcript levels and for *BCR-ABL1* kinase domain mutations. Blood counts should be performed every 1 to 2 weeks until CHR and at least every 3 months thereafter or more frequently as clinically indicated⁽³⁶⁾. Cytogenetic analysis is the only test that gives reliable information regarding the presence of additional chromosomal aberrations.

At baseline, all patients undergo a marrow analysis to establish the diagnosis and provide a sample for cytogenetic testing. This also allows for proper staging in terms of the blast and basophil percentage. Presently, it is recommended that patients have a follow-up bone marrow study at 3, 6, and 12 months after starting therapy⁽³⁷⁾. An alternative method to determine cytogenetic response is with the use of FISH on peripheral blood. If a patient is responding optimally, and the FISH study is negative at 6 or 12 months,

it may be reasonable to omit further marrow exams, as the patient is likely to be in stable CCyR^(38,39). Once a patient achieves a stable CCyR, particularly if associated with MMR, bone marrow aspirations with cytogenetics are recommended only every 1 to 3 years or if there are significant changes in the transcript levels or peripheral blood counts.

For patients in durable CCyR, periodic molecular monitoring every 3 to 6 months using quantitative RT-PCR is acceptable and useful, but may lead to erroneous changes in treatment due to discordance in results between labs or even within the same lab. This is harmful to patients because it leads to potentially discontinuing a useful therapy that the patient may have been tolerating well. One strategy to minimize this is to use interphase FISH as a complementary diagnostic test along with the molecular test to detect possible false-positive or false-negative results generated by either assay⁽³⁹⁾. For patients in CCyR, the achievement and maintenance of an MMR is questionable. Studies evaluating patients receiving imatinib or second-generation TKIs found that patients in CCyR have similar survival whether there is achievement of MMR or not⁽⁴⁰⁻⁴²⁾. For patients in MMR, periodic molecular monitoring every 6 months is useful.

The value of early molecular response has been shown in a number of studies to have strong prognostic value. This has been applied to each of the TKIs appropriate for use in the frontline setting. A *BCR-ABL1* transcript level of less than 10% at 3 months has been shown to separate groups into high- and low-risk categories for long-term outcomes (ie, progression, survival)^(40,43,44). An important question is what to do with a patient who does not meet the 3-month benchmark. One option is to switch TKIs early, but there are currently no data showing this would alter long-term outcome. Several experts have suggested that a follow-up measurement at 6 months will help define patients clearly in need of a change in therapy⁽³⁷⁾. This has been retrospectively analyzed with conflicting results⁽⁴⁵⁻⁴⁷⁾. At least two independent studies suggested that patients with *BCR-ABL1* transcript levels greater than 10% at 3 months do not necessarily have an inferior outcome^(46,47). Patients who continued on therapy and achieved transcripts levels less than 10% by 6 months had the same long-term favorable outcome as patients with optimal molecular responses at 3 months.

Although achieving undetectable or the lowest possible transcript level is desirable, molecular positivity above the levels of MMR in the context of a CCyR is not an indication of failure of therapy. Some studies have suggested that increasing transcript levels may increase the risk of developing mutations or failure of therapy, but the magnitude of the increase that may predict for such events is variable, partly due to the variability of the testing in different laboratories. This may lead to erroneous changes in treatment, which

Table 4-7 Main Features of the Monitoring Techniques Available for CML

Parameter	Cytogenetics	FISH	PCR
No cells evaluated	20	200	>10,000
Rapidity (days)	14-21	1-3	7-10
Source	BM	BM/PB	BM/PB
Clonal evolution	Yes	No	No
False negativity	NA	Yes	Yes
False positivity	No	≤10%	NA

BM, bone marrow; FISH, fluorescent in situ hybridization; NA, not applicable; PB, peripheral blood; PCR, polymerase chain reaction.

is harmful, as it leads to potential discontinuation of viable and tolerable therapy. A single elevation in transcript levels should be confirmed in a subsequent determination 1 to 3 months later, and incremental increase in *BCR-ABL1* transcript levels should be determined to be greater than the variability of the laboratory test. In such situations, compliance with therapy should first be revisited. The risk of relapse or emergence of mutations is mostly associated with a sizeable (five- to tenfold) increase in the *BCR-ABL1* transcript levels that is associated with a loss of MMR or occurs in a patient who never achieved an MMR. Changes still below the level of MMR have little if any prognostic significance. Several studies evaluating patients receiving imatinib or second-generation TKIs showed that patients in CCyR have similar survival with or without MMR^(40, 41). ABL kinase domain mutation screening should be performed in patients who have an inadequate initial response (defined as failure to achieve CHR at 3 months, partial cytogenetic response at 6 months, and CCyR at 12 months), in patients who show hematologic or cytogenetic relapse, or in patients with sustained 1-log increase in *BCR-ABL1* transcript ratio⁽³⁶⁾. All patients who progress to AP or BP CML should have ABL kinase mutations tested (Table 4-7).

When to Switch Therapy

Achievement of CCyR should be expected by 12 months of therapy, especially for standard-dose imatinib, whereas it may be reasonable to expect CCyR for second-generation TKIs within 3 to 6 months of treatment⁽⁴⁸⁾. Patients who do not achieve a CHR by 3 months should be considered for a change in therapy. If considering a change in therapy at 3 or 6 months for *BCR-ABL1* transcript level greater than 10% for patients on imatinib or second-generation TKIs, it is worth noting that very early switching has not yet been shown to influence the long-term outcomes⁽⁴⁹⁾. As such, it can

be advocated that if the transcript level at 3 months is greater than 10%, providers should perform serial molecular monitoring between 3 and 6 months for definitive treatment response evaluation⁽³⁷⁾. If patients retain >10% transcript level at 6 months, change in therapy is indicated, because the chance of CCyR would be low. Patients who meet all of the relevant responses by the first 12 months are monitored periodically using FISH and PCR testing, and if there are clear signs of possible relapse or failure, bone marrow examination with conventional cytogenetics and kinase domain sequencing should be performed. Not achieving CCyR by 12 months or any extent of later cytogenetic relapse requires a change in therapy. Fluctuating molecular levels during concurrent CCyR should only prompt closer monitoring and a compliance assessment.

Response definitions recommended by the 2013 European LeukemiaNet guidelines are summarized in Table 4-8. Lack of MMR or CMR should not be interpreted as signal for change in TKI therapy. Achieving CMR allows for possibility of treatment discontinuation, which is only recommended in the setting of a clinical trial.

MANAGEMENT OF RESISTANCE

A subset of patients treated with imatinib may develop resistance. Among patients treated in CP, the rate of resistance is less than 4% per year and decreases after the first 3 years to approximately 0.5% to 1% per year. Following achievement of CCyR, the rate of resistance after year 3 of imatinib therapy is less than 1%, suggesting a durable CCyR on imatinib and the predictability of the CML course once such a response is obtained.

Mechanisms of resistance to imatinib can be *BCR-ABL1* dependent or independent. The first, more common group includes amplification or overexpression of BCR-ABL1 or its protein product⁽⁵⁰⁾ and point mutations of the ABL sequence⁽⁵¹⁾. The second group includes multidrug-resistance expression and overexpression of Src kinases⁽⁵²⁾. *BCR-ABL1*-dependent mutations have been identified in approximately 50% of patients who develop clinical resistance to imatinib⁽⁵³⁾. More than 90 different mutations with varied significance and imatinib sensitivity have been described in relevant kinase domains, including the ATP-binding domain (P-loop), the catalytic domain, the activation loop, and amino acids that directly interact with imatinib. The “gatekeeper” mutation of particular importance is the T315I, which is resistant to all available TKIs except ponatinib. Most of the clinically relevant mutations develop in a few residues in the P-loop (G250E, Y253F/H, and E255K/V), the contact site (T315I), and the catalytic domain (M351T and F359V)⁽⁵⁴⁾.

Table 4-8 Response Definitions to Imatinib in Chronic Phase CML (2013 European LeukemiaNet Guidelines)

Evaluation Time Point	Response		
	Optimal Response	Warning (close monitoring)	Failure (switch TKI)
Baseline	—	CCA in Ph+ cells High-risk Sokal (>1.2), Euro Score (>1,480) or Eutos-Score (>87)	—
3 months	BCR/ABL1 ^{IS} ≤10% and/or Ph+ ≤35% (PCyR)	BCR/ABL1 ^{IS} >10% and/or Ph+ 36%-95%	No CHR and/or Ph+ >95%
6 months	BCR/ABL1 ^{IS} ≤1% and/or Ph+ 0% (CCyR)	BCR/ABL1 ^{IS} 1%-10% and/or Ph+ 1%-35%	BCR/ABL1 ^{IS} >10% and/or Ph >35%
12 months	BCR/ABL1 ^{IS} ≤0.1% (MMR)	BCR-ABL1 ^{IS} 0.1%-1%	BCR/ABL1 ^{IS} >1% and/or Ph >0%
Any time	MMR or better	CCA in Ph- cells (–7 or 7q–)	Loss of CHR Loss of CCyR Loss of MMR confirmed ^a Mutations CCA in Ph+ cells

CCA, clonal chromosomal abnormalities; CCyR, complete cytogenetic response; CHR, complete hematologic response; IS, BCR-ABL1 on International Scale; MMR, major molecular response; PCyR, partial cytogenetic response; TKI, tyrosine kinase inhibitor.

^aIn two consecutive tests, of which one was ≥1%.

A list of mutations following imatinib resistance with their half-maximal inhibitory concentration values is shown in Table 4-5⁽²³⁾. The long-term outcome of patients with CML treated with second-generation TKIs after imatinib failure is predicted by the in vitro sensitivity of *BCR-ABL1* kinase domain mutations⁽⁵⁵⁾. It is unclear if the identification of small mutated clones is clinically relevant^(56,57).

Although the sequential use of kinase inhibitor therapy often rescues a response, it can also result in further gain of mutations by the same (compound mutations) or different (polyclonal mutations) Ph clones, which represents a significant hurdle in the treatment of CML⁽⁵⁸⁾. High molecular dynamics in particular yield compound *BCR-ABL1* kinase domain mutations (polymutants), which represent two or more codon changes in the same *BCR-ABL* mRNA transcript⁽⁵⁹⁾. Ultra-deep sequencing to resolve qualitative and quantitative complexity of mutated populations surviving TKIs has recently suggested that conventional Sanger sequencing might be inadequate for this evaluation⁽⁶⁰⁾, although a recent report argues that many *BCR-ABL1* compound mutations may actually be artifacts due to PCR-mediated recombination⁽⁶¹⁾.

Before labeling a patient as having TKI resistance and modifying therapy, treatment compliance and drug-drug interactions must be evaluated. Lower adherence rates observed more commonly in younger individuals, patients with adverse effects on treatment, and patients who have required dose escalations correlate

with worse outcomes⁽⁶²⁾. Mutation analysis should be carried out only in instances of failure criteria.

Imatinib Dose Escalation

Imatinib escalation was the main option for managing suboptimal responses and treatment failures before the era of second-generation TKIs. In a phase II study that reported a 2-year follow-up after high-dose imatinib (400 mg twice daily; n = 49) for patients with CP CML and resistance to imatinib at doses from 400 to 600 mg, the major cytogenetic response (MCyR), CCyR, and MMR were 33%, 18%, and 12%, respectively, with an estimated PFS of 65% at 2 years⁽⁶³⁾. In another dose-escalation study from the University of Texas MD Anderson Cancer Center, 84 patients with CP CML were dose escalated to imatinib 600 to 800 mg/d after developing hematologic failure (n = 21) or cytogenetic failure (n = 63) to standard-dose imatinib⁽⁵⁵⁾. Among patients who met the criteria for cytogenetic failure, 75% (47 of 63 patients) responded to imatinib dose escalation. In contrast, in patients in whom imatinib was dose escalated because of hematologic failure, 48% achieved a CHR and only 14% (3 of 21 patients) achieved a cytogenetic response. Patients more likely to respond to imatinib dose increase are those who have previously achieved a cytogenetic response and then lost it and who have not developed any mutations unresponsive to imatinib. With mutations, a switch to a second-generation TKI is preferable.

SECOND- AND THIRD-GENERATION TYROSINE KINASE INHIBITORS

Dasatinib was first approved by the US Food and Drug Administration at a dose of 70 mg orally twice daily based on its efficacy and safety in a series of phase II trials in patients with all stages of CML (and those with Ph-positive ALL) who were resistant to, or intolerant of, imatinib⁽⁶⁴⁻⁶⁶⁾. Over 50% of patients treated with dasatinib in CP after imatinib failure achieved a CCyR. Responses to dasatinib, nilotinib, bosutinib, and ponatinib among patients in CP, AP, and BP after imatinib failure or resistance are summarized in Table 4-9.

A randomized trial of dasatinib versus higher dose imatinib (800 mg daily) among patients who failed prior therapy with imatinib (400-600 mg) showed a significantly higher rate of response and PFS for patients receiving dasatinib, particularly among those who were already receiving imatinib 600 mg, those with *BCR-ABL1* mutations, and those who had never achieved a cytogenetic response with imatinib, establishing second-generation TKIs as the preferred approach after failure to imatinib standard-dose therapy⁽⁶³⁾.

In a long-term, 6-year follow-up of a phase III trial of 670 CP CML patients who were resistant (74%) or intolerant (24%) to imatinib, patients were randomized to receive dasatinib 100 mg once daily, 50 mg twice daily, 140 mg once daily, or 70 mg twice daily⁽⁶⁷⁾. At 6 years, PFS rates were 49%, 51%, 50%, and 47%, respectively, and OS rates were 71%, 74%, 77%, and 70%, respectively. The 6-year MMR rates were 43% and 40% in patients treated in the 100 mg once daily arm and all other arms combined, respectively. Dasatinib 100 mg once daily retained high activity and was associated with less toxicity, particularly pleural effusions and myelosuppression (grade 3 or 4 neutropenia or thrombocytopenia, 30% each), and the lowest rate of drug discontinuation for toxicity. Based on these results, the standard dasatinib dose for patients in CP became 100 mg daily. Similar results established 140 mg once daily as the preferred dose in advanced-stage disease.

In a phase II study, 321 CP CML patients who were resistant or intolerant to imatinib were treated with nilotinib 400 mg twice daily⁽⁶⁸⁾. At the 48-month follow-up, 45% of the patients achieved CCyR; the PFS and OS rates were 57% and 78%, respectively⁽⁶⁹⁾. Deeper levels of molecular responses at 3 and 6 months correlated with improved long-term outcomes. In the expanded access ENACT trial, 1,422 patients in CML CP or AP after imatinib failure were treated with nilotinib 400 mg twice daily⁽⁷⁰⁾. After a median follow-up of 18 months, the CCyR rate was 50% and the PFS rate was 80%.

Bosutinib

Bosutinib (SKI606) is an orally available dual Src/Abl inhibitor that is 30 to 50 times more potent than imatinib against unmutated *BCR-ABL1*. It has activity against most imatinib-resistant *BCR-ABL1* mutants with the exception of T315I. In contrast to other available TKIs, bosutinib has minimal inhibitory activity against C-Kit and PDGFR. It was initially studied in patients resistant or intolerant to imatinib⁽⁷¹⁾. Among 288 patients treated in a phase I/II trial, more than two-thirds of the patients had imatinib-resistant CML. The primary end point, MCyR at 6 months, was achieved in 31%. Overall, 41% of patients achieved a CCyR, and 64% of them achieved MMR. The 2-year PFS and OS rates were 79% and 92%, respectively. Responses to bosutinib in CP, AP, and BP after imatinib resistance or failure are summarized in Table 4-9.

Bosutinib also was assessed as third- or fourth-line therapy in 118 patients with CP CML who had been previously treated with imatinib followed by nilotinib and/or dasatinib⁽⁷²⁾. Bosutinib resulted in a CCyR rate of 24%. The 24-month PFS and OS rates were 73% and 83%, respectively. Clinical efficacy in the relapse setting led to the evaluation of bosutinib as frontline therapy.

Treatment with bosutinib has been generally well tolerated with no pleural effusions and modest myelosuppression. The most common adverse events were gastrointestinal (nausea, vomiting, diarrhea) and were usually grade 1 or 2, manageable, and transient and diminished in frequency and severity after the first 3 to 4 weeks of treatment⁽⁷²⁾. A multicenter phase III randomized trial is ongoing to compare a lower dose (400 mg daily) of bosutinib and standard-dose imatinib (400 mg) in patients with newly diagnosed CP CML.

Ponatinib

Ponatinib (formerly AP24534) is a rationally designed third-generation TKI that efficiently inhibits Bcr-Abl as well as *FLT3*, *PDGFR*, *VEGF*, and *C-KIT*⁽⁷³⁾. It is more than 500 times more potent than imatinib at inhibiting *BCR-ABL1* and is the first compound in the class to inhibit T315I mutation⁽⁷³⁾. Ponatinib was approved following the phase II PACE trial, in which 449 patients with heavily pretreated CML or Ph-positive ALL, resistant to or intolerant to dasatinib or nilotinib or with the T315I mutation, were enrolled⁽⁷⁴⁾. The dose of ponatinib was 45 mg once daily. Among the 267 patients who received ponatinib in CP, 56% achieved an MCyR by 12 months (MCyR rate of 70% in patients with a T315I mutation). Patients responded more favorably if they had received fewer TKIs. After a median follow-up of 3.5 years, 59% of patients achieved MCyR; 83% of those remained in MCyR.

Table 4-9 Important Phase II Trials of Second- and Third-Generation TKIs After Prior TKI Failure

Percent Response																
	Dasatinib					Nilotinib				Bosutinib			Ponatinib

AP, accelerated phase; BP, blast phase; CHR, complete hematologic response; CP, chronic phase; LyBP, lymphoid blast phase; MyBP, myeloid blast phase; NEL, no evidence of leukemia; MaHR, major hematologic response; NR, not reported; TKI, tyrosine kinase inhibitor.

at 3 years. Furthermore, 39% of patients achieved an MMR or better. The 3-year PFS and OS rates were 60% and 81%, respectively (⁷⁵). Arterial occlusive events occurred in 28% of patients (23% serious). The most common all-grade treatment-emergent adverse events were abdominal pain (46%), rash (46%), thrombocytopenia (45%), headache (43%), constipation (41%), and dry skin (41%) (⁷⁵). Grade 3 or 4 toxicities included myelosuppression (48% overall, observed less commonly in CP CML patients), hepatotoxicity (8%), pancreatitis (5%), hemorrhagic events associated mostly with grade 4 thrombocytopenia (5%), treatment-emergent symptomatic hypertension (2%), neuropathy (2%), and cranial neuropathy (<1%).

As of early 2014, ponatinib labeling included a revised warning regarding risk of thrombotic events (13% per year), vascular occlusions, heart failure, and hepatotoxicity; revised dosing information; and indications limited to adults with T315I mutation and those for whom no other TKI is indicated (⁷⁶). Vascular occlusion adverse events were more frequent with increasing age and in patients with prior history of ischemia, hypertension, diabetes, or hyperlipidemia (⁷⁷). Factors associated with increased risk of vascular occlusion events include older age, higher dose, history of myocardial infarction or prior vascular events, and longer duration of CML (⁷⁸).

Choosing a Second- or Third-Line Option

When faced with treatment failure, a bone marrow with cytogenetic assessment should be completed to determine disease phase and possible clonal evolution. Mutational testing for *BCR-ABL1* kinase domain mutations should also be performed, because it helps guide the decision on TKI selection. Dasatinib, nilotinib, and bosutinib are effective against most mutations known to elicit resistance to imatinib (^{71,79}). For dasatinib, bosutinib, and nilotinib, in vitro and in vivo data have identified mutations that have differential responses to different agents: dasatinib and bosutinib perform better with Y253H, E255K/V, or F359C/V mutations, whereas nilotinib has activity with V299L and F317L mutations, which confer resistance to dasatinib and bosutinib (^{80,81}). If mutational information is not available, one can resort to considerations regarding toxicity. Bosutinib is a valid choice for patients who fail imatinib and who have pulmonary and vascular risk factors. Ponatinib should be considered the agent of choice for any patient with T315I mutation or compound mutations, in patients who have failed prior second-generation TKIs, and in patients with advanced-phase disease. Vascular thrombotic events represent a serious risk but are likely outweighed by the risks of T315I-mutated disease, for which effective treatment options are scarce.

NON-TYROSINE KINASE INHIBITORS

Omacetaxine mepesuccinate is a cephalotaxine ester and a derivative of homoharringtonine that has a mechanism of action independent of tyrosine kinase inhibition. It is a multitarget protein synthesis inhibitor with an excellent bioavailability through the subcutaneous route. Unaffected by the presence of mutations, it has been in clinical development for several years with activity against CML (⁸²). It has recently also been found to affect the leukemic stem cell compartment, making it an attractive option for the potential total elimination of the leukemic burden and potential cure.

Omacetaxine was approved in the United States for the treatment of patients with CP or AP CML with resistance and/or an intolerance to two or more TKIs on the basis of pooled data from two phase II, open-label, international, multicenter studies (CML-202 and CML-203), in which patients were treated with omacetaxine 1.25 mg/m² twice daily for 14 days every 28 days until response, followed by maintenance for 7 days every 28 days (^{83,84}). Initial results showed that 20% of patients with CP CML achieved a durable MCyR with a median response duration of 17.7 months (⁸³) and 27% of patients with AP CML achieved a major hematologic response (MHR) that was maintained for a median of 9 months (⁸⁴). After a minimum follow-up of 24 months, 18% of patients in CP CML achieved a MCyR with a median duration of 12.5 months and 14% of patients in AP CML achieved or maintained an MHR for a median of 4.7 months (MCyR was not achieved); median OS times for CP CML (n = 50) and AP CML (n = 14) patients who received more than three cycles of treatment were 49 and 25 months, respectively (⁸⁵). Grade 3 or higher hematologic toxicities (including thrombocytopenia, anemia, or neutropenia) were the major side effects (79% and 73% for CP CML and AP CML, respectively), with discontinuation due to toxicity in 10% of CP and 5% of AP patients. Further analyses of CP and AP CML patients with the T315I mutation (n = 16 and n = 2, respectively), showed that three CP patients achieved MCyR, whereas one AP patient achieved no evidence of leukemia (⁸⁵).

ALLOGENEIC STEM CELL TRANSPLANTATION

After the successful introduction of TKIs, there has been a paradigm shift in the approach to CML therapy. An allogeneic stem cell transplant (ASCT) is no longer recommended as a first-line therapy and is instead reserved as a third-line or later strategy. It still has an important role in patients who evolve to AP or BP. Transplantation carries significant risks of

acute and chronic graft-versus-host disease (GVHD), veno-occlusive disease, life-threatening infections, secondary malignancy, and poorer overall quality of life, although recent advances in the field have significantly improved some of these risks. Current recommendations for an ASCT are restricted to patients who are in AP or BP CML, those in CP who have failed at least two TKIs and acquired compound mutations, and patients harboring the T315I mutation after a trial of ponatinib therapy⁽⁸⁶⁾. Prior exposure to TKIs does not have a negative impact on the transplant outcome; in fact, patients referred to transplant may have a better outcome if undergoing transplant with less CML burden⁽⁸⁷⁾. Recommendations for the role and timing of ASCT CML are outlined in the [Table 4-10](#)⁽⁷⁶⁾.

Table 4-10 Recommendations for Role and Timing of Allogeneic HSCT in CML

Status	TKIs	Allogeneic HSCT
AP, BP	Interim treatment to MRD	If in remission
Imatinib or first-line second-generation TKI treatment failure in CP, with T315I mutation	Ponatinib	If not responding well to ponatinib
Imatinib or first-line second-generation TKI treatment failure in CP, no clonal evolution, no mutations, good initial response to imatinib	Long-term treatment with TKI in second-line setting	Third-line, after second TKI treatment failure
Imatinib or first-line second-generation TKI treatment failure in CP, with clonal evolution, with mutations resistant to second-generation TKIs, no CyR to imatinib	Interim treatment with ponatinib eventually to MRD	As soon as possible if no response to ponatinib
Elderly patients, age >70 years, after imatinib treatment failure	Long-term treatment with TKI in second-line setting	Forego allogeneic HSCT for many years (maximize quality of life)

AP, accelerated phase; BP, blast phase; CML, chronic myeloid leukemia; CP, chronic phase; CyR, cytogenetic response; HSCT, hematopoietic stem cell transplantation; MRD, minimal residual disease; TKI, tyrosine kinase inhibitor.

TREATMENT DISCONTINUATION

Few studies have addressed the issue of discontinuing TKI therapy. The Stop Imatinib (STIM) trial evaluated the risk of relapse in patients who stopped treatment with imatinib after being in CMR (MR^{4.5}) for longer than 2 years. At the most recent follow-up of 50 months, among 100 patients monitored, 61% developed molecular relapse, with most of these events occurring within 7 months of imatinib discontinuation. Nearly all patients regained CMR on retreatment with imatinib (one patient lost CCyR and was treated with dasatinib)^(88,89). This study suggested that approximately 40% of patients with durable CMR might be cured with TKI alone. Overall, low-risk Sokal score and duration of imatinib therapy greater than 60 months predicted for preservation of CMR following discontinuation of therapy.

The TWISTER study followed 40 patients who stopped imatinib after greater than 2 years of undetectable MRD (MR^{4.5})⁽⁹⁰⁾. During the median follow-up of 43 months (minimum, 15 months), 22 patients (55%) became molecularly positive, and nearly 70% of molecular relapses occurred within the first 6 months of treatment cessation. Following the resumption of TKIs, patients regained molecular responses. None of the relapsing patients developed kinase domain mutation, AP, or BP.

A pan-European Stop Tyrosine Kinase Inhibitor trial (EURO-SKI study) aimed to define factors associated with durable deep MR after stopping TKI. An interim analysis of 200 patients with 6-month follow-up of molecular events was reported⁽⁹¹⁾. Adults in CP CML on TKI treatment in confirmed deep molecular response (molecular response with a 4-log reduction in *BCR-ABL* transcripts from baseline [MR⁴]; *BCR-ABL* <0.01%) for at least 1 year (>4 log reduction on TKI therapy for >12 months confirmed by three consecutive PCR tests) and on TKI treatment for at least 3 years were eligible. Median duration of TKI treatment was 8 years (range, 3-12.6 years), and median duration of MR⁴ before TKI cessation was 5.4 years (range, 1-11.7 years). Overall, 123 of the 200 patients remained without relapse in the first 6 months. Recurrence of CML, defined as loss of MMR, was observed in 47 (47%) of 114 patients treated for <8 years, as compared to 27 (27%) of 86 patients treated for >8 years ($P = .003$). The duration of MR⁴ >5 years versus <5 years was predictive for a lower relapse rate ($P = .03$).

The feasibility of second-generation TKI discontinuation has also been tested in the French STOP 2G-TKI study for patients treated with nilotinib or dasatinib as frontline therapy or after imatinib failure or intolerance⁽⁹²⁾. Twenty-four months of persistent MR^{4.5} was a requirement for discontinuation of TKI. Interim outcome of 52 patients with a median follow-up of

32 months (range, 12-56 months) reported treatment-free survival of 54% (majority of relapses occurred early, with a median duration of 4 months).

At present, given the uncertainty in selecting the best candidate patients for discontinuation of TKI therapy and the lack of long-term follow up, TKI discontinuation should not be recommended outside the context of a clinical trial.

ADVANCED-STAGE (ACCELERATED PHASE/BLAST PHASE) CHRONIC MYELOID LEUKEMIA

Patients in AP or BP CML may receive initial therapy with newer generation TKIs (preferred over imatinib) to reduce the disease burden and may be considered for early ASCT⁽⁹³⁻⁹⁵⁾. Nonlymphoid BP response rate is 40% with a combination of TKIs and chemotherapy, with a median OS of 6 to 12 months. With TKI and antilymphoid therapy, the response rate in lymphoid BP is 70% to 80%, and the median OS is 12 to 24 months^(96,97). Tyrosine kinase inhibitors provide hematologic responses in 80% of patients, with an estimated 4-year OS of 40% to 55% in AP, but only a 40% response rate with a median OS of 9 to 12 months in BP. De novo AP responds better to frontline TKI therapy compared to AP transformed from antecedent CP, with a 6- to 8-year OS on TKI therapy of 60% to 80%⁽⁹⁸⁾. These patients may continue on TKI therapy indefinitely, provided they attain CCyR. Currently, the only curative therapy for AP or BP CML is ASCT, with a cure rate of 15% to 40% for AP and 5% to 20% for BP⁽³⁷⁾. Patients in both phases should be encouraged to participate in clinical trials.

RECOMMENDATIONS FOR TREATMENT

Chronic Phase

Standard-of-care, category 1 recommendation for the treatment of patients with newly diagnosed CP CML includes any of the three TKIs: imatinib, dasatinib, or nilotinib. Comorbidities, disease risk factors, side effect profiles, and cost may help in choosing one over another. Second-generation TKIs have demonstrated higher rates of early optimal responses; however, their impact on long-term OS remains to be evaluated. Achievement of CCyR is the primary goal of TKI therapy, and it may be desired by 3 to 6 months of therapy with dasatinib or nilotinib. Patients should be carefully monitored with an emphasis on compliance as well as treatment of side effects to minimize unnecessary treatment interruptions and dose reductions.

Allogeneic stem cell transplantation or other chemotherapy agents are no longer recommended as frontline treatments given the excellent responses and long-term OS achieved with TKIs. Kinase domain mutation profile is of relevance in the CML cytogenetic or hematologic relapse setting only and should be considered for patients who are failing imatinib or second-generation TKIs or who progress to AP or BP.

Accelerated and Blast Phase

Newer generation TKIs are preferred over imatinib as the frontline therapy. Allogeneic stem-cell transplantation, ideally in second CP, should be considered early for all AP patients based on response to TKI therapy. De novo AP may be treated long-term with TKI therapy alone provided CCyR is achieved. Tyrosine kinase inhibitor monotherapy or combination with chemotherapy (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone [hyper-CVAD] for lymphoid, AML-type for myeloid phenotype) may be considered for patients who are poor transplant candidates or as a bridge to ASCT.

FUTURE DIRECTIONS

In 2016, multiple TKIs are available for the treatment of CML, including imatinib, dasatinib, nilotinib, bosutinib, and ponatinib, in addition to omacetaxine and other older therapeutic agents. Following the dramatic refinement of therapeutic options for CML over the last 15 years, the majority of patients with CML are expected to have a normal life expectancy, provided that compliance with therapy is maintained and optimal monitoring is closely implemented, modifying therapy for early signs of resistance or treatment failure. The prevalence of CML will continue to increase over the next two decades. This will offer an opportunity to celebrate this success, but also will be a burden in terms of potential long-term side effects and costs of care. Future efforts will address improving complete molecular eradication of CML and achieving durable CMRs, even after therapy discontinuation (molecular cure). New-generation TKIs in novel combinations with available agents (eg, omacetaxine, decitabine, pegylated IFN) or with new investigational therapies (eg, JAK2 inhibitors, hedgehog inhibitors, stem cell toxins or vaccines, bcl2 inhibitors, other immune approaches) are likely to play a key role in the ultimate cure of CML.

Myelodysplastic Syndromes: The MD Anderson Cancer Center Approach

Carlos Bueso-Ramos
Guillermo Garcia-Manero

Myelodysplastic syndromes (MDS) refer to a group of hematopoietic disorders characterized by ineffective hematopoiesis and increased risk of transformation to acute myelogenous leukemia (AML). Most patients with MDS succumb to causes related to the disease. The median age of patients with MDS is 70 to 75 years. It is likely that environmental factors play an important role in the pathogenesis of this disease. Myelodysplastic syndromes are classified according to the World Health Organization (WHO) criteria, and a number of prognostic scores can be used to calculate survival and risk of transformation. Cytogenetic, genomic, and epigenetic alterations are common in MDS and help in the prediction of prognosis and potentially in the selection of therapy. Over the last decade, we have witnessed significant improvements in supportive care and therapeutic modalities for patients with MDS. These include growth factors, immune modulatory agents (lenalidomide), and hypomethylating agents (5-azacitidine and decitabine). We also better understand patient subgroups, such as those with hypomethylating failure disease. In this chapter, we summarize our knowledge of MDS and the treatment approach we use at MD Anderson Cancer Center.

THE MD ANDERSON APPROACH TO THE PATIENT WITH MDS

Every year, approximately 350 to 400 patients are referred to our center with a diagnosis of MDS. Nearly 20% of patients referred with a diagnosis of MDS receive a different diagnosis in our center. In most

instances, the final diagnosis is that of AML or a form of higher-risk MDS. Other benign and malignant conditions can also be observed. In a study of 915 patients referred between 2005 and 2009 and using very strict criteria, 12% were reclassified when initially evaluated here (¹). This justifies our practice to repeat a confirmatory bone marrow aspiration and biopsy at the time of initial MDS evaluation at MD Anderson.

Once the diagnosis is confirmed, the next important step is to calculate the “risk” of the patient. Most clinicians and investigators still use the International Prognostic Scoring System (IPSS) (²) score to perform such analysis, but newer potentially more precise models, such as the Revised International Prognostic Scoring System (IPSS-R), have been developed (³⁻⁵). In general, patients with low or intermediate-1 risk by the IPSS or those with less than 10% blasts in the bone marrow are considered as having “lower” risk disease, whereas those with excess blasts or intermediate-2 or high-risk disease are considered as having “higher” risk disease.

Patients with lower risk disease can be candidates for a wide range of interventions, depending on their specific characteristics and transfusion needs. Patients with minimal cytopenias, who are transfusion independent, who have a low percentage of blasts in the bone marrow, and have diploid cytogenetics are more frequently observed, as their 4-year survival is close to 80% (⁴). At the end of the spectrum, older patients with significant cytopenias and transfusion needs can have very poor prognosis, particularly if their cytogenetics are abnormal (⁴). The median survival of these patients is less than 12 months; around 60% to 70% of patients with MDS are in this category, but there are

few interventions known to alter the natural history of these patients. Transfusion and growth factor support are usually started. Interventions such as lenalidomide have significant activity in improving red cell counts in patients with deletion of chromosome 5⁽⁶⁾ but are significantly less active in patients without this alteration⁽⁷⁾. The role of the hypomethylating agents 5-azacitidine or decitabine is less clear in this situation, although they are frequently used. Allogeneic stem cell transplantation (alloSCT) is not frequently used up front in patients with lower risk disease⁽⁸⁾. It is currently accepted that delaying transplantation until the time of progression is associated with longer survival even if transplant outcomes are poorer when performed at that time. A new subset of patients has emerged that is constituted by patients with lower risk disease but with hypomethylating failure. We recently described their natural history⁽⁹⁾. New investigational strategies are needed for this subset of patients.

Treatment decisions are relatively simpler for patients with higher risk MDS. The data with the hypomethylating agents indicate that treatment with these agents improves survival significantly when compared to supportive care or low-dose chemotherapy approaches. The optimal approach for younger (those less than 60 to 65 years) patients with MDS is unclear. These patients can be treated with hypomethylating agents or an AML-like induction therapy or can be considered for up-front alloSCT. No study has compared these treatments in younger patients. An approach followed by our group is to stratify patients based on cytogenetics. Younger patients with normal karyotype are usually offered induction therapy with an AML-like approach followed when possible by alloSCT. In contrast, younger patients with abnormal karyotypes are offered hypomethylating agent-based therapy followed by alloSCT. It is not our routine to proceed with transplant up front in patients with excess blasts. Older patients benefit significantly from the use of hypomethylating agents, and there is basically no upper age limit that may contraindicate their use⁽¹⁰⁾. Finally, the group of patients with higher risk disease and hypomethylating failure constitute a major medical need⁽¹¹⁾.

A comprehensive review of current knowledge in MDS is provided next. Current areas of intense research are the development of newer forms of therapy for patients with newly diagnosed disease and strategies for patients who have relapsed or not responded to hypomethylating agent-based therapy.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of MDS increases with age. Most patients diagnosed with this condition are more than 60 years old; the median age at diagnosis is 75 years⁽¹²⁾.

The incidence is higher in males than females, with a 2:1 ratio⁽¹²⁾. The incidence in the United States is 30 to 35 individuals per million per year with a relative yearly increase in the reported incidence, probably related to increase awareness of the disease and reporting efforts⁽¹³⁾.

The risk of developing MDS is related to the individual's racial background. In the United States, the incidence is highest in the white population⁽¹²⁾. Patients with MDS from Asia present at a younger age⁽¹⁴⁾. The underlying cause of this phenomenon is not known but may reflect genetic differences between different racial groups. Asian patients have a similar frequency of karyotype abnormality as European and American cohorts, although they may have less frequent alterations of chromosomes 5 and 7⁽¹⁴⁻¹⁶⁾. The combination of younger age at diagnosis and lack of chromosome 7 alterations can explain the longer survival observed in patients from Asia.

There is no known cause of MDS. Genetic or environmental risk factors may contribute to MDS. Genetic syndromes, such as Down syndrome, Bloom syndrome, and Fanconi anemia, are associated with an increased risk of MDS, which often presents earlier in life^(17, 18). Genetic polymorphisms that influence the activity of enzymes responsible for metabolizing toxic chemicals or chemotherapy drugs may influence an individual's predisposition to MDS. Polymorphisms have been described in the cytochrome p450 3A, glutathione-S-transferase, and NAD(P)H quinone oxidoreductase enzyme systems that increase the risk of developing myeloid malignancy⁽¹⁹⁻²¹⁾.

Environmental agents may contribute to the development of MDS by causing toxic damage to hematopoietic stem cells. A causal relationship between occupational exposures to benzene and radiation and the development of myeloid malignancy has been demonstrated⁽²²⁾. Exposure to organic solvents and pesticides has also been implicated in the development of MDS⁽²³⁻²⁵⁾. There is no correlation between MDS and socioeconomic status⁽²⁴⁾.

The most significant risk factor for the development of MDS is previous exposure to chemotherapy or radiotherapy used to treat other cancers. Treatment-related MDS (t-MDS) constitutes a minority of MDS diagnoses but may be increasing in prevalence with improved survival rates after successful cancer therapies for tumors. Usually, t-MDS presents 5 to 6 years after initial cancer treatment and generally has a poor prognosis⁽²⁶⁾. Patients treated for lymphoma are at risk of this long-term complication⁽²⁷⁾. Patients who undergo autologous hematopoietic stem cell transplantation have a higher risk (10%-15%) of developing treatment-related MDS or AML, with incidence rates in some centers of up to 10%⁽²⁸⁾. In our experience with t-MDS at MD Anderson in 281 patients, most of

the risk was associated with complex cytogenetics or presence and alteration of chromosome 7⁽²⁹⁾.

CLINICAL AND LABORATORY FEATURES

Most patients with MDS are diagnosed incidentally during routine complete blood cell count (CBC) analysis or because of nonspecific symptoms. Anemia is the most common cytopenia in MDS and is associated with fatigue. A lower percentage of patients presents with bleeding or bruising secondary to thrombocytopenia or with infections related to neutropenia. Physical examination is often normal. Hepatosplenomegaly may be present in patients with chronic myelomonocytic leukemia (CMML) or overlap myeloproliferative neoplasms. A change in the severity of cytopenia or rapid worsening of symptoms may indicate disease transformation. Patients suspected to have MDS transformation require prompt investigation because 20% to 30% of patients will develop acute leukemia throughout their disease course⁽²⁾.

Initial assessment should include a CBC, reticulocyte count, and serum chemistry, including evaluation of B₁₂ and folate, iron studies (ferritin), and erythropoietin level examination. Other causes of cytopenias or MDS-mimicking syndromes (eg, HIV [human immunodeficiency virus], other infections, autoimmune disorders, or copper deficiency) should be ruled out through appropriate tests. A bone marrow aspirate and biopsy with samples taken for an iron stain and cytogenetic studies are required. Morphological assessment of the disease is still required for MDS. Cytogenetic studies may confirm the presence of clonal hematopoiesis and provide additional important prognostic information. Analysis of specific gene mutations, such as *TET2*, *DNMT3A*, *ASXL1*, *TP53*, splicing factors, *NRAS*, *FLT-3*, *IDH1*, *IDH2*, and *JAK2* may improve our prognostic and predictive evaluation and may in time allow for the use of targeted interventions using selective inhibitors (eg, *FLT3*, *JAK2*, or *IDH1/2* inhibitors) or allow earlier consideration of alloSCT. However, it should also be noted that these molecular abnormalities⁽³⁰⁾ may be present in older individuals with or without cytopenias and may not necessarily point to an MDS diagnosis^(31, 32). In general, no patient should be diagnosed as having MDS without knowledge of the clinical and drug history or while on growth factor therapy, including erythropoietin.

MORPHOLOGICAL FEATURES

Morphological classification of MDS is based on a 500-cell differential count on the bone marrow aspirate and leukocyte differential performed on the blood

Table 5-1 Classification of MDS According to World Health Organization Criteria

• Refractory cytopenia with unilineage dysplasia (RCUD)
• Refractory anemia (RA)
• Refractory neutropenia (RN)
• Refractory thrombocytopenia (RT)
• Refractory anemia with ring sideroblasts (RARS)
• Refractory cytopenia with multilineage dysplasia (RCMD)
• Refractory anemia with excess blasts (RAEB-1, -2)
• Myelodysplastic syndrome with isolated del(5q)
• Myelodysplastic syndrome, unclassifiable (MDS,U)
• Childhood myelodysplastic syndrome
• Refractory cytopenia of childhood (RCC)

Data from Vardiman JW, Thiele J, Arber DA, et al. The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: rationale and important changes. *Blood*. 2009;114(5):937-951.

smear⁽³³⁾. Table 5-1 shows the different subsets of MDS under the newly revised WHO MDS classification. This analysis determines the percentage of blasts present in the blood and bone marrow and provides an assessment of the number of myeloid lineages involved in the dysplastic process, and the iron stain determines the presence and number of ring sideroblasts (Fig. 5-1)⁽³³⁾.

Blood cell abnormalities on the peripheral blood smear are variable⁽³³⁾ (see Fig. 5-1). Red cells may be macrocytic and frequently display anisopoikilocytosis. Polychromasia or basophilic stippling may be present. Dysplastic granulocytes may show abnormal folding of the nucleus, and cytoplasmic granules are often reduced or absent. Platelets are of variable size and may also be hypogranular. The presence of circulating blast cells or an excess of monocytes is important for the classification of high-risk MDS and CMML, respectively.

Definitive diagnosis requires a bone marrow aspirate and biopsy. The bone marrow is usually normocellular or hypercellular, reflecting that hematopoiesis is ineffective. Abnormal maturation of hematopoietic cells results in a variable proportion of myeloblasts that are significantly increased in the more aggressive MDS. Morphological abnormalities found in the nucleus of erythroblasts include nuclear budding, internuclear bridging, karyorrhexis, multinuclearity, and megakaryoblastoid changes (see Fig. 5-1). Cytoplasmic features include the presence of ring sideroblasts and abnormal vacuolization. Abnormal or absent granulation is a common feature of dysplastic granulocyte series. Aberrant nuclear folding of the neutrophil precursor can produce a dysplastic bilobed nucleus, the pseudo-Pelger-Huet anomaly. Megakaryocytes may have a very variable morphology, and a small dysplastic form called the micromegakaryocyte is a typical finding.

FIGURE 5-1 Morphological features of peripheral blood and bone marrow in the myelodysplastic syndromes. **A.** Peripheral blood film from a patient with refractory anemia with excess blasts-1. The erythrocytes show hypochromasia, anisocytosis, and macroovalocytes. There is also an occasional blast (*center*). **B.** Peripheral blood film from a patient with refractory cytopenia with multilineage dysplasia demonstrating pseudo-Pelger-Huet cell (*center*) with hypercondensed chromatin and bilobed nuclei and hypogranular cytoplasm. **C.** Dysplastic small megakaryocytes, some with monolobated or with separated nuclei and mature granular cytoplasm in the bone marrow aspirate from a patient with refractory anemia with excess blasts. **D.** Increased blasts, dysgranulopoiesis, and dyserythropoiesis in the bone marrow aspirate from a patient with refractory anemia with excess blasts. **E.** Ring sideroblasts and Pappenheimer bodies from a patient with refractory anemia with ring sideroblasts. **F.** Hypercellular (100%) bone marrow biopsy with increased immature cells and dysplastic megakaryocytes in a 70-year-old male with refractory anemia with excess blasts.

A normal megakaryocyte has a polyploid nucleus that can be altered with dysplasia to produce hypolobulation or nuclei that are dispersed throughout the cell. The bone marrow biopsy provides the best assessment of the overall cellularity and allows examination of the architecture of the marrow and surrounding bone (Fig. 5-2). The presence of fibrosis can be assessed on biopsy with specific stains for reticulin and collagen. In normal bone marrow, the immature blast cells are frequently located near the endosteal surface. In MDS, these cells may be distant to this site and form aberrant clusters referred to as abnormal localization of immature precursors (ALIP). Immunohistochemical staining of biopsies can aid diagnosis, with CD34 staining to identify blast and progenitor cells and CD42 or CD62 for quantitation and assessment of megakaryocytes (³⁴) (see Fig. 5-2).

Nonclonal diseases may cause dysplastic morphological changes in blood cells. Secondary causes of dysplasia should be excluded in the initial assessment and can potentially complicate the diagnosis. Blood cell dysplasia is seen with exposure to heavy metals or antituberculous therapies, B₁₂ and folate deficiency, HIV infection, excessive alcohol consumption (³³), and occasionally normal aging (³⁵). Dysplastic features are commonly observed after chemotherapy or with the therapeutic use of granulocyte colony-stimulating factor (G-CSF). These diagnoses should be assessed in the history and may require exclusion with further laboratory testing. Diagnostic difficulties may occur in patients with marked hypocellularity of the bone marrow and in patients with prominent fibrosis as there are often very few cells in the aspirate sample to allow morphological assessment of dysplasia. For patients with prominent hypocellularity of the marrow, it may be difficult to distinguish from aplastic anemia, for which morphological dysplasia of the erythroid lineage may also be observed. In cases of marked fibrosis, bone marrow aspiration is often unsuccessful. Some patients with mild dysplastic changes in the bone marrow and a diploid karyotype may be difficult to definitively diagnose at initial presentation and may require a period of observation to confirm the underlying diagnosis. These patients require review with repeat investigations performed in 3 to 6 months.

CYTOGENETIC AND MOLECULAR ANALYSIS

A cytogenetic abnormality is found in 40% to 50% of patients with primary MDS and lower risk disease; it is higher in patients with more advanced MDS. Cytogenetic analysis of hematopoietic cells derived from the bone marrow aspirate provides important prognostic and predictive information and may direct

FIGURE 5-2 Morphological and immunohistochemical feature of bone marrow biopsy in the myelodysplastic syndromes. **A.** Trephine bone marrow biopsy with numerous dysplastic monolobated megakaryocytes in a 60-year-old female patient with refractory anemia with excess blasts type 1. **B.** CD61 immunohistochemical stain highlighting many dysplastic micromegakaryocytes. CD61 may be helpful in detecting dysplastic micromegakaryocytes to aid in confirming dysmegakaryopoiesis and abnormal translocation of megakaryocytes to endosteal surfaces. **C.** CD34 immunohistochemical staining highlighting the presence of an increased number of blasts and increased blood vessels.

therapy (eg, lenalidomide therapy with deletion 5q or earlier alloSCT with complex or adverse karyotypes). A karyotypic abnormality provides evidence for the presence of a clonal blood disorder, which may be particularly important if the morphological changes are not clear. Typically, cytogenetic analysis will assess 20 bone marrow metaphases⁽³⁴⁾. Multiple different cytogenetic abnormalities have been described⁽³⁶⁾. These are summarized in Table 5-2. No specific cytogenetic abnormalities characterize MDS. Unlike AML and chronic myeloid leukemia, genetic translocations are rare in MDS, but deletions are common.

The presence or absence of a cytogenetic abnormality has a marked influence on prognosis⁽³⁶⁾. Median survival of patients with normal karyotypes is approximately 53 months, compared to less than 12 months for patients with three or more cytogenetic abnormalities (complex). Del(5q) and del(20q) are associated with a favorable prognosis. However, when these abnormalities are present in association with other cytogenetic abnormalities, especially as a component of a complex karyotype, the prognosis is poor. Abnormalities of chromosome 7, usually deletions, are associated with poor prognosis regardless of the presence or absence of other abnormalities. Complex cytogenetic abnormalities are more frequently observed in patients with increased marrow blasts. A progressively worse prognosis is observed with increasing complexity.

Patients with six or more abnormalities have a very poor median survival of 5 months⁽³⁶⁾. In 2012, a new comprehensive scoring cytogenetic system was developed using data from 2,902 patients⁽³⁷⁾. This analysis resulted in 19 new cytogenetic categories and 5 prognostic subgroups (Fig. 5-3). This scoring system serves as the basis for the IPSS-R⁽³⁵⁾.

Treatment-related MDS has a particularly high incidence of cytogenetic abnormalities, with karyotypic changes observed in 70% to 90% of cases^(26, 29, 36). A high incidence of abnormalities is associated with an unfavorable prognosis for this group of patients. Abnormalities of chromosomes 5 and 7 are frequently observed after exposure to alkylating agents^(38, 39). Translocations involving 11q23 are seen after treatment with topoisomerase II inhibitors⁽³⁸⁾.

The high frequency of chromosomal deletions has prompted interest in the identification of epigenetic repressive alterations, such as aberrant DNA methylation in MDS. Aberrant DNA methylation of multiple promoter CpG islands has been associated with poor prognosis in MDS⁽⁴⁰⁾. At this point, we do not have evidence of specific molecular pathways that are epigenetically inactivated in MDS.

An association between a genetic abnormality and disease phenotype was reported in a few specific subsets of MDS. An example is the 5q- syndrome. A minority of patients with an interstitial deletion of

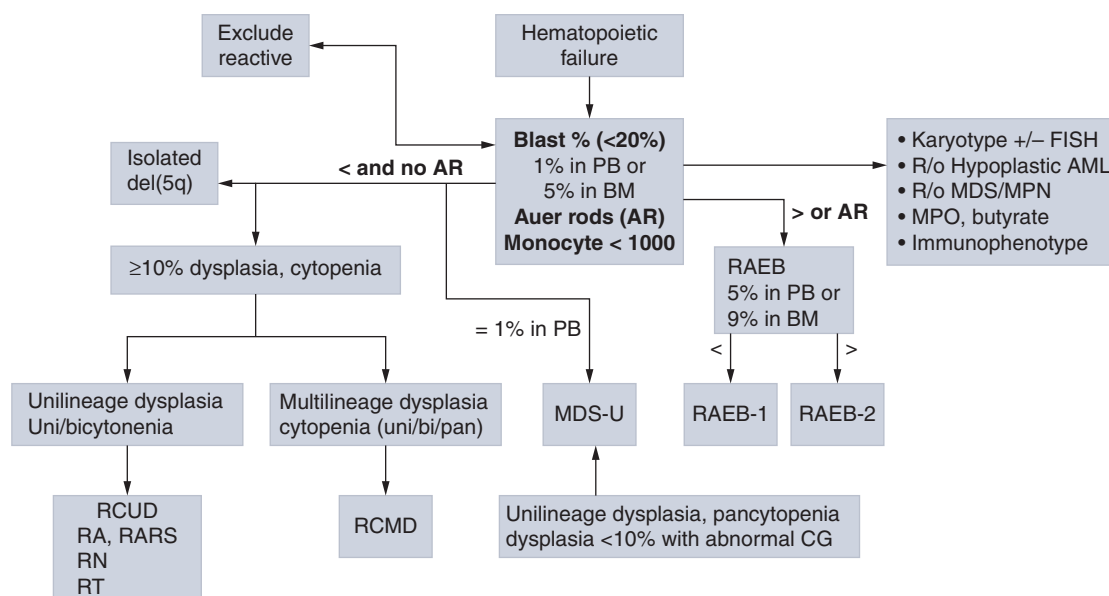

FIGURE 5-3 Algorithm for the classification of adult-onset primary myelodysplastic syndromes (MDS). This classification system is based on the 2008 criteria of the World Health Organization. AML, acute myeloid leukemia; FISH, fluorescence in situ hybridization; RAEB, refractory anemia with excess blasts; RARS, refractory anemia with ring sideroblasts that are equal to or greater than 15% of bone marrow erythroid precursors; RCMD, refractory cytopenia with multilineage dysplasia; RCUD, refractory cytopenia with unilineage dysplasia.

chromosome 5q display an indolent anemia with relative preservation of the platelet count associated with hypolobated megakaryocytes in the bone marrow. This array of findings is called the 5q- syndrome⁽⁴¹⁾ and is recognized as a separate diagnostic entity in the current WHO classification. The genetic defect within the deleted region that is responsible for the disease is not known. Research has focused on one candidate gene, *SPARC*, that may potentially contribute to the malignant phenotype⁽⁴²⁾. *CTNNA1* is another gene on chromosome 5q identified to be important in MDS and AML but without specific features of the 5q- syndrome⁽⁴³⁾. Ebert et al. reported the identification of *RPS14* as haplo-insufficient in 5q- MDS. *RPS14* is involved in ribosomal biogenesis, and its deficiency has a role in anemia in this syndrome⁽⁴⁴⁾. It is likely that a complex network of genes cooperate in the pathogenesis of this syndrome. Indeed, microRNA 145 and 146a have been found to be involved in the biology of 5q- syndrome⁽⁴⁵⁾.

A small number of patients have been described with a deletion of 17p associated with abnormalities in the *p53* gene. This specific disorder has a poor prognosis and may be suspected when morphological characteristics of prominent dysgranulopoiesis, including neutrophils exhibiting the Pelger-Huet anomaly and abnormal vacuolization, are present⁽⁴⁶⁾. Acquired hemoglobin H disease produces red cell changes on the blood smear reminiscent of α -thalassemia. This red cell phenotype is secondary to decreased expression of α -globin within the bone marrow MDS clone

and is associated with a mutation in the *ATR* gene in most cases⁽⁴⁷⁾. These rare syndromes represent a small minority of patients with MDS, and specific gene defects are not identified in most patients.

Several groups have used large-scale single-nucleotide polymorphism (SNP) arrays in MDS⁽⁴⁸⁾. This has allowed the identification of areas of micro-deletions and uniparental disomy in MDS⁽⁴⁹⁾. It is likely that these genomic regions harbor genes important in MDS, such as *c-CBL*⁽⁵⁰⁾. Over the last 5 years, we have accumulated significant information regarding genomic alterations in MDS^(30, 51). The data are summarized in Fig. 5-4 from a study reported by a

FIGURE 5-4 Bone marrow morphology of MDS with deletion of chromosome 5.

consortium of European investigators⁽⁵¹⁾. Common mutations affect genes involved in gene splicing, epigenetic regulators (eg, *TET2*, *DNMT3A*, *ASXL1*, and *EZH2*), and other pathways, such as *TP53*. The presence of mutations in *TP53* and *EZH2* is associated with poor prognosis⁽³⁰⁾. A recent analysis correlated specific genomic alterations with gene expression patterns that may explain some of the phenotypic features of the disease⁽⁵²⁾.

OTHER LABORATORY STUDIES

Flow cytometry is not required for the routine diagnosis of MDS, but it may sometimes provide valuable supplementary information. Flow cytometry can confirm the presence of specific myeloid lineages within the marrow and may also identify aberrant expression of cell surface markers indicative of a clonal cell population. This may have diagnostic significance in confirming abnormal hematopoiesis, particularly in the setting of inconclusive morphological changes and a normal karyotype. Quantitation of the number of CD34-positive cells in the bone marrow may assist in the differentiation of hypoplastic MDS from aplastic anemia. In MDS, the number of CD34 cells is usually normal or increased, compared to aplastic anemia, for which it is frequently reduced⁽⁵³⁾.

Fluorescent in situ hybridization (FISH) techniques using probes specific for specific chromosomes (ie, covering chromosomes 5, 7, 8, 20) have not been fully

standardized in MDS. Their use should not be considered standard of care in MDS and cannot yet replace conventional cytogenetics.

DIAGNOSIS

The classification systems used to group different MDS have evolved over time with increased understanding of the biology and genetics of the disease. The first widely accepted classification was that proposed by the French-American-British (FAB) study group⁽⁵⁴⁾. The FAB categorized MDS primarily on the percentage of blasts in the peripheral blood and bone marrow, with disease entities defined by increased numbers of blasts associated with a more aggressive clinical course. Patients with a bone marrow blast percentage greater than 30% were considered to have acute myeloid leukemia. This classification used only morphological criteria to define disease groups and provided a framework that allowed the study of the natural history of MDS and its response to therapy.

The WHO classification of MDS was developed with the objective of using all features of disease biology, including morphology, cytogenetics, immunophenotype, and clinical behavior⁽⁵⁵⁾. This classification was updated in 2008⁽⁵⁶⁾ (see Table 5-1). **Figure 5-5** shows an algorithm for the morphological diagnosis of MDS. In the original WHO classification, the importance of morphological assessment of blast percentage within the bone marrow and peripheral blood was retained,

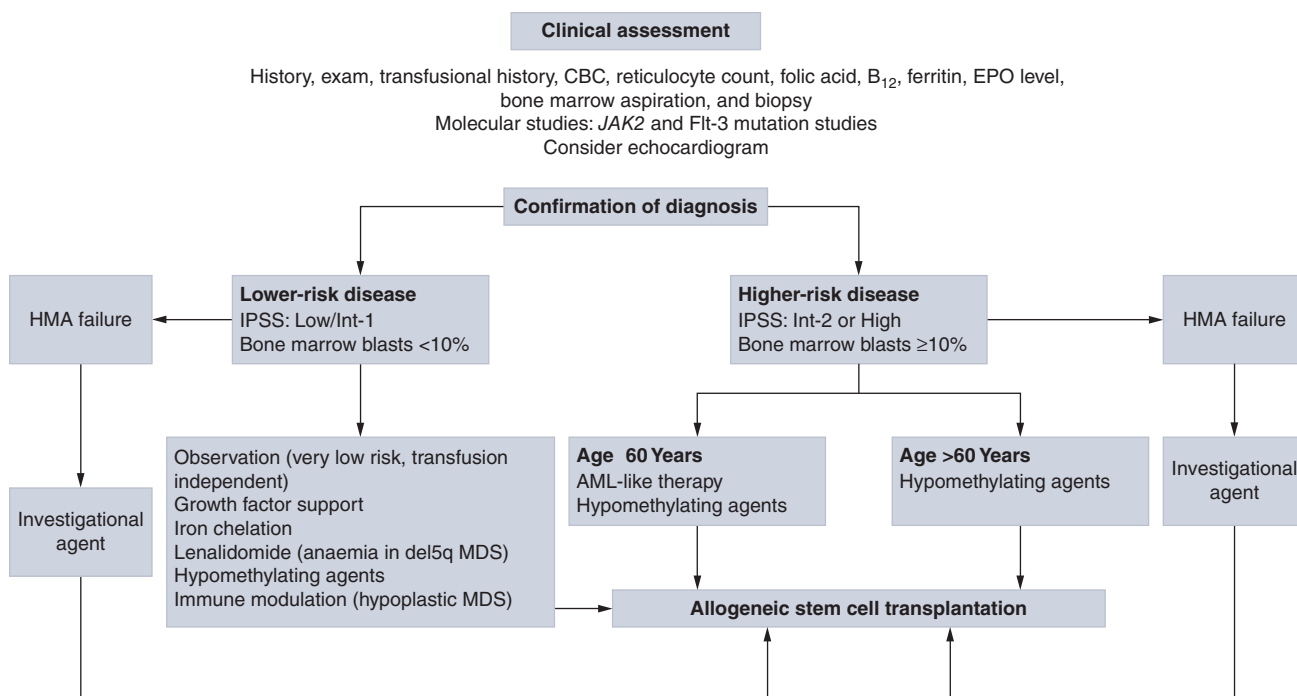

FIGURE 5-5 An approach to the management of MDS.

although the threshold level for the diagnosis of acute leukemia was altered. Patients with more than 20% bone marrow blasts were considered to have AML. Patients with 20% to 29% blasts had a similar prognosis as patients with greater than 30% blasts. Within the WHO MDS categories with an increased blast percentage, the magnitude of the blast elevation was quantified between refractory anemia with excess blasts (RAEB) types 1 and 2, reflecting the worse prognosis of patients with an elevated blast count (²). In patients with a normal proportion of blast cells within the bone marrow, the relatively indolent refractory anemia (RA) and RA with ring sideroblasts (RARS) introduced in the FAB system were further delineated by assessment for the presence of multilineage dysplasia. Patients with dysplastic maturation limited to the erythroid lineage have a more favorable prognosis than patients with cytopenia and dysplasia present in multiple myeloid lineages. Also, WHO introduced the 5q- syndrome as a separate diagnostic entity primarily on the basis of a genetic abnormality rather than morphological features alone. Deletions involving chromosome 5q are relatively common in MDS, and the WHO classification tightly defined the syndrome as an isolated del(5q) associated with anemia, a preserved or increased platelet count, and hypolobated megakaryocytes on the bone marrow biopsy (Fig. 5-6). The WHO classification has been validated by a number of independent groups (^{57, 58}). The most recent WHO classification (⁵⁶) included the following changes: (1) specific guidelines for the requirement of specimen collection and blast and blast lineage assessment, as well as for the analysis of genetic alterations; (2) an effort to report new changes in the diagnosis and classification of MDS/MPN; (3) inclusion of

patients with cytopenias but not clear morphological evidence of MDS in the bone marrow as presumptive MDS; (4) inclusion of refractory cytopenia with unilineage dysplasia; and (5) disappearance of the category of refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS) (⁵⁶).

PROGNOSIS

The prognosis of patients with MDS is heterogeneous. The development of clinical systems that allow accurate prognostication of individual patients into low- and high-risk categories has proven essential to guide rational management decisions and allow the introduction of investigational drug protocols. The IPSS (²) is the most widely used system for assessment of prognosis and treatment planning. It provides an assessment of the prognosis of patients with primary MDS at the time of initial diagnosis. It was designed by the retrospective analysis of a large pool of 816 patients with MDS and followed the natural history of the disease to determine important factors related to patient outcome. Overall survival and the risk of transformation to acute leukemia were related to the number of blood cytopenias, the percentage of myeloblasts in the bone marrow, and the presence of specific cytogenetic abnormalities. The risk associated with cytogenetic abnormalities was determined to be good if a normal diploid karyotype, isolated del(5q), isolated del(20q), or isolated -Y were present. Poor risk abnormalities were defined as abnormalities involving chromosome 7 or complex karyotypes with the presence of three or more karyotypic abnormalities. All other cytogenetic abnormalities were considered

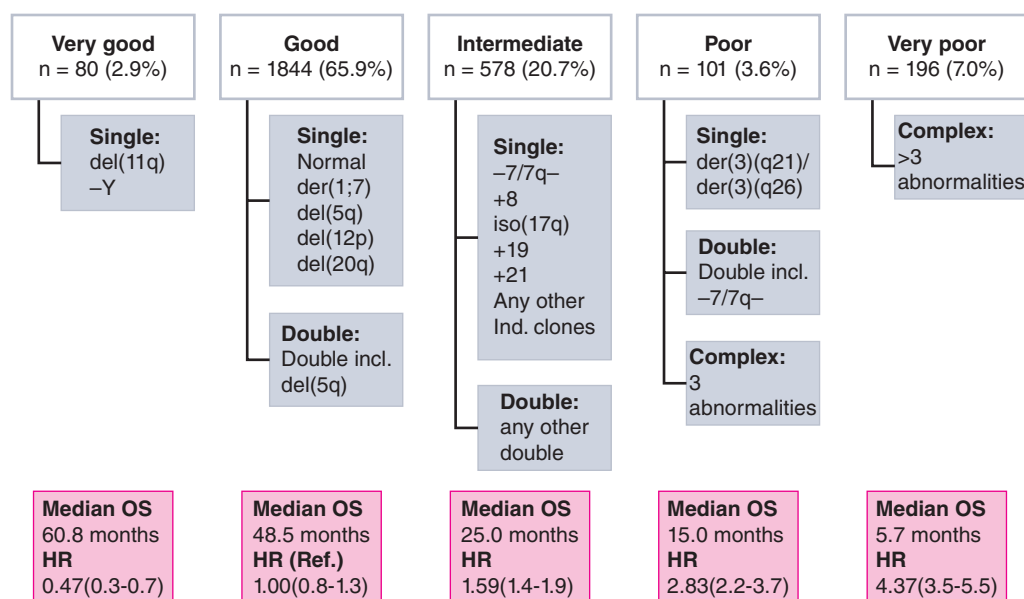

FIGURE 5-6 Cytogetic score.

Table 5-3 International Prognostic Scoring System (¹)

A: IPSS Score Is the Sum of the Three Listed Prognostic Factors					
Score	0	0.5	1	1.5	2

B: Prognosis Determined by IPSS Score					
		Median Survival (Years)			
Risk Group	IPSS Score	≤60 years	>60 years	≤70 years	>70 years
Low	0	11.8	4.8	9	3.9
Intermediate-1	0.5-1.0	5.2	2.7	4.4	2.4
Intermediate-2	1.5-2.0	1.8	1.1	1.3	1.2
High	≥2.5	0.3	0.5	0.4	0.4

Cytopenias defined as hemoglobin concentration <10 g/dL, neutrophils <1.5 × 10⁹/L, and platelets <100 × 10⁹/L.

^aGood: normal, -Y, del(5q), del(20q); poor: complex (≥3 abnormalities) or chromosome 7 anomalies; intermediate: other abnormalities.

intermediate risk. The IPSS weighed these variables to produce a score that stratifies patients into four separate risk groups: low, intermediate-1, intermediate-2, and high risk (Table 5-3). Survival and risk of transformation to acute leukemia are then predicted from cohorts of different ages as illustrated in Table 5-3B. Patients classified as IPSS low and intermediate-1 risks are generally considered to have low-risk MDS, and patients classified as having IPSS intermediate-2 and high are grouped into those with high-risk MDS.

Low-risk MDS are typically treated more conservatively than higher risk MDS. Prognostication in this low-risk group may be particularly important as it is unclear at this time whether some low-risk patients may benefit from early therapeutic intervention. To determine which low-risk patients should be considered for treatment protocols investigating early intervention, patients with low-risk MDS at MD Anderson were analyzed to further stratify prognosis in low and intermediate-1 IPSS groupings (⁴). Factors associated with worse prognosis in this low-risk group included thrombocytopenia (platelets <50 × 10⁹/L), anemia (hemoglobin concentration <10 g/dL), age (>60 years), blast count >4%, and a karyotype that was not diploid or del(5q). This model stratified low-risk patients into three subgroups with a median survival of 80, 27, and 14 months, respectively. Increased ferritin and β₂-microglobulin were also associated with worse survival, but these factors were not included in the prognostic model. As patient survival was significantly different between these low-risk categories, investigation of early intervention protocols in low-risk patients with relatively poor survival may be warranted (Table 5-4). We described the cause of death of patients with lower risk MDS (⁵⁹). Approximately 80% of patients died from a complication intrinsic to MDS and not due to disease progression, which only occurred

in 10% to 20% of patients. The most frequent cause of death was infection, followed by bleeding. Patients with increased percentage of blasts and a monosomy 7 had an increased risk of transformation to AML (⁵⁹).

Table 5-4 A Low-Risk MDS-Specific Model

A			
Adverse Factor	Coefficient	P Value	Assigned Score
Unfavorable cytogenetics	0.203	<.0001	1
Age ≤60 years	0.348	<.0001	2
Hemoglobin <10 (g/dL)	0.216	<.0001	1
Plt <50 × 10 ⁹ /L	0.498	<.0001	2
(50-200) × 10 ⁹ /L	0.277	.0001	1
BM blasts ≤4%	0.195	.0001	1

6	86	16	7
7	13	9	NA

The score is calculated in patients with MDS and an IPSS score of low or intermediate-1. **A.** Significant characteristics by multivariate analysis. Each one has an assigned score. The calculated total score can then be used in **B** to predict median and 4-year survivals (³).

The IPSS determines risk at the time of initial diagnosis, but it does not provide information regarding changes in risk as patients progress through the course of their disease. A dynamic prognostication system has been developed to address this deficiency and provides a score that is predictive of survival and leukemic transformation over time. The WHO classification-based Prognostic Scoring System (WPSS) weights three variables: WHO diagnostic classification, karyotype abnormalities categorized according to the IPSS criteria, and transfusion requirement⁽³⁾. This stratifies patients into five disease groups that demonstrate different survival and risk of evolution to acute leukemia over time. Very low-risk patients in this classification have an overall mortality rate that was not different from the general population. This model incorporates changes in the disease risk profile over time, allowing further refinement in prediction of survival and leukemic progression as the disease progresses. A model has been developed by the MD Anderson group that accounts for both de novo and secondary disease and includes CMML. It also allows prognostication at diagnosis or any time during the course of MDS⁽⁶⁰⁾. The characteristics of this model are shown in **Tables 5-5, 5-6, and 5-7**.

The presence of fibrosis on the bone marrow biopsy occurs in a minority of patients with MDS, but this pathological feature is not incorporated into routine diagnostic classifications or prognostic systems. Fibrosis is more frequently observed in patients with multilineage dysplasia or with karyotype abnormalities and, when present, is associated with a more rapid progression to severe bone marrow failure and shortened survival⁽⁶¹⁾. In younger patients, it may warrant early consideration of alloSCT.

Table 5-5 MDACC Model—Simplified Myelodysplastic Syndrome Risk Score

Prognostic Factor	Coefficient	Points
Performance status		
≤2	0.267	2
Age (years)		
60-64	0.179	1
≤65	0.336	2

5-10	0.222	1
11-29	0.260	2
White blood cells >20 × 10 ⁹ /L	0.258	2
Karyotype: Chromosome 7 abnormality or complex ≤3 abnormalities	0.479	3
Prior transfusion, yes	0.107	1

MDACC, MD Anderson Cancer Center. Score points were obtained by dividing the coefficients by 0.15 and rounding to the nearest integer.

Recently, an international consortium developed a new MDS classification known as IPSS-R, or Revised IPSS⁽⁶⁾. The basis for this effort was to improve on known limitations of the initial IPSS. IPSS-R includes a refined cytogenetic annotation and newer thresholds of cytopenias and blast percentages. **Tables 5-8 and 5-9**

Table 5-6 MDS MDACC Model—Estimated Overall Survival by Prognostic Score

show the characteristics of this new classification. The IPSS-R divides patients into five categories (very low, low, intermediate, high, and very high). Algorithms have been developed to calculate expected survival and time to progression based age and IPSS-R score. Although IPSS-R is the classification that the MDS expert community wishes it used when reporting on patients with MDS, practically and clinically it has not been adopted by MD Anderson. The main issues are the complexity of the score and the fact that it is unclear how to approach patients with intermediate risk disease. Furthermore, all drugs currently used in MDS were approved under IPSS or FAB criteria. Finally, it is likely that all these classifications will soon be modified to incorporate newer molecular data.

Patients with MDS are older and may suffer from other comorbidities. We have calculated the impact of comorbidities using the ACE-27 (Adult Comorbidity Evaluation-27) comorbidity score on the outcome of patients with MDS⁽⁶²⁾. This analysis indicated synergism between the presence of comorbidity and disease score. The same was observed when ACE-27 was calculated with IPSS-R⁽⁶³⁾.

THERAPY

The number of effective drug treatments available to treat MDS has expanded in recent years, providing a range of management alternatives. Some treatments

improve hematopoietic function and alleviate symptoms related to blood cytopenia; other therapies alter the natural history of the disease and improve survival. Both approaches may be appropriate in different clinical contexts, and many patients receive different combinations of treatments throughout their disease course.

The goals of therapy in MDS vary in different patient populations. A management plan should consider the patient's age, comorbidities, and disease risk. Patients with low-risk MDS most commonly experience problems related to chronic anemia, and the disease may remain stable for prolonged periods. If these patients are elderly, they may best be managed with relatively nontoxic therapies that aim to maintain quality of life. Treatment options include transfusions of blood products, growth factor therapies (erythropoietin with or without colony-stimulating factors), and non-growth factor therapies with immune modulators (lenalidomide) and epigenetic drug treatment (azacitidine and decitabine). High-risk MDS has a poor prognosis and forms a continuum with acute myeloid leukemia. Aggressive therapies may be warranted in these high-risk patients to eradicate the malignant clone and improve survival. Intensive therapies may include high-dose chemotherapy and consideration of alloSCT in younger patients. Intensive treatment protocols are not suitable for all patients because they expose the patient to significant risks of treatment-related morbidity and mortality. An algorithm for treatment approaches at MD Anderson Cancer Center is shown in Fig. 5-7.

FIGURE 5-7 Molecular data.

Assessing response to treatment in MDS can be complex as treatment goals in low- and high-risk disease may be different. Clinical response criteria in low-risk disease usually measure improvements in peripheral blood cell counts and quality-of-life factors. Response in high-risk disease is typically more stringent, with measures of resolution of bone marrow changes by morphological and cytogenetic criteria. Standardized criteria are available to assess response to treatment in MDS and are particularly useful to allow comparisons between drug trials ⁽⁶⁴⁾.

Supportive Care

Chronic blood cytopenia is a principal characteristic of MDS. Therapies aimed at alleviating problems related to anemia, neutropenia, and thrombocytopenia are an essential component of management. Bacterial infections require aggressive treatment with antibiotics. Platelet transfusions are administered for episodes of bleeding or for prophylaxis in patients with severe thrombocytopenia. Transfusion thresholds at MD Anderson include a hemoglobin level of 8 g/dL (unless the patient is otherwise symptomatic) and a platelet count of less than 10 K/UL (unless there is evidence of bleeding). Additional hemostatic support with the use of antifibrinolytic agents may be considered for problematic mucosal bleeding or for surgical procedures. The role of prophylactic antibiotics is less established in neutropenic patients. It is our practice at MD Anderson to use triple therapy (antibacterial with a quinolone, antiviral, and antifungal) in all patients with severe neutropenia who are receiving therapy.

Symptomatic anemia is often the major clinical problem in patients with low-risk MDS. In this group, red cell transfusion is effective symptomatic therapy, but a prolonged transfusion program may cause problems with transfusion-related hemosiderosis, alloantibody formation, and volume overload in patients with impaired cardiac function. Deposition of iron in body tissues is treated with iron chelation. The efficacy of iron chelation therapy is best demonstrated in thalassemia major, where regular deferoxamine therapy reduces iron deposition in organs and improves survival ⁽⁶⁵⁾. In MDS, it is hypothesized to have similar advantages ⁽⁶⁶⁾, but this needs to be confirmed in ongoing randomized clinical trials. The parenteral administration of deferoxamine is inconvenient. The development of effective oral iron-chelating drugs, such as deferasirox, has allowed iron chelation to be performed more easily ⁽⁶⁷⁾. Iron chelation should start with parenteral deferoxamine or oral deferasirox after 20 to 40 units of red cells have been administered, particularly if there is an expectation of prolonged survival and continued transfusion therapy. Serum ferritin may be used as a guide to chelation therapy, with

a ferritin concentration greater than 1,000 µg/L typically attained after transfusion of 20 red cell units ⁽⁵⁸⁾. Iron chelation therapy should also be considered in a younger patient who may be a candidate for allogeneic transplantation. An elevated pretransplant ferritin has been associated with a lower overall survival after allogeneic transplantation and an increase in the hepatic transplant complication of veno-occlusive disease ⁽⁶⁸⁾.

Hematopoietic Growth Factors

Hematopoietic growth factors are the primary regulators of blood progenitor cell proliferation and are used therapeutically to promote effective hematopoiesis. Erythropoietin therapy has been explored as an alternative to red cell transfusion in patients with low-risk MDS. Recombinant erythropoietin (rEPO) in various forms, including epoetin α , epoetin β , and the long-acting darbepoetin, has been studied in different cohorts of patients. Overall, erythroid responses in unselected patients were modest, in the range of 10% to 20% ⁽⁶⁹⁾. The best responses were identified in patients with low-risk MDS, a low serum EPO level (<200 IU/L), and no red cell transfusion requirement ⁽⁷⁰⁾. In this favorable subgroup of patients with MDS, an erythroid response to rEPO therapy was observed in 40% to 60% of patients ⁽⁷⁰⁾. The median duration of response was 2 years, and therapy was associated with improved quality of life ⁽⁷¹⁾. Data suggest that patients who respond to growth factor therapy have better survival than historical control cohorts who received supportive care alone ⁽⁷⁰⁾.

Erythropoietin in combination with G-CSF is also effective, with response rates of 40% to 50% in selected cohorts ^(71, 72). The combination of these two hematopoietic cytokines appears to offer a synergistic clinical benefit and allows improvements in hemoglobin levels in some patients who fail to respond to EPO monotherapy. The benefit of this combination may be most marked in RARS and RCMD, but this has not been confirmed ⁽⁷⁰⁾. Disease transformation is a theoretical risk in patients receiving chronic hematopoietic growth factors, but long-term observations of these patients suggested that these cytokines do not promote leukemic transformation ^(70, 72). Hematopoietic growth factor therapy should be considered to treat anemia in patients with low-risk MDS associated with a low serum EPO. Erythropoietin can be initiated as monotherapy with the addition of G-CSF if there is no objective response in 2 to 3 months.

Thrombopoietin has been used to promote platelet production and minimize the bleeding complications related to severe thrombocytopenia. Initial trials with recombinant thrombopoietin were disappointing. New second-generation thrombomimetic agents are now being tested ⁽⁷³⁾. These drugs should not be used

outside the context of clinical trials due to potential concerns of increased blasts and fibrosis.

Lenalidomide

Lenalidomide is a chemical analogue of thalidomide with diverse biological actions that encompass immune modulation and antiangiogenic effects. Selective activity of lenalidomide against MDS associated with an interstitial deletion on the long arm of chromosome 5 was first suggested in a study examining the effects of this drug on anemia in patients with low-risk MDS (⁷⁴). Erythroid responses were noted in 56% of the cohort, with the most significant response found in the subgroup with a del(5q) abnormality. This observation was confirmed in a larger multicenter phase II study of lenalidomide (⁶). This second trial demonstrated an overall erythroid response in 76% of patients with the del(5q) abnormality. Responses were prolonged and occurred rapidly, with a median time to a hematologic response of 4 to 5 weeks. A cytogenetic response was documented in 73% of patients, with 44% developing complete cytogenetic remission. Cytogenetic responses were observed in patients with the del(5q) abnormality alone and in patients with the del(5q) abnormality associated with additional cytogenetic defects. This clearly demonstrated that the activity of lenalidomide was not limited to patients with the 5q- syndrome but was also observed in patients with low-risk MDS, with a variety of WHO classifications associated with a del(5q) abnormality on cytogenetic studies. A randomized trial comparing different doses of lenalidomide versus observation further confirmed the activity of the drug at a dose of 10 mg daily (⁷⁵). Although none of these studies was powered to document improvement in survival, a recent analysis indicated that achieving a cytogenetic response with lenalidomide was associated with prolonged survival (⁷⁶).

Lenalidomide therapy in MDS is usually started at 10 mg daily. A favorable response is typically characterized by normalization of anemia and cytogenetic response (⁶). The most important side effect of therapy with lenalidomide is myelosuppression, which may necessitate dose reduction in patients with persistent thrombocytopenia and neutropenia. Interestingly, the degree of myelosuppression has been associated with response. Thrombocytopenia at diagnosis (platelet count $<100 \times 10^9/L$) has been associated with a worse response to lenalidomide treatment. This may reflect repeated or prolonged treatment interruptions secondary to myelosuppression.

Lenalidomide and thalidomide also demonstrated activity in low-risk MDS without the del(5q) abnormality. Lenalidomide has been studied in 214 patients with low-risk MDS (IPSS low and intermediate-1) and

predominantly a normal karyotype (⁷). In this cohort, 26% of patients achieved transfusion independence, and 17% developed a reduction in transfusion requirement. The median duration of transfusion independence was 41 weeks, and cytogenetic responses were documented in 19% of patients with karyotypic abnormalities. These results were confirmed in a randomized trial (⁷⁷).

Hypomethylating Agents

5-Azacitidine and 5-aza-2'-deoxycytidine (decitabine) are chemically related drugs with a spectrum of activity that includes both low- and high-risk MDS. The mechanism of action of these drugs is uncertain, although both agents reverse abnormal promoter DNA methylation that surrounds the promoter of some tumor-suppressor genes in cancer cells. Aberrant promoter methylation is associated with transcriptional repression, or silencing, and may contribute to the loss of tumor-suppressor gene function in MDS. Decitabine and 5-azacitidine are both cytidine analogues that incorporate into DNA and form covalent bonds with DNA methyltransferase enzymes. Depletion of methyltransferase activity within the cell then causes newly synthesized DNA to be hypomethylated compared to the parent strand. After at least two cycles of cell division, DNA becomes globally hypomethylated with alteration in gene expression within the leukemic cell. Both agents display cytotoxicity at high doses, while hypomethylating activity remains prominent at lower doses. These biochemical changes are an attractive target for drug therapy as normal tissues have little gene promoter methylation, so hypomethylating therapy may have some degree of specificity for the malignant clone.

5-Azacitidine first demonstrated broad-spectrum activity in MDS. Comparison of azacitidine (75 mg/m² subcutaneously for 7 days every 28 days) to best supportive care in a randomized control trial demonstrated an overall response rate of 48% with azacitidine compared to 5% with supportive care (^{78, 79}). Azacitidine therapy was associated with a prolongation in the time to leukemic transformation and better quality of life. The median time to response was three cycles, and response rates were independent of MDS classification. Complete responses were observed in relatively few patients (10%), with most patients experiencing hematologic improvement. A report of a multicenter phase III study of azacitidine in patients with high-risk MDS demonstrated an increase in overall survival of approximately 9 months for patients receiving azacitidine compared to other standard therapies (⁸⁰). This was the first drug trial that demonstrated a survival advantage in MDS. A subset analysis of the trial data suggested that azacitidine may have significant

activity in MDS associated with abnormalities in chromosome 7, a cytogenetic abnormality associated with a poor outcome.

Decitabine has similar clinical activity to azacitidine and has been studied in various dose regimens in predominantly high-risk MDS and AML. Comparison of decitabine (45 mg/m² in three divided doses administered for 3 consecutive days every 6 weeks) to best supportive care in a randomized trial demonstrated an overall response rate of 17%, with complete remissions in 9% of patients with predominantly high-risk MDS⁽⁸¹⁾. Subgroup analysis revealed that patients who received decitabine had a longer median time to transformation to AML or death if they were treatment naïve or had high-risk MDS. Myelosuppression was the major drug toxicity. Data from this trial may underestimate the efficacy of the drug as a significant proportion of patients on decitabine received a small number of treatment cycles, which may have been insufficient to demonstrate a response. This is supported by previous phase II trial data that suggested decitabine had an overall response rate similar to azacitidine⁽⁸²⁾. Subsequent clinical trial development with decitabine has focused on improving response rates by lowering the daily dose and lengthening administration schedules. One such schedule of intravenous administration of decitabine for 5 days every 4 weeks demonstrated a complete response rate of 39% in a high-risk MDS cohort^(83, 84). Improvements in hematopoietic function are often delayed after the initiation of azacitidine or decitabine therapy, and drug treatment should continue for four to six cycles before cessation because of poor response.

Chemical modification of histone proteins by acetylation contributes to the regulation of gene expression and probably interacts with abnormal DNA methylation to cause transcriptional suppression of tumor-suppressor genes. Histone deacetylase inhibitors alter chromatin structure to promote gene transcription, and their combination with hypomethylating agents demonstrates significant *in vitro* synergy⁽⁸⁵⁾. Initial clinical drug trials in MDS and AML at MD Anderson indicated increased clinical activity with this type of combination^(86, 87) azacitidine. None of the randomized trials (hypomethylating agent with or without HDAC inhibitor) showed a survival improvement⁽⁸⁸⁾.

Cytotoxic Chemotherapy

The relatively poor prognosis associated with high-risk MDS has initiated intensive treatment strategies incorporating high-dose chemotherapy in the same protocols used to treat acute myeloid leukemia. In high-risk MDS, AML-type treatments produce a complete response rate of about 40% to 60%, but remissions are brief^(89, 90). This poor response to high-dose

chemotherapy is due, at least in part, to the relatively greater proportion of patients diagnosed with RAEB having poor prognosis cytogenetics involving complex changes of chromosomes 5 and 7. Elderly patients with significant comorbidities tolerate high-dose chemotherapy poorly.

Patients with high-risk MDS have been treated with a variety of intensive chemotherapy regimens at MD Anderson Cancer Center^(91, 92). Studies have examined using intermediate- to high-dose cytosine arabinoside (ara-C) (A) in various combinations with idarubicin (I), cyclophosphamide (C), fludarabine (F), and topotecan (T), as regimens: IA, FA, FAI, TA, and CAT. The overall complete response rate for these regimens was 55% to 58%. A short antecedent history of hematological disorder, a normal karyotype, performance status, age, and treatment in a laminar airflow environment were all predictive of attaining a complete response. This intensive approach was beneficial in some patients as those who developed a complete response within 6 weeks of chemotherapy obtained a survival advantage. However, these regimens were toxic, with significant treatment-related mortality in the first 6 weeks, ranging from 5% with TA to 21% with FAI. Consolidation chemotherapy was used in most cases where a remission was achieved with a regimen containing the drugs used in induction but at a reduced intensity of 50% to 66% of the initial dose. Survival of patients treated with IA and TA therapies were comparable and superior to those patients treated with FA, FAI, and CAT regimens, but prognosis remained poor. Nevertheless, this approach does benefit some younger individuals (<65 years) with a normal karyotype, achieving an encouraging 5-year survival rate of 27% with intensive treatment. For older patients, the TA combination can be considered as it has a relatively low treatment-related mortality and it does not contain anthracycline drugs (relatively contraindicated in the presence of heart disease).

Immunosuppressive Therapy

Immune dysfunction contributes to blood cytopenia in some patients with MDS, producing a clinical overlap with aplastic anemia. Immunosuppressive therapy with antithymocyte globulin (ATG) with or without the addition of cyclosporine has been explored in small numbers of patients with MDS. Response rates of 30% to 50% have been observed in selected cohorts of patients with low-risk MDS administered a course of ATG, with a minority of patients experiencing prolonged remission⁽⁹³⁻⁹⁵⁾. Features that may predict a good response to immunosuppressive therapy include younger age, HLA-DR status, shorter duration of red cell transfusion, low-risk IPSS, and bone marrow hypocellularity⁽⁹⁵⁻⁹⁷⁾. Selection of appropriate patients for immunosuppression is important as ATG therapy

is poorly tolerated in an older population with low-risk MDS⁽⁹⁸⁾. The PD-1 axis is expressed in patients with MDS. This may allow the development of new forms of therapy and combinations using inhibitors of this pathway⁽⁹⁹⁾.

Hematopoietic Stem Cell Transplantation

In MDS, alloSCT is potentially, but the therapy carries significant risk associated with treatment toxicity, prolonged cytopenia, infection, and graft-versus-host disease. In young patients with suitable donors, the transplant procedure offers the best chance of cure, with a long-term disease-free survival of 30% to 50%⁽¹⁰⁰⁻¹⁰⁴⁾. Given the risks associated with this procedure, patient suitability and timing of the transplant are important issues.

Allogeneic transplantation with myeloablative conditioning has been examined exclusively in younger patients (median age in the mid-30s) in most studies. Patients with low-risk disease (RA/RARS) have experienced the best survival rate. However, this is also the subgroup of patients predicted to experience prolonged survival without aggressive therapies. This procedure is associated with a significant treatment-related mortality of up to 30% to 50% in some studies^(102, 103). Relapse after transplantation occurs in approximately 20%, and the relapsed disease has a relatively poor response to donor lymphocyte infusion^(102, 103, 105). Increased risk of allogeneic transplantation mortality in MDS is associated with older age, poor risk cytogenetics (particularly abnormalities of chromosome 7 or a complex karyotype), the presence of excess blasts in the bone marrow, and longer duration of disease^(106, 107). Patients with treatment-related MDS also have a poor transplant outcome, but this is related to the frequency of high-risk cytogenetic changes^(107, 108).

The development of nonmyeloablative allogeneic transplantation with reduced-intensity conditioning has allowed allogeneic transplantation to be considered in older patients with MDS and in patients whose comorbidities or organ dysfunction would exclude them from myeloablative treatment⁽¹⁰⁹⁾. This procedure has reduced the transplant-related mortality, the major problem limiting the availability of this potentially curative therapy to older patients. This therapy aims to minimize organ toxicity related to initial chemo- or radiotherapy and allow stable engraftment of donor cells that provide the curative potential associated with the graft-versus-leukemia effect. Comparison of reduced-intensity conditioning transplantation with standard myeloablative conditioning showed reduced transplant-related mortality but increased relapse rate, resulting in comparable rates of overall survival between the two transplantation strategies^(106, 110, 111).

Statistical modeling based on historical allogeneic transplantation outcomes for matched sibling transplantation suggested that the maximal overall survival is achieved by different transplant strategies in different MDS risk groups⁽¹¹²⁾. Patients with low-risk disease (IPSS low and intermediate-1 groups) maximize overall survival by delaying transplantation after diagnosis until evidence of disease progression but before the development of overt acute leukemia. This delayed transplant approach provided the greatest survival benefit to younger patients (<40 years).

Specific features of disease progression have not been defined, but evidence of new cytogenetic abnormalities, progressive cytopenia, and increasing blast percentage in the bone marrow are suggested as potential triggers for transplantation. Patients with high-risk disease (IPSS intermediate-2 and high) should ideally receive the transplant as soon as possible after diagnosis. The presence of bone marrow fibrosis delays engraftment in allogeneic transplantation and its presence is an additional risk factor in transplant outcome in high-risk MDS. In this group, fibrosis considerably increases transplantation risk.

Early consideration of transplantation is suggested in a younger patient with significant MDS-associated fibrosis⁽¹⁰⁸⁾. The IBMTR studied the outcomes of patients older than 60 years of age with MDS treated with either reduced-intensity transplantation or hypomethylating agents⁽⁸⁾. The results of this analysis indicated that transplant should not be considered as first-line therapy in lower risk MDS. Of interest, in higher risk MDS it appears that there is a benefit toward transplant compared to hypomethylating-based therapy, but survival curves cross significantly later than after 24 months of therapy. This indicated that there is probably a specific group of patients, not yet defined, that derive the maximal benefit from transplantation.

SPECIFIC CLINICAL SITUATIONS

Despite the clinical activity of several agents described earlier, most patients with MDS will eventually succumb to their disease. This emphasizes the need to develop better strategies both up-front and in patients who have failed prior therapies.

Treating Patients With Lower-Risk Disease and Poor Prognosis

It is now demonstrated that the prognosis of patients with lower-risk MDS is very heterogeneous, with a significant subset of patients having poor prognosis⁽⁴⁾. Because most of these patients die as a consequence of

MDS, introducing therapy early in this selected group of patients may help. This has significant implications not only for the role of alloSCT in MDS but also for the incorporation of disease-modifying strategies. We have studied the role of very low-dose or oral schedules of hypomethylating agents in this setting^(113, 114). Randomized phase III trials are being conducted to investigate the impact of these interventions on survival.

Hypermethylator Failure MDS

One of the major problems is the treatment of patients who have failed therapy with a hypomethylating agent. Data from MD Anderson indicated that prognosis is very poor for patients with higher risk disease and hypomethylating failure with a median survival of less than 5 months⁽¹¹⁾. The survival of patients with lower risk disease and hypomethylating failure is less than 17 months⁽¹¹⁾. In general, this group of patients is refractory to most conventional antileukemia agents available, such as cytarabine. These patients should be treated with investigational new agents or be considered for alloSCT as soon as possible. Agents currently being studied include nucleoside analogues (clofarabine and sapacitabine) and the multikinase inhibitor ON1910. Following encouraging pilot data, a phase II randomized trial of ON1910 versus best standard of care (2:1) in patients with MDS and failure of hypomethylation therapy showed a trend for survival benefit with ON1910 (median survival 8.5 vs 5.5 months; $P = .08$), which was significant in the subsets of patients with primary resistance to hypomethylating agent therapy or with higher risk MDS⁽¹¹⁵⁾. Additional studies of ON1910 in MDS are under consideration. Other investigational agents of interest include vosaroxin (topoisomerase inhibitor), volasertib (polo-like kinase inhibitor), omacetaxine, checkpoint inhibitors (eg, PD-1 and PDL1 inhibitors), ACE11, and others.

Hesham M. Amin

INTRODUCTION

The field of myeloproliferative disorders (MPDs) has evolved considerably since the sentinel observations made by William Dameshek in 1951. He had commented in an editorial in the journal *Blood*: “To put together such apparently dissimilar diseases as chronic granulocytic leukemia, polycythemia, myeloid metaplasia and di Guglielmo’s syndrome may conceivably be without foundation, but for the moment at least, this may prove useful and even productive. What more can one ask of a theory?” (1).

The central feature among the MPDs is effective clonal myeloproliferation without dysplasia. Other features shared by most MPDs include involvement of a multipotent hematopoietic progenitor cell, marrow hypercellularity, predisposition to thrombosis, hemorrhage, and marrow fibrosis, and more recently, mutations in different tyrosine kinases (TKs), for example, JAK2 (Janus kinase 2), platelet-derived growth factor receptor (PDGFR), and KIT (2-5). When the concept of MPDs was first proposed, it consisted of five disorders: chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIMF), and erythroleukemia. Over the years, erythroleukemia was reclassified under acute myeloid leukemia (AML). The remaining four (CML, PV, ET, CIMF) are recognized as classic MPDs.

The World Health Organization (WHO) 2001 classification assigned the classic MPDs to a broader category of chronic MPDs that also included atypical MPDs, namely, chronic neutrophilic leukemia (CNL),

chronic eosinophilic leukemia/hypereosinophilic syndrome (CEL/HES), and chronic MPD, unclassifiable (MPD-U). The MPDs were, in turn, classified among one of the five categories of myeloid neoplasms, the others being: (1) AML, (2) myelodysplastic syndromes (MDS), (3) MDS/MPD, and (4) mast cell disease (MCD).

In the revised 2008 WHO classification system for chronic myeloid neoplasms, the phrase *disease* in both MPD and MDS/MPD has been replaced by *neoplasm*, reflecting the neoplastic nature of these conditions, so that MPD is now referred to as myeloproliferative neoplasm (MPN) (6). In addition, MCD is now included within the MPN category (Table 6-1). Also, CIMF has recently been renamed as primary myelofibrosis (PMF). Chronic myelogenous leukemia, characterized by the reciprocal translocation of chromosomes 9 and 22, is discussed elsewhere. Here, we discuss classic MPNs, as well as CEL/HES, CNL, and MCD, for which important advances have been made, both in the understanding the disease pathology and in clinical management.

POLYCYTHEMIA VERA

Polycythemia vera is a clonal disorder characterized by an accumulation of phenotypically normal red cells, granulocytes, and platelets. The word *polycythemia* is composed of the Greek words *poly* (“many”), *cyt* (“cells”), and *hemia* (“blood”), indicating too many blood cells (red, white, and platelets). The term *vera* is from the Latin word meaning true, making a distinction between PV and a host of other conditions that

Table 6-1 2008 World Health Organization Classification Scheme for Myeloid Neoplasms

1.	Acute myeloid leukemia
2.	Myelodysplastic syndromes (MDS)
3.	Myeloproliferative neoplasms (MPNs)
	3.1 Chronic myelogenous leukemia
	3.2 Polycythemia vera
	3.3 Essential thrombocythemia
	3.4 Primary myelofibrosis
	3.5 Chronic neutrophilic leukemia
	3.6 Chronic eosinophilic leukemia, not otherwise categorized
	3.7 Hypereosinophilic syndrome
	3.8 Mast cell disease
	3.9 MPNs, unclassifiable
4.	MDS/MPN
	4.1 Chronic myelomonocytic leukemia
	4.2 Juvenile myelomonocytic leukemia
	4.3 Atypical chronic myeloid leukemia
	4.4 MDS/MPN, unclassifiable
5.	Myeloid neoplasms associated with eosinophilia and abnormalities of PDGFRA, PDGFRB, or FGFR1
	5.1 Myeloid neoplasms associated with PDGFRA rearrangement
	5.2 Myeloid neoplasms associated with PDGFRB rearrangement
	5.3 Myeloid neoplasms associated with FGFR1 rearrangement (8p11 myeloproliferative syndrome)

can result in an increase in the number of red blood cells. The main feature of the disease is elevated red cell mass (RCM) associated with predisposition to thrombosis. Polycythemia vera occurs mainly in older adults. In a large observational study of 1,638 patients with PV, median age at diagnosis was 62.1 years, and only 4% of patients were younger than 40 years (⁷). The median survival is long, approximately 20 years (although inferior to the general population).

The JAK2–signal transducers and activators of transcription (JAK2-STAT) pathway has been known to play an important role in hematopoiesis, which is mediated in part by erythropoietin (Epo) and thrombopoietin (Tpo) via their cognate receptors. In 2005, four different groups identified an activating mutation in the *JAK2* gene in up to 97% of patients with PV (²⁻⁵). The JAK proteins are bound to the cytoplasmic domains of type I cytokine receptors (eg, the Epo and Tpo receptors), and the binding of cytokines or growth factors

(eg, Epo and Tpo) to the receptors induces dimerization and phosphorylation of the JAKs. The activated JAK then phosphorylates the cytoplasmic domains of the cytokine receptors. STATs bind to these phosphorylated receptor sites and in turn are phosphorylated by the JAKs. These phosphorylated and activated STAT molecules regulate the transcription of the target genes in the nucleus. JAK2 has two domains: JH1 (the active kinase domain) and JH2 (pseudokinase domain: inhibits kinase activity of JAK2). The most common mutation in PV is a guanine-to-thymine substitution in exon 14, resulting in a valine-to-phenylalanine substitution at position 617 (JAK2V617F). This gain of function mutation, which renders JAK2 constitutively active, results in Epo-independent proliferation of erythroid precursors. The pathologic nature of this mutation has been illustrated by many studies. Mice that receive bone marrow (BM) cells expressing the JAK2 mutation develop erythrocytosis (³). In contrast to wild-type JAK2, mutated JAK2 allows for the Epo-independent growth of cell lines in culture (³⁻⁵). The JAK2V617F mutation is present in approximately 95% to 97% of patients with PV and is not present in secondary polycythemia. Mutations in exon 12 of *JAK2* have been identified in the remaining patients with PV who are negative for JAK2V617F mutation (⁶). Therefore, with current sensitive testing, almost all patients with PV should have mutations in either exon 14 or exon 12 of *JAK2*.

Clinical Features

Presenting constitutional symptoms (seen in 30%-50% of patients) include headache, weakness, pruritus, fatigue, dizziness, and sweating. Thrombosis and hemorrhage due to increased blood viscosity and reduced blood flow are the most common serious complications. Mild splenomegaly is seen in up to 70% of patients. Mild leukocytosis can occur with PV, as can thrombocytosis. Thrombocytosis can lead to ocular migraine and erythromelalgia (burning pain in feet or hands associated with warmth and erythema). Some patients are asymptomatic and are diagnosed after abnormal findings on a routine blood examination. The BM is typically hypercellular with megakaryocyte pleomorphism. In the polycythemia vera study group (PVSG01) study, cellularity of the pretreatment BMs (n = 281) ranged from 36% to 100% (mean 82%), with absence of stainable iron in 94% of the patients (⁹). Cytogenetic abnormalities are infrequent. In two large retrospective studies of patients with PV (n = 137 and n = 133), cytogenetic studies were abnormal in 11% to 14% (trisomy 8 being the most common) and had no impact on either thrombosis risk or survival (^{10, 11}).

Thrombosis and Bleeding

Thrombosis is the most serious complication of PV (Table 6-2) and is a presenting manifestation in 15% to 20% of patients^(9, 12). In a large study of 1,213 patients with PV, thrombosis (both arterial and venous) occurred in 41% of patients overall (64% of thrombotic events were at presentation or before diagnosis and 36% during follow-up)⁽¹²⁾. In a more recent study of 1,545 patients diagnosed using 2008 WHO diagnostic criteria, thrombosis occurred in 23% of patients before diagnosis and in 21% during follow-up^(13, 14). Arterial thrombosis is more common overall than venous thrombosis. Ischemic stroke and transient ischemic attacks account for a majority of arterial thromboses at diagnosis^(12, 13). The overall rate of thrombotic events was estimated to occur in 2.6% to 4.4% of patients per year^(12, 13, 15). The rate of thrombotic events increases with age (1.8/100 patients per year for those in the <40 year age group to 5.1/100 patients per year for those >70 years)⁽¹²⁾. Older age and a previous history of thrombosis have been established as risk factors for thrombosis^(12, 13). In the PVSG studies, one-third of the individuals who survived the initial thrombotic event had recurrent thrombosis⁽¹⁶⁾. Budd-Chiari syndrome (BCS) can be a presenting manifestation of PV. PV is the underlying cause in 50% of patients with BCS⁽¹⁷⁾, and JAK2 mutation has been found in 40% to 58% of patients with BCS⁽¹⁸⁾.

The development of myelofibrosis (MF; called post-PV MF) and AML are the two major late complications of PV. Post-PV MF develops in 10% to 20% of patients with PV and is characterized by clinical features similar to PMF (anemia, cytopenias, leukoerythroblastosis, and progressive splenomegaly). Trisomy 1q is the most common chromosomal abnormality in post-PV MF. A longer disease duration (>10 years) is associated with a 15-fold higher risk of transformation to MF ($P < .0001$)⁽¹⁵⁾. Passamonti et al reported outcomes on a series of 647 patients with PV; 68 patients developed MF after a median of 13 years⁽¹⁸⁾. The median survival for post-PV MF was 5.7 years⁽¹⁹⁾. In the Efficacy and Safety of Low-Dose Aspirin and Polycythemia Vera (ECLAP) study, 22 of the 1,638 patients (1.3%) developed AML after a median of 8.4 years from the diagnosis of PV. Older age and exposure to chemotherapy (³²P, busulfan, and pipobroman; $P = .002$), but not hydroxyurea (HU) alone, was associated with an increased risk of AML⁽⁷⁾. In a prospective study of 338 patients, 8 developed MF and 10 developed AML after a median of 3.2 years. JAK2V617F allele burden was significantly related to the risk of developing MF but not AML⁽²⁰⁾.

The most common fatal complication in PV is thrombosis, accounting for 19% to 31% of deaths during follow-up (see Table 6-2). In a study of 1,213 patients, the most frequent fatal complications were thrombosis

(30%) and cancer (15% AML, 15% other cancers)⁽¹²⁾. In the ECLAP study ($n = 1,638$), the most common causes of death were cardiovascular diseases, AML, and solid tumors in 45%, 13%, and 19.5%, respectively⁽¹⁵⁾. In the International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) IWG-MRT study ($n = 1,545$), the most common causes of death were cancer (22% AML, 22% other cancers) and thrombotic complications (19.5%). As is the case with thrombotic risk, older age and history of thrombosis were associated with increased mortality⁽¹⁵⁾. Leukocytosis (white blood cell [WBC] count $>15 \times 10^9/L$) at diagnosis of PV has been correlated with an increased risk of thrombosis (especially myocardial infarction)⁽²¹⁾, leukemic transformation⁽²²⁾, development of post-PV MF⁽¹⁹⁾, and worse survival⁽²²⁾. In a prospective study of 338 patients with PV, only age greater than 60 had a significant effect on thrombosis risk or survival; neither leukocytosis (WBC count $>11 \times 10^9/L$) nor the JAK2V617F allele burden correlated with the risk of thrombosis⁽²⁰⁾, but JAK2V617F allele burden was associated with transformation to MF. A study from the IWG-MRT suggested a new prognostic model using data from 1,545 patients with PV⁽¹⁴⁾. The final model included age (57-66 or ≥ 67), leukocytosis ($\geq 15 \times 10^9/L$), or venous thrombosis as independent predictors of worse survival. Independent risk factors for shorter leukemia-free survival included age greater than 61 years, abnormal karyotype, and leukocyte count $\geq 15 \times 10^9/L$. Previous arterial thrombosis and hypertension were associated with an increased risk of arterial thrombosis, while previous venous thrombosis and age of 65 or older were risk factors for venous thrombosis⁽¹³⁾.

Diagnosis

As our understanding of PV has improved with development of newer molecular markers such as JAK2 mutation, so have the diagnostic criteria for PV (Table 6-3). As JAK2V617F or similar activating mutations, such as exon 12 mutations, are present in almost 100% of patients with PV, the 2008 WHO classification appropriately incorporated JAK2 mutation as a major criterion for the diagnosis of PV. Compared to the PVSG criteria, for which RCM measurement was mandatory, the WHO criteria have placed less reliance on direct RCM measurement and established hemoglobin (Hb) cutoffs (Hb >18.5 g/dL in men or Hb >16.5 g/dL in women; Hb >17 g/dL in men and >15 g/dL in women if associated with a documented and sustained increase of at least 2 g/dL from an individual's baseline value that cannot be attributed to correction of iron deficiency) for diagnostic purposes. This view is not universally held, and some experts still advocate use of direct RCM measurement⁽²³⁾. For patients suspected to have PV (based on elevated Hb/hematocrit [Hct], presence of

^aData from Passamonti F, Brusamolino E, Lazzarino M, et al. Efficacy of pipobroman in the treatment of polycythemia vera: long-term results in 163 patients, *Haematologica* 2000;85(10):1011-1018.

Table 6-3 2008 World Health Organization Diagnostic Criteria for Polycythemia Vera

Major criteria
• Hb >18.5 g/dL in men or Hb >16.5 g/dL in women or other evidence of increased red cell volume
• Presence of JAK2V617F or other functionally similar mutations, such as JAK2 exon 12 mutation
Minor criteria
• Bone marrow biopsy showing hypercellularity for age with panmyelosis with prominent erythroid, granulocytic, and megakaryocytic proliferation
• Serum erythropoietin level below the reference range for normal
• Endogenous erythroid colony formation in vitro
Diagnosis: Both major criteria with one minor or first major with any two minor criteria

Reproduced with permission from Tefferi A, Thiele J, Orazi A, et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. *Blood*. 2007;110(4):1092-1097.

symptoms or thrombotic/hemorrhagic complications), initial evaluation should include an analysis of peripheral blood for the JAK2 mutation and measurement of serum EPO (Fig. 6-1). As red cell proliferation is autonomous in PV, serum Epo is generally low, and erythroid colonies can grow in vitro without the addition of exogenous Epo.

FIGURE 6-2 Bone marrow biopsy from a patient with PV shows remarkable hypercellularity because of myeloid hyperplasia and markedly increased megakaryocytes. Although morphologically some of the megakaryocytes demonstrate slight size variations, most of the megakaryocytes are unremarkable (x200).

For patients who have not received prior chemotherapy, the endogenous (Epo-independent) erythroid colony formation test has sensitivity and specificity approaching 100%; however, the test is not commercially available. Classical morphologic features seen in BM biopsies in PV and post-PV MF are shown in Figs. 6-2 to 6-4.

FIGURE 6-3 Extensive bone remodeling and osteosclerosis are occasionally encountered features in bone marrow biopsies during the postpolycythemic myelofibrosis phase of PV ($\times 40$).

TREATMENT

The main goal of therapy is to prevent thrombotic events. The cornerstone of therapy is phlebotomy. This was established by the PVSG01 trial, in which patients were randomized to phlebotomy alone, phlebotomy plus chlorambucil, or phlebotomy plus ^{32}P . The incidence of thrombosis during the first 2 years of the trial was significantly higher in the phlebotomy arm (23%) than in the ^{32}P arm (16%). However, median survival

FIGURE 6-4 In contrast to the relatively normal megakaryocytes seen during early stages of PV, megakaryocytes become markedly atypical during postpolycythemic myelofibrosis phase. The atypical morphologic features include pronounced size variations, usually because of the presence of numerous small forms. Classically, megakaryocytes nuclei become hyperchromatic during this advanced stage of PV ($\times 200$).

was significantly higher in the phlebotomy only arm (12.6 years vs 10.9 years in the ^{32}P arm and 9.1 in the chlorambucil arm). In addition, the AML risk was 1.5%, 9.6%, and 13.2% in the phlebotomy only, ^{32}P , and chlorambucil arms, respectively. The incidence of MF was similar in all three arms. Given the increased risk of AML and reduced survival in the chlorambucil arm, further use of chlorambucil in PV was abandoned. The desired goal of phlebotomy is to reduce the Hct to 45% or less for males and 42% or less for females. Regular phlebotomy also induces iron deficiency, which has not been shown to be detrimental in the absence of anemia. Patients with PV who become iron deficient due to phlebotomy use should not receive iron supplementation.

The use of high-dose aspirin (acetylsalicylic acid, ASA) (900 mg daily), initially studied by PVSG, was found to increase the risk of gastrointestinal bleeding and was not pursued further (24). Low-dose ASA was proposed as an alternative after it was discovered that thrombosis in PV is mediated in part by increased thromboxane synthesis (25), and that low-dose ASA can effectively suppress its production. In the ECLAP study, Landolfi et al randomized 518 patients with PV to low-dose ASA (100 mg daily) or placebo (26). All patients had been previously treated with phlebotomy, cytoreductive therapy, or both. The use of ASA resulted in a 60% reduction in the risk of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, and death from cardiovascular causes ($P = .03$). Overall mortality, cardiovascular mortality, major venous thrombosis, and pulmonary embolism were not statistically different between the two groups. Major cerebrovascular events were less frequent in the low-dose ASA group, but the difference was not significant (3.8 vs 1.2%; $P = .08$). The incidence of major bleeding episodes was not significantly increased in the low-dose ASA group. A subgroup analysis indicated that ASA was more effective in patients with a disease duration of 5 years or less, platelet count less than $334 \times 10^9/\text{L}$, and Hct of 48% or greater and those who had not been treated with cytoreductive therapy. The median Hct achieved during the study was 46%, higher than the recommended targets for PV, leading to the argument that effective Hct control may lessen the beneficial effects of ASA. A recent meta-analysis from the Cochrane Hematological Malignancies Group in 630 patients with PV randomized to low-dose ASA versus placebo found nonsignificant lowering of fatal thrombotic events (odds ratio [OR] 0.20, 95% confidence interval [CI], 0.03-1.14), without excess major bleeding (27). They predicted that 19 fatal thrombotic events will be prevented for every 1,000 people treated with ASA. Therefore, all patients with PV should receive low-dose ASA unless contraindicated.

Target Hct values (<45% for men, <42% for women) for patients treated with phlebotomy or cytoreductive therapy were based on a retrospective study showing that thrombotic events increased at Hct levels greater than 44%⁽²⁸⁾. The CYTO-PV trial then evaluated the benefit of maintaining stringent control of Hct (target Hct <45%). The study randomized 365 patients with PV treated with phlebotomy or HU into two arms: one with a target Hct less than 45% and another with a target Hct between 45% and 50%⁽²⁹⁾. Patients with tight control of Hct (<45%) had a significantly lower rate of major thrombosis and death from cardiovascular causes. Hydroxyurea is the preferred cytoreductive therapy for PV patients; however, resistance or intolerance can develop in up to 13% of patients⁽³⁰⁾. Aggressive chemotherapy is not recommended. In a large study with 1,213 patients, the risk of death due to cancer was four times higher in patients who had received ³²P or myelosuppressive (alkylating or nonalkylating) agents compared with those receiving phlebotomy or other pharmacological treatments (6.7% vs 1.6%; $P = .06$), supporting PVSG01 data⁽¹²⁾. Similarly, in a study of 1,545 patients, exposure to pipobroman or P³²/chlorambucil was associated with leukemic transformation, while exposure to HU or busulfan was not⁽¹⁴⁾. In a population-based study from Sweden, exposure to two or more cytoreductive treatments (commonly HU followed by alkylating agents) was associated with a 2.9-fold increased risk of transformation to AML. However, exposure to HU alone, even at the highest dose levels, was not significantly associated with an increased risk of AML⁽³¹⁾.

Interferon alpha (IFN- α), has been reported to be effective at suppressing erythrocytosis in 82% of patients, with a similar number reporting reduction in spleen size and alleviation of pruritus⁽³²⁾. Interferon alpha is not teratogenic, making it the cytoreductive therapy of choice in pregnancy. It is also nonleukemogenic⁽⁷⁾. However, up to one-third of patients discontinue treatment due to side effects (fever, malaise, and depression).

Longer-acting pegylated forms of IFN- α (PEG-IFN- α -2a) have also been studied. Kiladjan et al reported the results of a phase II multicenter French study of PEG-IFN- α -2a in 40 patients⁽³³⁾. At 12 months, all 37 evaluable patients had a hematologic response, including 94.6% complete hematologic responses (CHRs), the study end point. Sequential samples tested for JAK2V617F allele burden in 29 patients showed a decrease in 26 (90%). Complete molecular response (CMR; undetectable JAK2V617F) was achieved in seven (24%) patients. Similar results were reported from another phase II study of 40 patients treated with PEG-IFN- α -2a⁽³⁴⁾. The overall hematologic response was 80%; the CHR was 70%. Of 35 patients evaluable for JAK2V617F allele burden, 54% showed a reduction

and 14% achieved a CMR. After a median time on treatment of 42 months, 76% of patients had achieved a CHR and 18% a CMR⁽³⁵⁾. A newer, longer-acting form of pegylated IFN- α (PEG-proline-IFN- α -2b), which allows for subcutaneous dosing every 2 weeks, is being tested in Europe in a randomized phase III trial against HU.

The oral JAK1/2 inhibitor ruxolitinib was approved by the Food and Drug Administration (FDA) for the treatment of myelofibrosis in 2011 and for PV in December 2014, based on the results of a randomized phase III clinical trial. In the phase II trial, 34 patients refractory to HU were treated with ruxolitinib; 97% had rapid and durable normalization of Hct (<45%) by week 24. After a median follow-up of 35 months, 59% had achieved a CR⁽³⁶⁾. Responses were defined by European Leukemia Network criteria established in 2009: A CR was defined as normalization of Hct (<45% males, <42% females), leukocyte counts, platelets, and spleen size in the absence of phlebotomies and thrombotic events. There was rapid and sustained normalization of WBC and platelet counts, reduction in spleen size, and improvement in systemic symptoms (pruritus, bone pain, night sweats). Five patients experienced grade 3 or higher anemia or thrombocytopenia. The pivotal phase III RESPONSE trial randomized patients refractory to, or intolerant of, HU requiring therapy to receive either ruxolitinib 10 mg twice daily ($n = 110$) or best-available therapy (BAT; $n = 112$)⁽³⁷⁾. Twenty-one percent of patients in the ruxolitinib arm achieved the primary end point (Hct control without phlebotomy and a $\geq 35\%$ reduction in spleen volume from baseline by magnetic resonance imaging at week 32) versus 1% in the HU arm. Overall, 77% of patients in the ruxolitinib group achieved one or more of the criteria for the primary end point, and 49% (vs 1% of BAT patients) had a 50% or greater improvement in the MPN-Symptom Assessment Form total symptom score, a validated measure of patient-reported symptoms⁽³⁸⁾. Ninety-six patients crossed over to the ruxolitinib arm after week 32. Grade 3/4 anemia or thrombocytopenia occurred in 1.8% and 5.5% of patients, respectively, compared with 0% and 3.6% of BAT patients, respectively. Ruxolitinib has been approved as therapy for PV after resistance to or intolerance of HU.

Treatment Conclusions

All patients with PV should undergo phlebotomy and receive low-dose ASA unless contradicted. Patients who are at high risk for thrombosis (age >60 years or history of thrombosis) should receive cytoreductive therapy (HU preferred; IFN- α can be considered, especially PEG-IFN- α -2a, in younger patients). The goal Hct is 45% or less for males and 42% or less for females.

With the approval of ruxolitinib for PV, patients resistant or intolerant to HU should be offered ruxolitinib, a JAK2 inhibitor.

ESSENTIAL THROMBOCYTHEMIA

Essential thrombocythemia is characterized by persistent thrombocytosis with a predisposition to thrombosis and bleeding. Essential thrombocythemia is not a cytogenetically or a morphologically defined disease entity and remains a diagnosis of exclusion. It is a disease of the elderly; the median age of diagnosis is 55 to 60 years. The female-to-male ratio is 2:1.

Reactive causes of thrombocytosis should be excluded. Most often, the underlying cause is apparent (postsplenectomy, acute infection, blood loss). Other MPNs, such as PV or CML, can also present with thrombocytosis and should be ruled out. In a population-based study (ages 18 to 65 years), 99 of the 9,998 persons studied (1%) had a platelet count greater than $400 \times 10^9/L$ at baseline, of whom only 8 (0.1% of the population studied) had persistent thrombocytosis at greater than 6 months⁽³⁹⁾. Three of the eight patients were confirmed to have ET at baseline, with one additional case of ET diagnosed after 5 years of follow-up. In another study of 732 patients with thrombocytosis ($>500 \times 10^9/L$), ET was present in 5.5% and reactive thrombocytosis in 87% patients⁽⁴⁰⁾. The magnitude of elevation in the platelet count does not distinguish between reactive and clonal thrombocytosis. In 280 consecutive patients with extreme thrombocytosis (platelet count >1 million), reactive thrombocytosis was noted in 82%, and 14% had MPNs, including ET in 4%⁽⁴¹⁾. Reactive thrombocytosis, irrespective of the degree of elevation of platelet counts, does not increase the risk of thromboembolic or bleeding complications. Such complications, if seen, are the results of underlying disease conditions (malignancy, iron deficiency from gastrointestinal bleeding) rather than of elevated platelets.

Pathophysiology

Thrombopoietin regulates the differentiation and proliferation of megakaryocytes. It is produced primarily by the liver parenchymal cells. The gene for Tpo is located on chromosome 3q27-28. It binds to the c-Mpl receptors on platelets and megakaryocytes. When the platelet count is low, more free Tpo is available to bind to megakaryocytes to stimulate proliferation, leading to a rise in the platelet count and vice versa. In most cases of reactive thrombocytosis, Tpo is increased via acute phase reactants, such as interleukin 6. Unlike PV, for which Epo levels are generally low, Tpo levels are high normal or abnormally increased in ET⁽⁴²⁾. This

may be due to the increased BM stromal production of Tpo or decreased clearance, as expression of platelet c-Mpl is markedly reduced in ET⁽⁴²⁾. Approximately 50% of patients with ET harbor the JAK2V617F mutation, and 3% to 5% have a mutation in the thrombopoietin receptor (MPL) (W515L/K; tryptophan to leucine or lysine substitution at residue 515)⁽⁴³⁾, both of which lead to dysregulated JAK-STAT signaling. Most patients with ET have JAK2V617F allele burdens less than 50%, suggesting that lower JAK2V617F gene dosage may lead to the development of ET versus PV, for which the allele burden is generally higher⁽⁴⁴⁾.

Recently, mutations in the gene encoding calreticulin (CALR) have been found in nearly 70% of patients with ET negative for JAK2 or MPL mutations (~25% of all patients with ET)^(45, 46). The CALR mutation may define a distinct subset of ET. In a series of 717 patients with ET, those with CALR mutations were younger and predominantly male and had a lower incidence of thrombosis, lower hemoglobin levels, lower leukocyte counts, and higher platelet counts than those with the JAK2V617F mutation⁽⁴⁷⁾. Additional studies are needed to fully elucidate the implications of molecular studies in clinical practice.

Clinical Features

With the increasing use of automated blood counters and routine blood count screenings, more patients with ET are being diagnosed while asymptomatic. Constitutional symptoms are uncommon in ET. Vasomotor manifestations such as dizziness, lightheadedness, acral paresthesia, livedo reticularis, and erythromelalgia were noted in 34% of patients in one study of 147 patients with ET⁽⁴⁸⁾. Mild splenomegaly (<5 cm) was noted in up to 40% of patients, leukocytosis in 30% to 40%, and mild anemia in 10% to 20%. Thromboembolic and bleeding complications are the major cause of morbidity and mortality in ET. A series of 322 patients with ET from one institution reported a 26% incidence of major thrombosis and 11% incidence of major bleeding at diagnosis⁽⁴⁹⁾. Hemorrhagic complications increase with extreme thrombocytosis (platelet count >1.5 million/ μL) and with the use of antiplatelet therapy such as ASA.

Most serious late complications of ET include transformation to AML and MF (post-ET MF). In a study of 605 patients with ET, the incidence of AML transformation was 3.3%, with a median time to transformation of 11.5 years⁽⁵⁰⁾. Risk factors for transformation included anemia, platelet count greater than $1,000 \times 10^9/L$, and increasing age. JAK2 mutational status or the type of therapy (including HU) did not influence the risk of leukemic transformation. In another series of 195 patients with ET, the median time to transformation to MF was 8 years, with an actuarial probability

of 2.7% at 5 years, 8.3% at 10 years, and 15.3% at 15 years⁽⁵¹⁾. In a large series from seven centers in Europe, patients were reclassified using 2008 WHO criteria⁽⁵²⁾. The diagnosis of ET was confirmed in 891 patients and revised to early/prefibrotic MF in 180 patients. Among patients with ET, the incidence of transformation to AML and MF was 1% and 4%, respectively. The 15-year cumulative incidence of transformation to AML or MF was 2.1% and 9.3%, respectively. In another series of 576 patients with ET, the cumulative incidence of AML was 3.8% and of transformation to MF was 9.5%⁽⁵³⁾.

Diagnosis

Essential thrombocythemia remains a diagnosis of exclusion. Reactive thrombocytosis must be excluded. An important change in the 2008 WHO classification was lowering the platelet count for ET diagnosis from $600 \times 10^9/L$ to $450 \times 10^9/L$ (Table 6-4). Bone marrow biopsy is mandatory for diagnosis to rule out PMF and MDS/MPN. A BM biopsy typically shows large but mature-appearing megakaryocytes with deeply lobulated or hyperlobulated nuclei (Fig. 6-5). The peripheral smear is significant for markedly increased platelets (Fig. 6-6). Reticulin staining should be done to rule out any underlying fibrosis. The presence of megakaryocytic dysplasia in the BM biopsy suggests “prefibrotic” MF, which implies a higher risk of transformation to overt MF or AML⁽⁵²⁾. Chronic neutrophilic leukemia should be ruled out by testing for the *Bcr-Abl* fusion gene. Testing for the JAK2, MPL, or CALR mutations is recommended to establish the clonal nature of the disease, ruling out reactive thrombocytosis (Fig. 6-7).

Table 6-4 2008 WHO Criteria for Diagnosis of Essential Thrombocythemia

1. Sustained platelet count $\geq 450 \times 10^9/L$
2. Bone marrow biopsy specimen showing proliferation mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis
3. Not meeting WHO criteria for PV, PMF, CML, MDS, or other myeloid neoplasm
4. Demonstration of JAK2V617F or other clonal marker, or in the absence of a clonal marker, no evidence for reactive thrombocytosis

Diagnosis of ET requires meeting all four criteria

Reproduced with permission from Tefferi A, Thiele J, Orazi A, et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. *Blood*. 2007;110(4):1092-1097.

FIGURE 6-5 Essential thrombocytosis is characterized by increased bone marrow cellularity, myeloid hyperplasia, and notably increased megakaryocytes ($\times 200$). The megakaryocytes in ET tend to display larger than normal size, and they also contain large hyperlobulated nuclei (inset; $\times 400$).

Prognosis

Like in PV, thrombosis and hemorrhage are the main complications of ET. Older age and history of prior thrombosis have been shown to predict for future thrombotic events in most studies, whereas cardiovascular risk factors have been predictive in only some. Platelet count does not correlate with risk of thrombosis in ET (Table 6-5). Some studies have found an inverse relationship between the platelet count and the thrombotic risk. This is thought to be due to acquired von Willebrand factor (vWF) disease with elevated platelet counts (eg, >1.5 million/ μL), predisposing to more bleeding and protection from thrombosis.

FIGURE 6-6 Peripheral blood smear from a patient with ET shows markedly increased platelets with scattered large forms ($\times 400$).

Classification and diagnosis of myeloproliferative neoplasms: the 2008 World Health Organization criteria and point-of-care diagnostic algorithms. *Leukemia*. 2008;22:14-22.)

Recent studies from the IWG-MRT of a series of 891 patients, from seven centers in Europe diagnosed with ET using 2008 WHO criteria, reported a 6% incidence of major bleeding at a rate of 0.79 patients/year⁽⁵⁴⁾. The incidence of thrombosis (fatal and non-fatal events) was 25% at a rate of 1.9% of patients/year^(52,55). The rate of nonfatal arterial events (1.2% of patients/year) was higher than that of venous events (0.6% patient/year)⁽⁵⁵⁾. Factors independently associated with bleeding included previous hemorrhage and ASA therapy⁽⁵⁴⁾. Factors independently associated with major thrombosis included age greater than 60 years; cardiovascular risk factors (diabetes, hypertension, or smoking); previous thrombosis; and JAK2V617F mutation⁽⁵⁵⁾. Leukocytosis ($>11 \times 10^9/L$) was an additional independent risk factor for arterial thrombosis; male gender increased the risk of venous thrombosis. Extreme thrombocytosis (platelet count $>1,000 \times 10^9/L$) was independently associated with a reduced risk of arterial thrombosis⁽⁵⁵⁾. This is thought to be due to acquired vWF disease with elevated platelet counts, predisposing to more bleeding and protection from thrombosis, which is consistent with previous reports showing an inverse relationship between platelet count and thrombotic risk⁽⁵⁶⁾.

Using these risk factors, a new prognostic model was proposed to predict risk of thrombosis in patients with ET (International Prognostic Score of Thrombosis in Essential Thrombocythemia [IPSET-Thrombosis])⁽⁵⁷⁾.

The prognostic score assigned weights to the four risk factors, and the patients could be stratified in three risk categories, with an annual risk of thrombosis ranging from 1.03% of patients/year for the low-risk group to 3.56% of patients/year for the high-risk group (Table 6-6).

Data from the same cohort of patients were used to develop a new possible score to predict overall survival at diagnosis (IPSET)⁽⁵⁸⁾. The final prognostic score included age 60 years or greater, leukocyte count $11 \times 10^9/L$ or greater, and prior thrombosis as independent risk factors for survival (see Table 6-6). The model stratified patients into three risk categories with median survival ranging from more than 25 years in the low-risk group to 14.7 years for the high-risk group. While the JAK2V617F mutation was associated with increased thrombosis risk⁽⁵²⁾, it was not predictive of survival, which was consistent with findings from other studies⁽⁵³⁾. In another study, JAK2V617F was identified as an independent predictor of pregnancy complications⁽⁵⁹⁾. Cytogenetic abnormalities are uncommon in ET ($<10\%$ at diagnosis) and have not been correlated with survival or transformation risk⁽⁶⁰⁾.

Treatment

The goal of therapy in ET is to prevent the major cause of morbidity and mortality: thromboembolic events.

Table 6-5 Risk Factors for Thrombosis in ET Patients

Risk Factors Studied								
Study	No. of Patients	Age >60 Years, Odds Ratio/Hazard Ratio/Significance Level	History of Thrombosis	Risk Factors for CV Events (Smoking, Diabetes, Hypertension, Hyperlipidemia)	Platelet Count >1,000 × 10 ⁹ /L	Leukocytosis	JAK-2 Status

Carobbio ⁽⁵⁶⁾	1,063	1.7 (age and previous thrombosis evaluated together)	1.7	–	Patients with WBC <11,000 and platelet <1,000: most likely to have JAK-2 mutation and highest risk of thrombosis			
Carobbio ⁽⁵⁵⁾	891	1.5	1.93	1.56	0.50	1.14	2.04	

NS, nonsignificant; (–), not studied.

Table 6-6 International Prognostic Score for Essential Thrombocythemia (IPSET) and IPSET-Thrombosis

Risk Factor	IPSET	IPSET-Thrombosis
Age >60 years	2	1
Previous thrombosis	1	2
WBC count $\geq 11 \times 10^9/L$	1	
Cardiovascular risk factors		1
JAK2V617F positive		2
Prognostic score (median survival or rate of thrombosis)		
Low	0 points (not reached)	<2 points (1.03% patients/y)
Intermediate	1-2 points (24.5 y)	2 points (2.35% patients/y)
High	3-4 points (14.7 y)	>2 points (3.56% patients/y)

As the majority of patients have a normal life expectancy, excess treatment that could cause potentially dangerous side effects should be avoided. Cardiovascular risk factors should be aggressively managed in all patients. Smoking was an important risk factor for thrombosis in many studies; all patients should be advised about smoking cessation. The two major classes of drugs used in ET are antiplatelet therapy and cytoreductive therapy (Table 6-7).

Antiplatelet Therapy

Antiplatelet therapy with ASA is useful in treating the microvascular symptoms of ET, especially erythromelalgia. The role of antiplatelet therapy in reducing thrombotic episodes in ET is less clear as no placebo-controlled, randomized trial is available. In a retrospective study, Van Genderen et al showed decreased thrombosis risk and improvements in microvascular symptoms with ASA monotherapy⁽⁶¹⁾. Extrapolating from the ECLAP study results in PV⁽²⁶⁾, the general consensus is to use low-dose ASA (75-100 mg daily) in patients with ET unless contraindicated by bleeding history. ASA also provides control of underlying ET-related systemic symptoms. Caution should be exercised in using ASA in patients with a very high platelet count ($>1500 \times 10^9/L$) due to the increased risk of bleeding from acquired von Willebrand disease⁽⁶²⁾. In the UK Medical Research Council Primary Thrombocythemia 1 (MRC PT-1) trial comparing HU and

Table 6-7 Treatment of Essential Thrombocythemia

Risk Category	Intervention
High risk (age <60 years or history of thrombosis)	Cytoreduction ^a and low-dose ASA
Intermediate risk (age <60 years and no history of thrombosis) with cardiovascular risk factors, especially smoking and/or platelet count $>1,000 \times 10^9/L$	Low-dose ASA (caution ASA use with extreme thrombocytosis; rule out von Willebrand disease first)
	Cytoreduction ^a if bleeding present; role of cytoreduction in absence of bleeding unclear
Low risk (age <60 years and no history of thrombosis)	Observation or low-dose ASA

^aCytoreduction: HU first choice; low-dose aspirin (ASA) indicated for microvascular symptoms for any risk group.

anagrelide in ET, all patients received antiplatelet therapy unless contraindicated⁽⁶³⁾. Possibly because of the synergistic effect of ASA with anagrelide, an increased risk of bleeding was noted in the anagrelide arm compared to HU. It has been suggested that low-dose ASA given twice a day may be effective in patients whose symptoms are not controlled with once-a-day dosing. A study with once-daily ASA found that most patients had incomplete inhibition of thromboxane A_2 , and that twice-daily dosing improved the response⁽⁶⁴⁾.

Cytoreductive Therapy

Hydroxyurea and anagrelide are the two main cytoreductive agents currently used in patients with ET. Hydroxyurea is a nonspecific, cytotoxic, and myelosuppressive drug. Anagrelide has a selective effect on megakaryocyte lineage. Two randomized studies in ET have established the role of HU. In the Italian study by Cortelazzo et al, 114 patients with high-risk ET (age >60 years, history of thrombosis, or both) were randomized to receive either placebo or HU, with a goal platelet count to less than $600 \times 10^9/L$ ⁽⁶⁵⁾. After a median follow-up of 27 months, 3.6% in the HU group had thrombotic episodes compared with 24% in the placebo group ($P = .003$). This study established the antithrombotic effect of HU in ET. Harrison et al reported concerning the UK MRC PT-1 study with 809 high-risk patients randomized to receive HU plus ASA or anagrelide plus ASA⁽⁶³⁾. The goal platelet count was less than $400 \times 10^9/L$. Anagrelide therapy was associated with higher rates of arterial thrombosis, serious

hemorrhage, or death from these complications but a lower rate of venous thrombosis compared with the HU arm. Serious hemorrhage with anagrelide was likely due to a synergistic effect with ASA. The risk of MF was significantly higher in the anagrelide arm (5-year risk 7% vs 2% in the HU arm), and significantly more patients in the anagrelide arm withdrew from the study because of side effects (22% vs 11%, $P = .001$). The risk of developing MDS/AML was similar in the two arms. Based on this trial, HU is now considered the standard first-line treatment in ET. However, the debate over the long-term safety of HU (especially potential leukemogenic risk) coupled with the recently reported ANA-HYDRET study showing noninferiority of anagrelide monotherapy compared with HU monotherapy have reignited the debate about the optimal first-line therapy in ET (⁶⁶).

Interferon alfa has been used to treat patients with ET, with a greater than 75% hematological response rate in various series. The average starting dose is 3 to 5 million units given subcutaneously daily or three times a week. Side effects (depression, flu-like symptoms) limit frontline use in ET. Because of its nonteratogenic nature, IFN- α is mainly used in pregnant women and women of childbearing age with high-risk ET.

Once-weekly PEG-IFN- α -2a has been evaluated in 39 patients (⁶⁴). A CHR (defined as normalization of platelet count in the absence of thromboembolic events) was noted in 76% of patients. Among 16 patients with serial samples available for testing JAK2V617F allele burden, 38% had some decrease in JAK2 allele burden; 6% achieved CMR. These results suggested PEG-IFN- α -2a may be useful in ET. An ongoing randomized trial is comparing PEG-IFN- α -2a versus ASA plus HU in patients with PV or ET (NCT01259856).

Special Issues

Management of Extreme Thrombocytosis (Platelet Count >1.5 Million/ μ L)

Aspirin should be avoided due to risk of bleeding secondary to acquired von Willebrand disease. The use of cytoreductive agents is suggested, especially when bleeding is present, to lower platelet counts and decrease the risk of bleeding. Many experts regard extreme thrombocytosis as a high-risk category and treat all such patients with cytoreduction; others reserve it for those with bleeding complications.

Management of Young Patients With Extreme Thrombocytosis

Ruggeri et al prospectively studied 65 asymptomatic patients who were younger than 60 years of age and with a platelet count less than $1,500 \times 10^9/L$ (⁶⁷).

No prophylactic cytoreduction was given, and ASA was used only for erythromelalgia symptoms. The risk of thromboembolic complications was found to be similar to the control population. The occurrence of pregnancy or minor surgical intervention was not associated with an increased risk of thrombosis. Cytoreductive therapy was needed in 27% of patients at a median of 34 months. Tefferi et al studied 74 young women (<50 years of age) with ET (⁶⁸). The risk of thrombosis and major hemorrhage was lower (7% at diagnosis and 18% at follow-up for thrombosis; 4% major hemorrhage at diagnosis and follow-up) than in the general ET population. Patients with a history of thrombosis had a 45% rate of subsequent thrombosis compared with 13% in those without prior thrombosis, indicating the need for cytoreduction with a history of thrombosis, even in younger patients. None of the 34 pregnancies in this study group was associated with a major thrombotic complication.

PRIMARY MYELOFIBROSIS

Primary myelofibrosis is a clonal disorder of a multipotent hematopoietic progenitor cell of unknown etiology; it is characterized by myeloid cell proliferation, megakaryocytic atypia, BM fibrosis, a leukoerythroblastic peripheral blood picture, extramedullary hematopoiesis (EMH), and splenomegaly. Primary myelofibrosis was previously called CIME, MF with myeloid metaplasia (MMM), or agnogenic myeloid metaplasia (AMM). The disease can occur either de novo or as a late complication of PV or ET. In either case, it manifests as progenitor cell-derived clonal myeloproliferation accompanied by intense marrow stromal reaction, including collagen fibrosis, osteosclerosis, and angiogenesis.

Pathophysiology

Fibrogenesis and angiogenesis are thought to develop consequent to the release of growth-promoting factors (such as vascular endothelial growth factor [VEGF], PDGF, basic fibroblast growth factor [bFGF] and transforming growth factor β [TGF- β]) from proliferating atypical megakaryocytes in the BM. The JAK2V617F mutation is found in 50% to 60% of patients with PMF. Persistent JAK-STAT signaling, resulting in the overproduction of proinflammatory cytokines, has been observed in all patients with PMF (^{69,70}). Proinflammatory cytokines have been associated with many of the symptoms of MF, including splenomegaly, transfusion dependence, thrombocytopenia, and shortened survival (⁷¹). Mutations in the thrombopoietin receptor (MPL) are found in 5% to 10% of patients, and CALR mutations in an additional 25% (^{45,46}). Rare inactivating

mutations in negative regulators of JAK-STAT signaling (eg, LNK, SOCS, and CBL) also contribute to the dysregulated JAK-STAT signaling in PMF (⁷²).

The exact contributions of mutations in JAK2, MPL, and CALR to disease pathogenesis remain unclear. Recent studies suggested that the heterogeneity of mutations in PMF may underlie the heterogeneity of its clinical phenotype; that is, these mutations may be associated with distinct clinical features. In a study of 617 patients with PMF, those with CALR mutations had a lower risk of anemia, thrombocytopenia, and leukocytosis (⁷³). In another series of 428 patients with PMF, CALR mutations were associated with younger age, lower leukocyte count, and higher platelet count, while MPL W515K/L mutations were associated with younger age and lower leukocyte count when compared with JAK2V617F mutations (⁵³). A number of other mutations have also been found in PMF, albeit at much lower frequencies than JAK2 and CALR mutations (eg, mutations in ASXL1, EZH2, SRSF2, CBL, IDH1/IDH2, TP53, TET2, and DNMT3) (⁷²). Unlike the JAK2/CALR/MPL mutations, which are mutually exclusive, the other less-frequent mutations may coexist with each other or with the three driver mutations.

Clinical Features

PMF is a heterogeneous disorder with variable age of onset, presenting features, phenotypic manifestations, and prognosis. The incidence of PMF increases with age. In a series of 1,054 patients, the median age at diagnosis was 64 years; 17% of patients were younger than 50 years and 5% younger than 40 years (⁷⁴). Clinical presentation can range from no or minimal symptoms, where disease is discovered during a workup for leukocytosis or splenomegaly, to severe symptoms. Severe fatigue is the most common presenting symptom. Constitutional symptoms (fatigue, weight loss, pruritus, low-grade fever, night sweats) are a prominent feature of PMF and can be debilitating. Myeloproliferation is one of the major features of the disease and can lead to sequestration of immature cells and production of blood cells in sites other than the BM, a phenomenon known as EMH. This commonly manifests as marked hepatosplenomegaly, with associated pain, early satiety, portal hypertension, and anemia and thrombocytopenia. Splenomegaly is present in 80% of patients and may extend into the pelvis. Hepatomegaly is seen in 40% to 70% of patients. EMH might cause symptoms in various other organs, leading to respiratory distress, pulmonary hypertension, ascites, pericardial tamponade, cord compression, and paralysis. Peripheral smear generally provides the first clue toward a diagnosis of PMF, with the presence of characteristic teardrop red cells and a leukoerythroblastic picture (presence of immature myeloid cells

including blasts in the peripheral blood). Progressive anemia generally develops, requiring transfusions. Some patients may present with leukocytosis and thrombocytosis; however, most develop leukopenia and thrombocytopenia in later stages of the disease. Among the most feared complications of PMF is transformation to AML, occurring in 10% to 20% of patients in the first 10 years from diagnosis. The outcome after transformation is poor, with a median survival of 5 months. Transformation to AML is the most common cause of death in MF, followed by MF progression without acute transformation, thrombosis, and cardiovascular complications, infection, bleeding, and portal hypertension.

Diagnosis

A diagnosis of PMF is made using the 2008 WHO criteria (see Table 6-8) (⁶). Symptoms such as splenomegaly, leukoerythroblastosis, anemia, poor quality of life, and BM megakaryocyte hyperplasia are suggestive of PMF. Marrow fibrosis by itself is not specific for a diagnosis of PMF. Various degrees of fibrosis are observed in other MPNs, and MDS with fibrosis must be excluded. Morphologic features of the BM during

Table 6-8 2008 WHO Criteria for Diagnosis of Primary Myelofibrosis (PMF)

Major criteria
1. Presence of megakaryocyte proliferation and atypia, usually accompanied by either reticulin and/or collagen fibrosis, or, in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased bone marrow cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (ie, prefibrotic cellular-phase disease)
2. Not meeting WHO criteria for PV, CML, MDS, or other myeloid neoplasm
3. Demonstration of JAK2617VF or other clonal marker (eg, MPL515WL/K) or, in the absence of a clonal marker, no evidence of bone marrow fibrosis due to underlying inflammatory or other neoplastic diseases
Minor criteria
1. Leukoerythroblastosis
2. Increase in serum lactate dehydrogenase level
3. Anemia
4. Palpable splenomegaly
Diagnosis of PMF requires meeting all three major criteria and at least two minor criteria

Reproduced with permission from Tefferi A, Thiele J, Orazi A, et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. *Blood*. 2007;110(4):1092-1097.

FIGURE 6-8 It is difficult to distinguish the prefibrotic (cellular) phase of PMF from other types of chronic myeloproliferative neoplasms based on morphological criteria alone. However, careful microscopic examination of the bone marrow biopsy usually reveals scattered atypical megakaryocytes with morphological criteria classical for PMF in the fibrotic phase. As shown, some of the megakaryocytes in this bone marrow biopsy are remarkably variable in size and shape and characteristically contain markedly hyperchromatic nuclei ($\times 200$).

the prefibrotic (cellular) phase of PMF are shown in Fig. 6-8, and those during the fibrotic phase are depicted in Figs. 6-9 to 6-11. Classical morphological features consistent with PMF and seen in the peripheral blood smear are demonstrated in Fig. 6-12. Bone marrow histology, especially megakaryocyte morphology,

FIGURE 6-9 During the fibrotic phase of PMF, bone marrow hematopoietic cellular elements tend to decrease in number with interstitial infiltration of the bone marrow by fibroblasts that leads to a streaming effect. Characteristically, the megakaryocytes demonstrate variability in size and shape, and megakaryocytes containing hyperchromatic and hyperlobulated nuclei are frequently encountered during the fibrotic phase of PMF ($\times 200$).

FIGURE 6-10 Another common feature of the bone marrow during the fibrotic phase is marked expansion of bone marrow sinusoids, which are usually rudimentary under normal conditions ($\times 100$). Hematopoietic cellular elements can be detected within the bone marrow sinuses; a megakaryocyte is shown, comprising what is known as intrasinusoidal hematopoiesis (inset; $\times 400$).

is a critical diagnostic criterion for PMF (Fig. 6-13). All patients suspected of having PMF should undergo bone marrow biopsy with reticulin and collagen staining and testing for JAK2V617F, CALR, and MPL mutations. Chronic myelogenous leukemia should be ruled out by testing for Bcr-Abl.

Prognosis

The median survival is 5 years. In a review of 1,054 patients with PMF, the median survival was 69 months (⁷⁴). Younger patients with good prognostic features may have a life expectancy exceeding 10 years. The most commonly used prognostic scoring systems are the International Prognostic Scoring System (IPSS), designed to be used at diagnosis, and the Dynamic IPSS (D-IPSS), which can be used at any point in the patient's disease course (^{74, 75}) (Table 6-9). Both prognostic scoring systems are based on clinical and laboratory characteristics: age (>65 years), constitutional symptoms (yes/no), hemoglobin (<10 g/dL), leukocyte counts ($>25 \times 10^9/L$), and circulating blasts ($\geq 1\%$). In the IPSS system, all factors are given a score of 1, while in the D-IPSS, hemoglobin below 10 g/dL is given 2 points. On the basis of these risk factors, patients are separated into four risk groups: low risk (0 points); intermediate-1 risk (1 point IPSS; 1-2 points D-IPSS); intermediate-2 risk (2 points IPSS; 3-4 points D-IPSS); and high risk (≥ 3 points IPSS; 5-6 points D-IPSS). Cytogenetic abnormalities are found in about half of the patients with PMF. Common abnormalities include del(13q), del(20q), trisomy 8 or 9, and abnormalities

FIGURE 6-11 During the fibrotic phase of PMF, the bone marrow is characterized by increased interstitial reticulin fibrosis (upper panel; $\times 100$), which might be associated with the abnormal presence of collagen fibers that are detected by trichrome staining (lower panel; $\times 200$).

of chromosome 1 [partial trisomy and $\text{der}(6)\text{t}(1;6)$] (⁷⁶). Tam et al analyzed 256 patients with PMF; 36% had chromosomal abnormalities (⁷⁷). They categorized patients into those with favorable cytogenetics (sole deletion of 13q or 20q, trisomy 9 +/- one other abnormality); diploid cytogenetics; unfavorable cytogenetics (abnormalities of chromosomes 5 or 7, or complex ≥ 3 cytogenetics); and very unfavorable cytogenetics (any abnormality of chromosome 17). The median survival times (for patients with assessment at diagnosis) were 63, 46, 15, and 5 months, respectively. Gangat et al added unfavorable karyotype, platelet count below $100 \times 10^9/\text{L}$, and transfusion dependence as independent risk factors for inferior survival in another prognostic model (DIPSS-plus) (⁷⁸).

Recent studies have explored the prognostic relevance of various mutations. In a study of 617 patients with PMF, CALR mutations were associated with longer survival (median 17.7 years) (⁷³). Patients without any mutation in JAK2, MPL, or CALR (“triple negative”) had a higher incidence of transformation to AML and a shorter survival (median 3.2 years). When the CALR, JAK2, and MPL mutations were added to the IPSS, patients could be further subdivided into five risk groups, with significantly different median survivals (⁷³). Another study of 428 patients with PMF reported similar findings (⁵³). Patients with CALR mutations had the longest survival (median 15.9 years), while patients without any of these mutations (triple negative) had the shortest survival (median 2.3 years) (⁵³). Mutations in epigenetic modulators (ASXL1, SRSF2, and EZH2) were associated with worse survival and increased risk of transformation to AML (⁷²). The negative prognostic impact of ASXL1 was shown in another series of 570 patients (⁷⁹). Patients who had ASXL1 mutations in the absence of CALR mutations had the worst survival (median 2.3 years). Future studies will explore further how to best implement the molecular information in everyday practice.

FIGURE 6-12 Careful examination of peripheral blood smears from patients with PMF usually reveals teardrop red blood cells (arrows, upper panel; $\times 400$). In addition, nucleated red blood cells (upper panel) and left-shifted granulopoiesis (lower panel; $\times 400$) are seen, two morphologic criteria collectively described as leukoerythroblastosis.

had a higher incidence of transformation to AML and a shorter survival (median 3.2 years). Classification and diagnosis of myeloproliferative neoplasms: the 2008 World Health Organization criteria and point-of-care diagnostic algorithms. *Leukemia*. 2008;22:14-22.)

Table 6-9 Prognostic Scoring Systems for Myelofibrosis

Factors	IPSS	D-IPSS	D-IPSS-plus
Age >65 years	1	1	1
Constitutional symptoms	1	1	1
Hemoglobin <10 g/dL	1	2	1
Leukocytes >25 × 10 ⁹ /L	1	1	1
Blood blasts ≥1%	1	1	1
Platelet count < 100 × 10 ⁹ /L			1
Transfusion dependence			1
Unfavorable karyotype			1
Risk stratification (median survival)			
Low	0 points (11.2 y)	0 points (not reached)	0 points (15.4 y)
Intermediate-1	1 point (7.9 y)	1-2 points (14.2 y)	1 point (6.5 y)
Intermediate-2	2 points (4 y)	3-4 points (4 y)	2-3 points (2.9 y)
High	≥3 points (2.3 y)	5-6 points (1.5 y)	≥4 points (1.3 y)

Treatment

Before the approval by the FDA of the JAK1/2 inhibitor ruxolitinib in 2011, treatment of MF was unsatisfactory. Cytreductive drugs such as HU or cladribine were used to control hyperproliferation, although their effects are transient and rarely result in complete spleen regression. Oral alkylating agents have also been used, but often induce severe myelosuppression and are associated with an increased risk of transformation to AML. Corticosteroids, erythroid-stimulating agents, and androgens have proven helpful in treatment of anemia. Patients with low serum Epo (<125 U/L) can be given subcutaneous injections of Epo (40,000 U/week). Corticosteroids (prednisone 0.5 to 1.0 mg/kg/day) or androgens (testosterone enanthate injections 400-600 mg/week; oral danazol 200 mg two or three times/day) have also been useful. Immunomodulatory agents (low-dose thalidomide and lenalidomide) have anticytokine and antiangiogenic effects and have been shown to reduce splenomegaly and improve anemia. They are usually used with tapering doses of prednisone for 3 months. Interferon alfa has been used with some success, but significant toxicity prevents its use in many patients. It may slow disease progression in patients with early MF, as well as reverse BM fibrosis in some patients⁽⁸⁰⁾. A recent retrospective study of Peg-IFN-α-2a in 62 patients with MF reported improvements in anemia and constitutional symptoms, normalization of platelet and leukocyte counts, and reduction in splenomegaly⁽⁸¹⁾. In selected patients, splenectomy or splenic radiation may help with symptom control or may improve blood cell count but these procedures carry significant side effects.

JAK Inhibitors

Two pivotal phase III randomized trials provided evidence for the regulatory approval of the oral JAK1/2 inhibitor ruxolitinib. COMFORT-I randomized patients to ruxolitinib ($n = 155$) or placebo ($n = 154$)⁽⁸²⁾, while COMFORT-II compared ruxolitinib ($n = 146$) to BAT ($n = 73$)⁽⁸³⁾. Significantly more patients in the ruxolitinib arms had 35% or more reduction in spleen volume (approximately 50% reduction by palpation) from baseline at week 24 (COMFORT-I) or week 48 (COMFORT-II). Both studies showed significantly better improvements in MF-related symptoms and quality of life in patients treated with ruxolitinib. Thrombocytopenia and anemia were the most common toxicities associated with ruxolitinib therapy. These effects mostly appeared within the first 3 to 6 months of treatment and were managed with dose reductions or transfusions.

Long-term follow-up analyses have demonstrated that the effects of ruxolitinib are durable. After a median follow-up of 2 years, more than 80% of patients treated with ruxolitinib in COMFORT-I who had achieved a 35% or greater reduction in spleen volume had maintained at least a 10% reduction⁽⁸⁴⁾. In COMFORT-II, at 144 weeks, the Kaplan-Meier estimated probability of maintaining a spleen response was 50%⁽⁸⁵⁾. Ruxolitinib also improved survival^(85,86). Long-term treatment with ruxolitinib may delay progression of or reverse BM fibrosis in some patients⁽⁸⁷⁾. Two case reports showed nearly complete resolution of marrow fibrosis and a reduction in JAK2V617F allele burden after long-term treatment with ruxolitinib^(88,89).

In our experience, most patients with symptomatic splenomegaly or systemic MF-related symptoms, even those with transfusion-dependent anemia, can be successfully treated with ruxolitinib for long periods of time if the patient is carefully monitored (particularly during the first 3-6 months) and the dose adjusted to avoid therapy interruptions. Recommended starting doses are 20 mg twice per day in patients with platelets above $200 \times 10^9/L$, 15 mg twice a day in patients with platelets between 100 and $200 \times 10^9/L$, and 5 mg twice a day in patients with platelet counts below $100 \times 10^9/L$. The dose can be increased to a maximum of 25 mg twice a day if tolerated. Avoidance of treatment interruption is important for treatment success, as symptoms return to baseline within 7 to 10 days. Ruxolitinib doses of 10 mg twice a day or higher are effective maintenance doses. Other JAK inhibitors, which appear to be less myelosuppressive (pacritinib) and may possibly reduce the need for red blood cell transfusions (mometinib), are in late-phase clinical development for MF.

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplant (alloSCT) is curative in MF; however, fewer than 10% of patients undergo

alloSCT due to older age or severe comorbidities. Reduced-intensity conditioning regimens are an option in older patients and those with comorbidities⁽⁹⁰⁾. Spleen size influences the rate of engraftment after transplant, but splenectomy before alloSCT is not recommended. The use of ruxolitinib pretransplant to reduce splenomegaly is being evaluated. A study of 14 patients treated with ruxolitinib (median duration 6.5 months) before alloSCT showed that, at the time of transplantation, 7 of 11 patients with splenomegaly had a 41% median reduction in palpable spleen size as well as improvement in disease-related symptoms⁽⁹¹⁾. Thirteen (93%) patients had engraftment, and 11 were alive after a median follow-up of 9 months. Treatment-related mortality was 7%. In a prospective study of 22 patients pretreated with ruxolitinib, 69% had reductions in spleen size, 86% had improvement in symptoms, engraftment was seen in all cases, and the estimated 1-year survival was 81%⁽⁹²⁾. Although the numbers were small, survival was longer in patients who responded to ruxolitinib ($n = 10$) than in those who did not ($n = 10$) (100% vs 60% estimated 1-year survival; $P = .02$).

Combination and Novel Therapies

Other targeted agents, such as epigenetic modifying agents (azacitidine, decitabine, panobinostat, and pracinostat); hedgehog inhibitors (LDE-225, IPI-926); PI3 kinase inhibitors (BKM120); antifibrotic agents (PRM-151); or telomerase inhibitor (imetelstat) have been tested. Most have not shown significant efficacy as single agents. Preclinical studies have shown synergistic effects when some of these agents were combined with ruxolitinib, suggesting a useful strategy to improve outcomes. Clinical trials testing ruxolitinib in combination with pracinostat, panobinostat, lenalidomide, decitabine, azacitidine, BEZ235, and LDE-225 are ongoing; results of these trials are eagerly awaited.

Treatment Conclusions

Patients with MF should first be assigned to a risk category using one of the standard prognostic tools (IPSS, D-IPSS). For patients with low-risk disease, a watch-and-wait approach is acceptable. Patients in the intermediate or high-risk groups should be treated based on their symptoms. In most cases, with careful titration and monitoring, ruxolitinib can be safely used. For younger patients in the intermediate-2 and high-risk categories, alloSCT can be offered. For patients who are not eligible for alloSCT or are intolerant or lose their response to other therapies, enrollment in clinical trials is recommended. Ruxolitinib and other JAK inhibitors have been effective in reducing splenomegaly, in

improving symptoms and quality of life, and in prolonging survival in patients with MF. JAK inhibitors have not been shown to eradicate the mutant clone, and patients lose their response to therapy over time. Results from ongoing trials of new targeted agents and their combinations are eagerly awaited.

CHRONIC EOSINOPHILIC LEUKEMIA/HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome is characterized by chronic eosinophil overproduction in the absence of obvious reactive or clonal causes of eosinophilia. Eosinophilic tissue infiltration may involve the heart, skin, central and peripheral nervous systems, lungs, spleen, liver, and gastrointestinal tract. A diagnosis of HES requires the presence of an absolute eosinophil count of more than $1.5 \times 10^9/L$ for at least 6 months and evidence of end-organ damage. Patients with hypereosinophilia who are found to have clonal disease (ie, a cytogenetic or molecular abnormality proving the existence of a malignant clone), peripheral blood blasts greater than 2%, or bone marrow blasts greater than 5% have CEL (⁹³). Hypereosinophilic syndrome and CEL have similar clinical presentations, and distinguishing between the two can be difficult unless proper testing for a molecular/cytogenetic marker is done. As most common causes of eosinophilia are reactive, conditions such as infections (especially parasitic), atopy, drug reactions, connective tissue disorders, or vasculitis must be ruled out.

In 2003, Cools et al described a karyotypically occult but fluorescent in situ hybridization (FISH)—apparent molecular aberrancy in a subset of patients with HES/CEL (⁹⁴). This abnormality consisted of an interstitial deletion of chromosome 4q12, leading to the fusion of the FIP1-like 1 (FIP1L1) gene to the PDGFR α gene. The resultant product, FIP1L1-PDGFR α , is a constitutively active TK highly amenable to inhibition by imatinib. Other molecularly defined HES/CEL subtypes include mutations involving the genes that encode for PDGFR β (located on chromosome 5q31-q33) and fibroblast growth factor receptor 1 (FGFR1; located on chromosome 8p11) (⁹⁵). All such patients have been reclassified using the new 2008 WHO classification into separate groups, as the resulting rearranged genes have become markers of disease clonality (see Table 6-1): myeloid neoplasms associated with eosinophilia and abnormalities of PDGFR α , PDGFR β , or FGFR1.

Hypereosinophilic syndrome is more common in men than women, and patients are usually younger (20-50 years old). The continuous presence of a large number of eosinophils in the blood can eventually cause multiple organ tissue damage due to tissue

FIGURE 6-14 In CEL/HES, bone marrow typically shows increased cellularity with striking interstitial infiltration by eosinophils ($\times 400$).

infiltration by eosinophils. The disease can range from presenting with minimal symptoms and a long survival to being rapidly fatal due to sudden, severe heart failure or acute leukemia. Clinical manifestations include pruritus, urticaria, angioedema, erythematous papules, valvular heart disease, mural thrombi, cardiomyopathy, polyneuropathies, optic neuritis, pulmonary infiltrates, and pleural effusion.

Diagnosis

Patients suspected to have HES must undergo bone marrow evaluation, cytogenetic analysis, and testing for FIP1L1-PDGFR α , as treatment modalities for patients with this mutation are different. **Figures 6-14 and 6-15** illustrate the morphological findings in HES/CEL. The incidence of the FIP1L1—PDGFR α rearrangement is

FIGURE 6-15 Markedly increased, morphologically unremarkable eosinophils are typically detected in the bone marrow aspirate smears from patients with CEL/HES ($\times 400$).

low in patients with hypereosinophilia. In the initial study by Cools et al, FIP1L1-PDGFR α was found in 56% of the patients⁽⁹⁴⁾. Other studies have reported a frequency ranging from 3% to 88%, likely reflecting the intrinsic heterogeneity among patients with hypereosinophilia and the impact of referral bias^(94,96). In the largest study to date, FISH analysis aimed at detecting a deletion/excision of the CHIC2 locus at chromosome 4q12 (indirect test for FIP1L1-PDGFR α abnormality) was performed in 741 unselected patients with eosinophilia; only 21 (3%) were positive⁽⁹⁶⁾. In another study of 376 patients with persistent unexplained eosinophilia, 40 patients (11%) were FIP1L1-PDGFR α positive⁽⁹⁷⁾. T-cell immunophenotyping and T-cell receptor gene rearrangement analysis should be performed in all patients, and if either clonal or immunophenotypically aberrant T cells are identified, a diagnosis of lymphoproliferative variant of HES is preferred. Chest x-ray, pulmonary function tests, echocardiogram, and measurement of serum troponin levels should be performed at diagnosis. An increased level of serum cardiac troponin correlates with the presence of cardiomyopathy in HES. A diagnostic algorithm for primary eosinophilia is presented in Fig. 6-16.

Treatment

For asymptomatic patients with no organ damage and normal troponin levels, no active HES therapy

is recommended. These patients should be followed closely. For patients with symptomatic disease or evidence of end-organ damage, therapy for HES generally entails the use of corticosteroids, IFN- α , or cytoreductive agents such as HU, vincristine, or cyclosporine. The first-line treatment of HES is usually prednisone (starting dose of 1 mg/kg/day), with a response rate of 70%. Relapses often occur with cessation of therapy, requiring alternative options, such as IFN- α or HU. Vincristine is useful for acute reductions when total eosinophil count is very high ($\geq 50 \times 10^9/L$).

For patients refractory to conventional therapies, the use of monoclonal antibody therapy should be considered. Two drugs are currently available: mepolizumab, which targets interleukin 5, and alemtuzumab, which targets the CD52 antigen expressed by eosinophils but not neutrophils. Rothenberg et al conducted a randomized, placebo-controlled trial evaluating the safety and efficacy of mepolizumab in patients with stable HES on steroids without life-threatening complications as a steroid-sparing agent⁽⁹⁸⁾. The primary end point (reduction of the prednisone dose to ≤ 10 mg/day for ≥ 8 consecutive weeks) was achieved in 84% of patients receiving mepolizumab compared with 43% of patients in the placebo group ($P < .001$). In a long-term extension study, 78 patients received mepolizumab for a median 251 weeks (range, 4-302 weeks), and 69% were still receiving mepolizumab at the end of the study. Sixty-two percent of patients were free

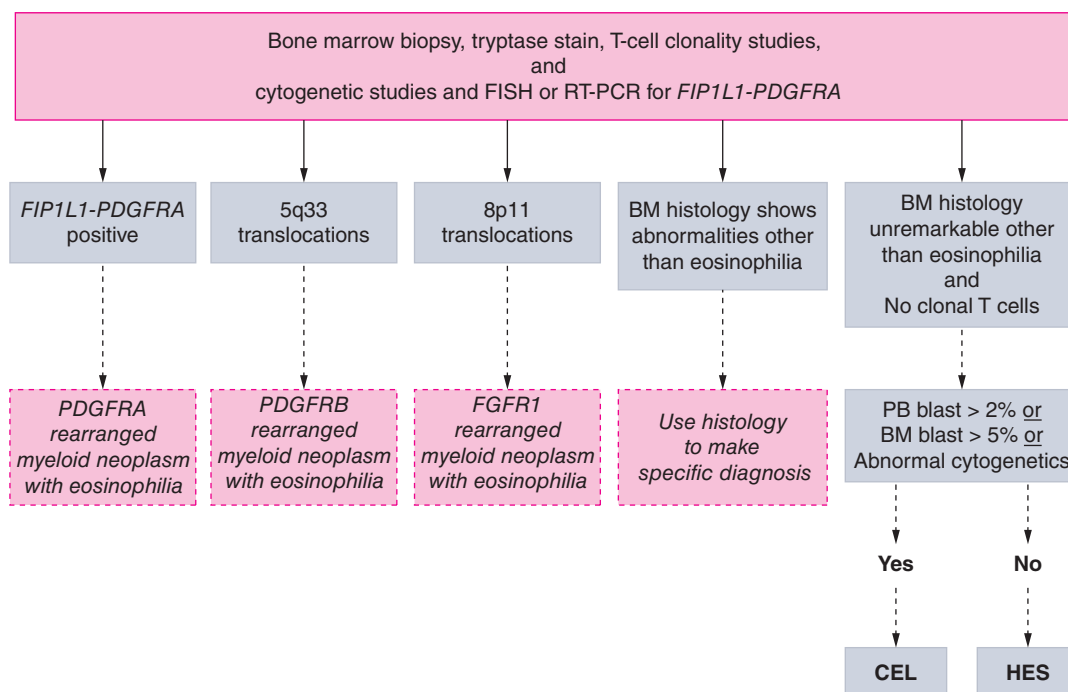

FIGURE 6-16 Diagnostic algorithm for suspected primary eosinophilia. BM, bone marrow; PB, peripheral blood; PDGFRA, platelet-derived growth factor receptor alpha; PDGFRB, platelet-derived growth factor beta. RT-PCR, reverse transcriptase polymerase chain reaction. (Reproduced with permission from Tefferi A, Vardiman JW. Classification and diagnosis of myeloproliferative neoplasms: the 2008 World Health Organization criteria and point-of-care diagnostic algorithms. *Leukemia*. 2008;22:14-22.)

of prednisone or other HES treatments for 12 weeks or more⁽⁹⁹⁾.

Mepolizumab is currently available on a compassionate use basis. Among 11 patients with HES/CEL (9 previously treated) treated with alemtuzumab⁽¹⁰⁰⁾, 10 (91%) achieved CHR (defined as the reduction of the absolute eosinophil count and the percentage of eosinophils in peripheral blood to normal values) after a median of 2 weeks, and symptoms completely resolved in 9 patients. Bone marrow eosinophilia resolved in four of the seven evaluable patients. The median duration of CHR was short lived (3 months), and 7 of the 10 CHRs relapsed. Although effective in eliminating the disease, therapy with alemtuzumab requires a maintenance phase, with alemtuzumab given periodically every few weeks or months on the first evidence of recurrent symptoms and signs of the disease. A long-term follow-up of nine of the original patients and three additional patients was recently published⁽¹⁰¹⁾. Ten of twelve patients treated with alemtuzumab achieved CHR and elimination of disease symptoms after a median of 1 week; this was sustained for a median duration of 66 weeks. Five patients with CHR receiving maintenance alemtuzumab for a median duration of 20 weeks (range, 1-266 weeks) had a significantly longer time to disease progression than those who were not given maintenance therapy ($P = .01$). Eleven patients eventually relapsed (only one who was on maintenance therapy). Five of six patients achieved a second CHR after rechallenge with alemtuzumab, with three of five receiving maintenance therapy.

Imatinib mesylate is a potent adenosine triphosphate (ATP)-competitive tyrosine kinase inhibitor (TKI) that is highly active against ABL, PDGFR, and KIT protein kinases. Imatinib therapy for patients with eosinophilia carrying the FIP1L1-PDGFR α has been established as effective in multiple studies^(94, 102). Baccarani et al reported a CHR of 99% in patients carrying FIP1L1-PDGFR α compared with 19% in patients without this mutation⁽¹⁰²⁾. Imatinib is standard of care for this subset of patients with hypereosinophilia, and therapy with imatinib is recommended even in the absence of symptoms to prevent the risk of end-organ damage.

In the United States, imatinib is approved for the treatment of adults with HES/CEL associated with the FIP1L1-PDGFR α kinase (starting dose of 100 mg daily with a dose increase to 400 mg daily if suboptimal response and lack of side effects) and for patients with HES/CEL whose FIP1L1-PDGFR α status is negative or unknown (recommended dose is 400 mg daily). As the response to imatinib in FIP1L1-PDGFR α -negative patients is limited, frontline therapy with imatinib for patients with HES should not be indiscriminate and should be reserved for patients who fail conventional therapy. Imatinib is also approved therapy for patients with eosinophilia and PDGFR β involvement, which is usually discovered on

cytogenetic testing, as it involves chromosomal translocations involving 5q31-q33. In some academic centers, an assay based on polymerase chain reaction (PCR) for PDGFR β gene expression is available and should be used as part of the workup of eosinophilia.

Treatment Conclusions

All patients suspected of having primary eosinophilia should undergo testing for a PDGFR α fusion gene. This is usually done using PCR to test for PDGFR α expression. Alternatively, FISH analysis can be performed to test for the absence of the *CHIC2* gene. Patients with this rearranged gene should be treated with imatinib 100 mg daily. PDGFR β gene overexpression can be documented by specific PCR or suspected by the presence of chromosome translocation involving 5q31-q33. For PDGFR α / β -negative patients, prednisone is the first line of treatment. For patients refractory to steroids or relapsing on steroids, IFN- α or HU can be used as second-line agents. Mepolizumab or alemtuzumab can be considered for refractory patients. Combination chemotherapy using cladribine and cytarabine has also been used.

CHRONIC NEUTROPHILIC LEUKEMIA

Chronic neutrophilic leukemia is extremely rare and was first included as a distinct entity in the 2001 WHO classification system⁽¹⁰³⁾. The disease is characterized by the chronic overproduction of mature neutrophils and an increased number of granulocytes in the bone marrow. Diagnostic criteria were not revised in 2008 (Table 6-10). The recent identification of mutations

Table 6-10 World Health Organization Diagnostic Criteria for Chronic Neutrophilic Leukemia

1. Peripheral blood leukocytosis $\geq 25 \times 10^9/L$, with $>80\%$ neutrophils, $<10\%$ immature granulocytes, and $<1\%$ myeloblasts
2. Hypercellular bone marrow with granulocytic hyperplasia, without dysplasia and $<5\%$ myeloblasts
3. Hepatosplenomegaly
4. No identifiable cause of physiologic neutrophilia or demonstration of clonality of myeloid cells
5. Negative for the BCR-ABL1 fusion gene and rearrangements of PDGFRA, PDGFRB, or FGFR1
6. No evidence of PV, ET, or PMF
7. No evidence of MDS or MDS/MPN; no granulocytic dysplasia or myelodysplastic changes in other myeloid lineages; monocytes $<1 \times 10^3/L$

in the colony-stimulating factor 3 receptor (CSF3R) in most patients with WHO-defined CNL is likely to result in a revision in the next edition. Deep sequencing of coding regions of 1,862 genes in patients with CNL ($n = 9$) and atypical CML (aCML) ($n = 20$) identified mutations in the CSF3R gene in eight of nine patients with CNL (¹⁰⁴). Most mutations were found in the membrane proximal region (T618I or T615A). Some cases also had nonsense mutations leading to a truncated cytoplasmic tail. Under normal conditions, CSF3R, which is activated by binding its ligand granulocyte colony-stimulating factor, promotes the differentiation of granulocyte progenitor cells into neutrophils. Mutations in the membrane proximal region lead to constitutive activation of the JAK-STAT pathway, while truncation mutations result in ligand hypersensitivity and activation of the downstream SRC kinase pathway.

Studies in mice support the role of CSF3R mutations in CNL: Deletion of CSF3R in mice leads to neutropenia, and mice transplanted with CSF3RT618I-positive hematopoietic cells develop a CNL-like phenotype, with mature granulocytosis, marrow hypercellularity, and infiltration of the spleen and liver with mature granulocytes (¹⁰⁵). In another study, the coding region of CSF3R was sequenced in patients with clinically suspected CNL ($n = 35$) or aCML ($n = 19$), as well as 170 cases of CMML and PMF (¹⁰⁶). The diagnoses were reevaluated using WHO criteria. Twelve cases of CNL were confirmed, 5 were associated with a monoclonal gammopathy-associated CNL, and 9 were confirmed as aCML. Of the 13 patients found to have the CSF3R mutation, 12 had WHO-defined CNL, and 1 had unconfirmed CNL. All mutations were found in the membrane proximal region, with CSF3RT618I being the most common (10 patients). None of the cases of monoclonal gammopathy-associated CNL had CSF3R mutations, suggesting that patients with evidence of a plasma cell dyscrasia should not be classified as having CNL.

Clinical Features

As with other MPNs, the clinical presentation of CNL is heterogeneous. In a long-term study of 12 cases of WHO-defined CNL and 28 cases from a critical literature review, the median age at diagnosis was 66 years (range, 15-86). Clinical manifestations included fatigue, palpable splenomegaly, weight loss, easy bruising, bone pain, and night sweats. Most patients have mild anemia, and platelet counts are usually normal or slightly low. The median survival in CNL is less than 2 years (^{106, 107}). Intracranial hemorrhage is the most common cause of death, followed by leukemic transformation (¹⁰⁷). Transformation was seen in 20% of patients after a median of 21 months from diagnosis. Genome sequencing studies suggested that SET binding

protein 1 (SETBP1) may be associated with accelerated or blast phase disease (¹⁰⁶).

Diagnosis

Most patients are asymptomatic at presentation and are diagnosed after a finding of leukocytosis on routine blood testing. The diagnosis is generally one of exclusion. The absence of Bcr-Abl1 and rearrangement of PDGFR α , PDGFR β , and FGFR1 are key diagnostic criteria.

Other diagnostic criteria include sustained peripheral blood leukocytosis with more than 80% neutrophils, less than 10% mature granulocytes, and less than 1% myeloblasts and a hypercellular bone marrow (>90% cellularity) due to granulocytic hyperplasia, with no dysplastic features (see Table 6-10). Unlike other MPNs, megakaryocytic hyperplasia or clusters of large atypical megakaryocytes is not seen. Most patients have normal cytogenetics.

Treatment

There is no standard treatment for CNL. Hydroxyurea is commonly used to control leukocytosis and splenomegaly. Interferon alfa has also been used. These agents can reduce leukocytosis but do not modify the natural disease course. Splenic radiation and splenectomy have been used, but splenectomy has been associated with further increases in neutrophil counts (¹⁰⁷). Induction chemotherapy has been used to treat patients in the blastic phase; however, outcomes are poor. Stem cell transplantation was used with some success in selected cases (^{107, 108}). Ruxolitinib has been reported as a therapy in two cases (^{104, 109}).

MAST CELL DISEASE

Mast cell disease is a heterogeneous group of disorders characterized by clonal expansion of mast cells (MCs) and their excessive accumulation in various organs such as skin, bone marrow, gastrointestinal tract, lymph nodes, liver, and spleen. Its clinical course can vary from no/minimal symptoms to diffuse systemic involvement. Mastocytosis has been classified into seven subtypes by the 2001 WHO guidelines: cutaneous mastocytosis, indolent systemic mastocytosis (ISM), systemic mastocytosis (SM) with an associated clonal hematological non-MC-lineage disease (SM-AHNMD), aggressive SM (ASM), MC leukemia, MC sarcoma, and extracutaneous mastocytoma (¹¹⁰). Systemic mastocytosis is defined by the presence of one major and one minor or three minor diagnostic criteria (Table 6-11). Patients with SM are further characterized with regard to the presence of so-called B and C findings (assessing disease burden and disease aggressiveness, respectively) (Table 6-12).

Table 6-11 World Health Organization Diagnostic Criteria for Systemic Mastocytosis

Major Criteria
1. Multifocal, dense infiltrates of mast cells (≥ 15 mast cells in aggregates) in bone marrow biopsy sections and/or in other extracutaneous organ(s)
Minor Criteria
1. Greater than 25% mast cells in bone marrow or other extracutaneous organ(s) show an atypical morphology (typically spindle shaped)
2. <i>c-kit</i> mutation at codon 816 is present in extracutaneous tissues
3. Mast cells in bone marrow coexpress CD117 and either CD2, CD25, or both (by flow cytometry)
4. Serum tryptase persistently is ≥ 20 ng/mL (not accounted for in patients with an associated, clonal, hematologic, nonmast cell disorder)
Diagnosis requires meeting either one major criteria and one minor criteria or three minor criteria

Data from Valent P, Horny HP, Escribano L, et al. Diagnostic criteria and classification of mastocytosis: a consensus proposal, *Leukemia Res* 2001 Jul;25(7):603-625.

Table 6-12 B and C Findings in Systemic Mastocytosis

B Findings: Indication of High MC Burden and Expansion of the Genetic Defect Into Various Myeloid Lineages
1. Infiltration grade of mast cells in bone marrow $>30\%$ on histology and serum total tryptase levels >200 ng/mL
2. Hypercellular bone marrow with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, or World Health Organization criteria for myelodysplastic syndrome or myeloproliferative disorder
3. Organomegaly: Palpable hepatomegaly, splenomegaly, or lymphadenopathy (>2 cm on computed tomography or ultrasound) without impaired organ function
C Findings: Indication of Impaired Organ Function Because of MC Infiltration (Confirmed by Biopsy in Most Patients)
1. Cytopenia(s): Absolute neutrophil count $<1,000/\mu\text{L}$, or hemoglobin <10 g/dL, or platelets $<100,000/\mu\text{L}$
2. Hepatomegaly with ascites and impaired liver function
3. Palpable splenomegaly with hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: Large osteolyses and/or severe osteoporosis causing pathologic fractures
6. Life-threatening organomegaly in other organ systems that definitively is caused by an infiltration of the tissue by neoplastic mast cells

Patients with SM with no findings are identified as having ISM, those with B findings as smoldering SM (SSM, a subtype of ISM with possibly more aggressive clinical course), and those with C findings as ASM. The 2008 WHO guidelines redefined mastocytosis as “mast cell disease,” reclassifying it as an MPN, with SM a subtype with bone marrow involvement.

Clinical Features

Symptoms of mastocytosis can be divided into those caused by the release of MC mediators or those caused by MC organ infiltration. Vasoactive mediators (histamine, leukotrienes, prostaglandins) released from MCs can lead to itching, flushing, light-headedness, syncope, palpitations, diarrhea, heartburn, fatigue, and headache and can be exacerbated by infections, alcohol, exercise, and medications. Common sites of organ infiltration include skin and gastrointestinal tract. Urticaria pigmentosa is the most common skin manifestation, characterized by reddish-brown macules and papules. Scratching of affected skin characteristically leads to development of urticaria and erythema (Darier sign). Gastrointestinal involvement can present as chronic diarrhea, steatorrhea, malabsorption, and ascites. Anemia is the most common hematological abnormality due to bone marrow infiltration, and peripheral eosinophilia is seen in around 20% of patients. Bone pain and fractures can also occur.

Diagnosis

Diagnosis relies primarily on the identification of neoplastic MCs in various organs (see Table 6-11). Bone marrow examination is imperative for diagnosis of SM, as most adults with mastocytosis have underlying bone marrow involvement. Figures 6-17 and 6-18 illustrate a case of SM detected in the bone marrow. Neoplastic MCs are characteristically spindle shaped and present in multifocal aggregates, and unlike normal MCs, neoplastic MCs express surface markers CD2 or CD25. Serum tryptase and urinary histamine levels are generally increased. Screening for the KIT D816V mutation should be considered for all patients. KIT is a TK receptor encoded by the *c-kit* gene located on chromosome 4q12 in humans. Binding of stem cell factor (SCF) to KIT leads to receptor dimerization and phosphorylation of the downstream signaling molecules (¹¹¹). KIT plays an important role in normal hematopoiesis, and its expression declines in hematopoietic cell lines with maturation, except in MCs. Furitsu et al first showed that KIT was constitutively activated and expressed in the absence of SCF in a MC line derived from a patient with MC leukemia (¹¹²). Using a sensitive PCR-based assay, a point mutation, resulting in the substitution of valine for aspartate at codon 816 (D816V) in the TK

FIGURE 6-17 Bone marrow biopsy from a patient with SM demonstrates total focal replacement of the normal cellular elements by mast cells ($\times 100$). Immunohistochemical staining performed on this specimen demonstrated that the neoplastic mast cells aberrantly expressed CD2 and CD25.

domain of the KIT receptor, is noted in more than 90% of patients with SM (¹¹³). Recently, TET2 mutation (a candidate tumor suppressor gene on chromosome 4q24) was reported in 29% of patients with SM and correlated with the presence of the KITD816V mutation, monocytosis, and female gender (¹¹⁴).

Treatment

There is a lack of effective treatment for SM. Symptomatic treatments include the use of oral antihistamines

FIGURE 6-18 In SM, mast cells tend to have abundant, colorless cytoplasm and contain elongated-to-oval nuclei ($\times 400$). In the bone marrow aspirate smears, the mast cells are increased in number and size and attain a spindle shape (inset; $\times 400$).

and MC stabilizers such as cromolyn sodium (¹¹⁵). Patients should avoid factors that can trigger MC degranulation, such as emotional stress, cold exposure, alcohol use, strenuous exercise, and the use of nonsteroidal anti-inflammatory drugs. Both sedating and nonsedating H1 antihistamines can be used to alleviate pruritus and itching. Randomized controlled trials evaluating the efficacy of antihistamines in SM are lacking. Cetirizine has been shown to be equivalent to hydroxyzine in relieving pruritus in patients with chronic urticaria, with the advantage that it does not cause sedation (¹¹⁶). Therefore, most patients initially are treated with nonsedating H1 antihistamines. Higher doses of sedating antihistamines could be used for those with severe symptoms.

As both H1 and H2 receptors are present in skin (85% cutaneous histamine receptors are H1 and 15% are H2), the addition of an H2 blocker should be considered for those not responding to H1 antihistamines alone (¹¹⁶). Cromolyn sodium is beneficial in patients with gastrointestinal symptoms (diarrhea, vomiting, abdominal pain). Short courses of prednisone can be considered for patients with severe symptoms, especially malabsorption and ascites. Aspirin can cause MC degranulation but may help with flushing. Therefore, patients should be on H1 and H2 antihistamine therapy before starting ASA therapy (¹¹⁵). Patients with a history of anaphylaxis or cardiovascular collapse should carry an epinephrine pen. Omalizumab (a humanized murine monoclonal antibody that inhibits immunoglobulin E binding to MCs and basophils) is effective in patients with SM and syncopal episodes and skin manifestations. For patients with osteoporosis, bisphosphonate therapy may help. Cyto-reductive therapies (IFN- α and cladribine) are used for severe disease symptoms. In a multicenter trial in 20 patients with SM, IFN- α 2b led to a partial or minor response in 13 (¹¹⁷). The combination of IFN- α 2b plus prednisone has also been studied. The use of cladribine in 33 patients with mastocytosis produced major response in 24 (¹¹⁸). Cladribine may be the best therapy for patients with ASM.

Various TKIs targeting KIT are now being studied in clinical trials. Imatinib is a potent inhibitor of various TKs, including wild-type KIT, but is not effective against the most common KIT mutation in SM, D816V. Imatinib binds KIT only in its inactive configuration, and the D816V mutation leads to stabilization of the active open configuration. Clinical experience with imatinib corresponded to the *in vitro* data, with no significant responses in patients with the KITD816V mutation (¹¹⁹). An important subgroup of patients with SM and imatinib responsiveness is the subset with the FIP1L1-PDGFR α mutation. Peripheral blood eosinophilia is seen in approximately 20% of patients (SM-eos) and bone marrow eosinophilia in 25%. In a study by Pardanani et al, 56% of patients with SM

and eosinophilia had the FIP1L1-PDGFR α fusion oncogene (¹²⁰). In that study, all treated SM-eos patients with the FIP1L1-PDGFR α mutation responded to imatinib 100 mg daily, while those without the FIP1L1-PDGFR α mutation did not respond (irrespective of the KITD816V mutation status). All patients with SM and eosinophilia should undergo testing for the FIP1L1-PDGFR α mutation. Imatinib is approved by the FDA for patients with ASM without the KITD816V mutation or unknown KIT mutation status (at 400 mg daily) and for ASM associated with eosinophilia (starting dose 100 mg daily with dose escalation to 400 mg daily if insufficient response and absence of side effects). Other TKIs under investigation in patients with the KITD816V mutation are dasatinib, nilotinib, and midostaurin. The clinical results have been modest.

Indolent Lymphomas

Loretta J. Nastoupil
Chan Yoon Cheah
L. Jeffrey Medeiros
Nathan H. Fowler

The indolent non-Hodgkin lymphomas (NHLs) represent approximately one-third of all malignant lymphomas (^{1, 2}); most are of B-cell lineage. Follicular lymphoma (FL) is the most common indolent lymphoma. Other indolent B-cell lymphomas include small lymphocytic lymphoma/chronic lymphocytic leukemia (SLL/CLL), the marginal zone B-cell lymphomas (MZLs; extranodal, nodal, and splenic), and lymphoplasmacytic lymphoma (LPL), most cases of which are more specifically classified as Waldenström macroglobulinemia (WM) (Table 7-1) (²). Mantle cell lymphoma can morphologically resemble indolent B-cell lymphomas, but it is often clinically more aggressive and therefore is not covered in this chapter. Indolent T-cell NHLs, such as mycosis fungoides, are also not covered in this chapter.

FOLLICULAR LYMPHOMAS

Epidemiology

Follicular lymphomas, the second most commonly occurring lymphoma in the United States, represents 22% of all NHLs (¹) and 80% of indolent B-cell lymphomas. Follicular lymphoma occurs almost exclusively in adults, with an equal frequency in men and women. The incidence rates are highest among Caucasians, and median age at diagnosis is approximately 58 years (³). Risk of FL has been shown to be increased in persons with a first-degree relative with NHL or who worked as spray painters and among women with Sjögren syndrome (³). Of FL cases, 2% to 3% transform annually

to diffuse large B-cell lymphoma (DLBCL) (⁴). Survival for patients with FL is improving, with a median survival of 8 to 10 years in the prerituximab era (^{2, 5, 6}); in more modern eras, median survival has been reported to be greater than 18 years (⁷).

Clinical Features

Patients with FL most often present with asymptomatic lymphadenopathy. Constitutional symptoms such as fever, drenching night sweats, and significant weight loss occur in approximately 15% of patients. Patients may have symptoms related to lymph node enlargement, especially when there are bulky masses in the retroperitoneum. Other symptoms can include fatigue and, occasionally, end-organ consequences such as obstructive uropathy or bone marrow compromise. Central nervous system (CNS) disease is rare. Urgent situations, such as superior vena cava syndrome or spinal cord compression, are rare, in part related to the usual slow pace of growth of lymphadenopathy in FL. Spontaneous regression of lymphadenopathy can occur in FL. Such regressions, however, are usually partial and are typically short-lived. The potential of FL to wax and wane provides one of several clues that suggest that the host immune system can play an important role in the disease course in FL. Consequently, FL has been a prime focus for immunotherapy approaches.

Approximately 80% to 90% of patients with FL present with advanced-stage disease (stage III or IV) with generalized lymphadenopathy. The bone marrow is involved in approximately 50% of patients.

Table 7-1 Indolent Lymphomas

Entities included	Follicular lymphoma Small lymphocytic lymphoma/chronic lymphocytic leukemia Extranodal marginal zone B-cell lymphoma (MALT lymphoma) Splenic B-cell marginal zone lymphoma Nodal marginal zone lymphoma Lymphoplasmacytic lymphoma (including Waldenström macroglobulinemia)
Age	Mostly a disease of older adults (usually over the age of 40 years)
Extent of disease	Often disseminated (except MALT lymphoma), with >80% having stage III-IV disease. Bone marrow involvement common
Natural history	Low proliferation fraction. Slow-growing; may have a waxing and waning course. Patients typically survive for many years. Transformation to large cell lymphoma can occur.
Curability	Although current therapy such as radiotherapy or chemotherapy can often control the disease, it usually fails to eradicate the tumor except for early-stage disease (including MALT lymphoma). This is reflected in a continuous downward slope of relapse-free survival curves for patients with these lymphomas.

Clinical features suspicious for transformation to DLBCL include rapidly progressive lymphadenopathy, systemic (B) symptoms, localized pain, and a rise in serum lactate dehydrogenase (LDH) level.

Histologic, Immunophenotypic, and Molecular Features

In FL, the normal lymph node architecture is partially or completely replaced by lymphoma, which typically forms follicles but rarely can be diffuse, composed of centrocytes (small, cleaved cells) and centroblasts (large, noncleaved cells). The method currently recommended in the World Health Organization (WHO) classification to grade FL is based on a count of the centroblasts (2,8). In grade 1 FL, centroblasts are rare, less than 5 per ×400 microscopic field. Grade 2 FL contains 5 or more but less than 15 centroblasts per ×400 microscopic field. The current WHO classification states that there is no prognostic benefit derived from distinguishing grade 1 from grade 2 cases and designates these tumors as FL grade 1 or 2. At least two types of grade 3 FL are described. In grade 3a, more than 15 centroblasts per ×400 microscopic field are present.

In grade 3b, sheets of centroblasts are present with rare or absent centrocytes (2). Recent data suggested that FL grade 3b has more features in common with DLBCL than with the indolent FL (9).

Some patients with B-cell lymphoma of germinal center cell origin may have histologic discordance (ie, low-grade FL in the bone marrow and DLBCL in a lymph node) (10). In addition, different lymph nodes biopsied in a given patient or a single lymph node can comprise different grades of FL.

Follicular lymphoma is a neoplasm of mature B-cell lineage. Most grade 1 and 2 tumors express immunoglobulin (Ig), but a subset of FLs, mostly grade 3, may be Ig negative. All FLs express pan B-cell markers and typically express Ig and B-cell antigens at high density (“bright” immunofluorescence by flow cytometry). These neoplasms also express the germinal center-associated markers CD10, Bcl-6, and LMO2 and are negative for T-cell antigens. *Bcl-2* is expressed in 80% to 90% of FLs but can be negative, most often in grade 3 neoplasms (2). Because *Bcl-2* is negative in reactive germinal centers, this marker is helpful in differential diagnosis (Fig. 7-1).

Using conventional cytogenetic analysis, approximately 75% of FL cases grow in culture and can be successfully karyotyped. The cytogenetic hallmark of FL is t(14;18)(q32;q21), which is identified in 80% to 90% of cases. A small subset of FLs lack the t(14;18), suggesting that a minor pathway of follicular lymphomagenesis may exist that is independent of t(14;18). This appears to apply particularly to grade 3b nodal FL, FLs arising in extranodal sites such as skin, and rare FLs that occur in children, which commonly lack the t(14;18).

As a result of the t(14;18), the *Bcl-2* oncogene on chromosome 18q21 is translocated adjacent to the joining region of the immunoglobulin heavy chain (IgH) gene on chromosome 14q32. The *Bcl-2* gene is deregulated by being placed under the influence of IgH gene regulatory elements (enhancer region). Insights about the role of the *Bcl-2* gene in FL were a gateway to the identification of a large family of proapoptotic and antiapoptotic genes, which play a role in a wide variety of hematopoietic and solid neoplasms (11-13).

The breakpoints on chromosome 18 are primarily clustered at two sites, the major (MBR) and minor (mcr) breakpoint cluster regions, involved in 50% to 60% and 10% to 20% of cases, respectively (14). Other breakpoint clusters have also been described, for example, the intermediate cluster region (ICR). The ICR is involved in approximately 5% of cases; there may be geographic variations in the frequencies of t(14;18) breakpoints (15).

The *Bcl-2* protein is a 25-kDa molecule that is overexpressed in FL and protects cells from programmed cell death (apoptosis) (11, 12, 16). Inhibition of apoptosis

FIGURE 7-1 Follicular lymphoma, grade 1. **A.** In this needle biopsy specimen, neoplastic follicles partially replace architecture. **B.** The neoplastic cells are Bcl-2 positive, supporting lymphoma (**A**, hematoxylin and eosin, $\times 100$; **B**, Bcl-2 immunostain $\times 100$).

prolongs cell life, resulting in an expanded compartment of B cells, thereby providing more opportunity for additional molecular defects, which presumably are involved in histologic transformation. The presence of the t(14;18) alone appears not to be sufficient for neoplastic transformation. The t(14;18) has been identified in rare cells in the tonsils and lymph nodes of normal individuals without clinical evidence of lymphoma (¹⁷).

Other cytogenetic abnormalities have been reported in FL. Of these, trisomy 7 and 18, abnormalities of 3q27-28 and 6q23-26, and 17p deletions are most frequent. Abnormalities of 3q27-28 involve the *Bcl-6* gene and most often occur in the form of translocations. Secondary cytogenetic and molecular genetic abnormalities have also been extensively studied, including in the context of transformation of FL to DLBCL (¹⁸⁻²⁰).

The importance of the immunologic microenvironment in the clinical behavior of FL has been an area of intensive study. Gene expression profiling methods have shown molecular signatures attributable to subsets of T cells and macrophages in FLs that influence the risk of disease progression and prognosis (²¹⁻²⁴).

Follicular Lymphoma In Situ

Follicular lymphoma in situ (FLIS) is thought to be a pre-neoplastic or possibly very early stage of FL (²⁵). Most often, FLIS is an incidental finding that occurs in lymph nodes excised for a variety of reasons (eg, axillary lymph nodes in a patient with breast carcinoma). The overall frequency of FLIS is low, approximately 2%.

Morphologically, FLIS is difficult to recognize in routine, tissue sections stained with hematoxylin-eosin. The lymph node architecture is normal, with widely scattered follicles that are of normal size and inconspicuous. The germinal centers have a sharp peripheral margin and are monotonous, composed almost exclusively of centrocytes, a morphologic clue to the diagnosis of FLIS (²⁶). Immunohistochemical analysis

is essential for the recognition of FLIS. The germinal center cells are strongly positive for BCL2 and CD10 (^{26, 27}). Typically, BCL2 expression by the FLIS cells is brighter than the expression level by mantle zone cells surrounding the germinal center. The cells of FLIS also express pan B-cell antigens and other germinal center B-cell markers, such as BCL-6 and LMO2. Cytogenetic and molecular studies have shown that the cells of FLIS carry t(14;18)(q32;q21) and monoclonal Ig gene rearrangements. Array comparative genomic hybridization and other methods performed on FLIS lesions have shown that the cells of FLIS carry the t(14;18) but have relatively few secondary genetic abnormalities, in contrast with fully developed FL (²⁸). *EZH2* mutations have been detected in FLIS, suggesting this is another early lesion in FL pathogenesis.

Evidence of overt lymphoma at another anatomic site also is present in a small subset of patients with FLIS (²⁶). In addition, some patients with FLIS subsequently develop a histologically discordant type of lymphoma. These cases suggest that FLIS could be a marker of genetic instability or a marker of genetic predisposition to lymphoma. Lymphomas most often reported in association with FLIS include classical Hodgkin lymphoma, splenic marginal zone lymphoma, and SLL/CLL (²⁷).

In aggregate, the data suggest that FLIS is a neoplastic process representing an early step in FL pathogenesis that is unlikely to affect patient survival if it is an isolated finding. However, because a subset of some patients with FLIS also has or may develop overt lymphoma at other anatomic sites, staging studies are indicated. If FLIS is the only disease discovered, over-treatment is to be avoided.

Diagnostic Workup and Staging

Clinical evaluation requires a comprehensive history, including age; sex; presence of B symptoms (fevers, chills,

drenching night sweats, unexplained weight loss of more than 10% of body mass over 6 months, pruritus); fatigue; and a history of malignancy. Physical examination should include identification and measurement of all accessible lymph node sites, including epitrochlear and occipital lymph nodes, and assessment of the abdomen for splenomegaly or hepatomegaly.

The diagnosis is best established by an excisional lymph node biopsy to provide adequate tissue for assessment of the lymph node architecture. The most easily accessible lymph node may not be the most informative or representative one. For example, if a small peripheral lymph node shows grade 1 FL but the patient has a large abdominal mass, a high serum LDH level, and other features suggestive of transformation, then an additional biopsy to exclude higher-grade disease should be considered because this would influence the selection of appropriate therapy. Core needle biopsies guided by radiographic or imaging techniques may be performed on masses that are not easily accessible. Fine-needle aspiration (FNA) can be misleading for initial diagnosis; complete classification may not be possible because the limited tissue sample prevents the assessment of architecture, and there is the possibility of sampling error. In the initial staging evaluation, FNA may play a role in documenting and defining sites of involvement.

Once the diagnosis of FL has been established, patients should undergo testing to determine stage, assess prognostic risk factors, and evaluate their general health. A complete blood cell count may show anemia or thrombocytopenia, which can result from bone marrow involvement or occasionally from hypersplenism or autoimmune problems. Leukemic involvement can occur in 10% of patients. Serum LDH and β_2 -microglobulin (B2M) levels may be elevated and are of prognostic significance. Bilateral bone marrow biopsies with unilateral aspiration are recommended for the staging workup because of the patchy nature of involvement. In FL, the bone marrow characteristically shows a paratrabecular pattern of involvement (Fig. 7-2). Because the lymphoma cells are associated with stroma and are not easily aspirated, bone marrow aspirate smears assessed by routine light microscopy may not be informative. Flow cytometry and molecular assessment (eg, polymerase chain reaction, PCR) of aspirate material can increase the sensitivity of bone marrow assessment, but in the absence of morphologic abnormalities, positive PCR or flow findings are traditionally not taken as evidence to warrant assignment of stage IV⁽²⁹⁾. For example, it is well established that patients at Ann Arbor stage I or II can have cells with the t(14;18) detected in the peripheral blood or bone marrow by PCR.

Imaging studies should include neck and chest computed tomography (CT) for delineation of

FIGURE 7-2 Follicular lymphoma involving bone marrow. **A.** The neoplasm is infiltrating the bone marrow with a paratrabecular pattern. **B.** Neoplastic small-cleaved cells adjacent to bone are seen in this field (**A, B**, hematoxylin and eosin; **A**, $\times 100$; **B**, $\times 400$).

lymphadenopathy. Abdominal and pelvic CT scans are essential for assessing lymphadenopathy as well as organomegaly. Positron emission tomography (PET) using fluorine-18 fluorodeoxyglucose (FDG) is a useful tool for assessing patients with FDG-avid lymphomas and Hodgkin lymphoma. The field is evolving, and PET combined with CT (PET-CT) is replacing PET alone. Compared with CT scans, PET-CT can improve the accuracy of staging for nodal and extranodal sites and leads to a change in stage in 10% to 30% of patients, more often upstaging these patients⁽³⁰⁾. Improving staging accuracy is important to ensure patients are appropriately treated. Although most lymphomas are FDG avid, there is great variability in FDG uptake⁽³¹⁻³³⁾. Imaging by PET can be less reliable in indolent lymphoma. Therefore, adoption of PET scanning for staging patients with indolent lymphoma has not been embraced to the same extent that it has for DLBCL and Hodgkin lymphoma. Recent consensus guidelines recommend the use of PET-CT for staging in clinical practice and clinical trials for patients with FL and may be used to select the best site to biopsy.

Prognostic Factors

The prognostic importance of histologically distinguishing grade 1 or 2 FL from the more aggressive grade 3 FL is well accepted. However, most investigators have not found a clear difference in long-term survival between patients with grades 1 and 2 FL, although older literature suggested that FL grade 2 (nodular mixed-cell lymphoma, in older nomenclature) was more prone to early progression than grade 1 if therapy was deferred⁽³⁴⁾. Higher degrees of nodularity have been associated in some reports with improved outcome. An increased proliferation rate is associated with a poorer prognosis^(35,36).

Variables that have been shown to correlate with survival in patients with FL include tumor burden, host factors, and response to therapy. Tumor burden can be estimated by assessing stage of disease, size of nodal disease, bone marrow involvement, serum B2M, LDH levels, and number of nodal sites. Adverse host factors include advanced age, B symptoms, low hemoglobin level, male gender, and poor performance status. The background cells in the diagnostic lymph node biopsy may also provide prognostic information, as shown in gene expression profiling studies^(22,24).

The International Prognostic Index (IPI) was devised for aggressive lymphomas and consists of five variables: age, performance status, Ann Arbor stage, extranodal involvement, and serum LDH level⁽³⁷⁾. The IPI is also a useful predictor of survival in patients with indolent B-cell lymphomas. One important limitation of this system is that only 11% of the patients fell into the high-risk group, and most of these patients had poor performance status and would be poor candidates for aggressive therapy.

Partly for that reason, a Follicular Lymphoma International Prognostic Index (FLIPI) was developed. Initially, an eight-parameter model (age ≥ 60 years, male gender, Ann Arbor stages III and IV, nodal sites ≥ 5 , bone marrow involvement, serum LDH level greater than normal, hemoglobin level < 12 g/dL, and lymphocytes ≥ 1000 /mL) was proposed⁽³⁸⁾. However, a simplified version of this model was found to be comparably predictive, using the five parameters of age, Ann Arbor stage, serum LDH, hemoglobin level, and number of nodal sites⁽³⁹⁾. This prognostic model separates patients into three prognostic groups: good risk with 0 to 1 factors, intermediate risk with 2 factors, and poor risk with 3 or more factors. The overall 5-year survival was 90% for the good-risk group, 78% for the intermediate-risk group, and 53% for the poor-risk group⁽³⁹⁾. The validity of the FLIPI model has been demonstrated in rituximab-treated patients⁽⁴⁰⁾. A FLIPI-2 model was developed through the prospective collection of prognostic data, producing a five-factor model that incorporates age (> 60 years adverse); hemoglobin level

Table 7-2 Prognostic Models for Lymphoma

Prognostic Factor	Model		
	IPI	FLIPI	FLIPI-2
Age	✓	✓	✓

LDH	✓	✓	
Hgb		✓	✓
B2M			✓

PS, performance status; B2M, serum β -2-microglobulin.

(< 12 g/dL adverse); serum B2M level (adverse if above normal range); bone marrow (adverse if involved); and size of lymphadenopathy (> 6 cm adverse), which has not been validated⁽⁴¹⁾.

There are more similarities than differences in these models. For instance, the importance of serum B2M was shown in the univariate analyses of both the IPI and FLIPI data sets, but the B2M data were collected prospectively only in the FLIPI-2 report. The importance of sampling the bone marrow, as shown in the FLIPI-2 report, deserves particular emphasis, because practice patterns indicate that the important data offered are often not collected. Easily applied models such as the IPI, FLIPI, or FLIPI-2 can provide a framework for selecting the timing or intensity of therapy, and can facilitate the interpretation of clinical trials, by providing a tool to assess for disparities in patient selection when results of various trials are compared (Table 7-2).

At the time of relapse, favorable predictors for survival in patients with FL include having achieved a complete response with initial therapy, having had a durable remission of more than 1 year following initial therapy, and being less than 60 years of age.

Posttreatment Monitoring

An international working group has recommended end-of-treatment assessment and defined response criteria for NHL. These criteria have recently been updated, with important modifications, including incorporation of PET-CT⁽³⁰⁾. In FDG-avid FL, PET-CT should be used for response assessment, using the 5-point scale (1, no uptake above background; 2, uptake \leq mediastinum; 3, uptake $>$ mediastinum but \leq liver; 4, uptake moderately $>$ liver; 5, uptake markedly

higher than liver and/or new lesions). The criteria based on PET-CT eliminate complete response unconfirmed (CRu) evaluation and improve the prognostic value of a partial response (PR). A complete metabolic response (PET-CT), even with a persistent mass, is considered a complete remission (CR). With CT-based assessment, a complete radiologic response is determined by nodal masses regressing to 1.5 cm or less in the longest diameter and no extralymphatic sites of disease. Bone marrow reevaluation is performed to confirm clinical remission if the bone marrow was initially positive.

Although the monitoring of patients with molecular studies is not currently considered standard practice, detection of the t(14;18)/*IGH-BCL2* by PCR techniques has been useful in the monitoring of subclinical disease. “Molecular remission,” the disappearance of cells with the t(14;18) detected by PCR, used to be considered a rarity in patients with FL treated with standard therapy. Gribben et al reported that only 1 of 212 (0.5%) patients achieved molecular remission following conventional chemotherapy (⁴²). With high-dose therapy and stem cell transplantation (SCT), however, molecular remissions could be attained, and those with molecular remission experienced more durable remissions. Improvements in therapy have changed this picture. Even before the advent of anti-CD20 monoclonal antibody (MAb) therapy, more potent chemotherapy regimens were capable of inducing molecular remission in over half of patients. With the availability of rituximab, which can largely eradicate B cells from the blood and bone marrow, it is now common to see molecular remission. Some recent studies continued to show that molecular remission correlates with more durable clinical remission(^{43, 44}), but other studies did not (⁴⁵).

Surveillance Imaging

There are limited data supporting patient benefit from surveillance imaging in FL. As a consequence, there is considerable variation in practice. Zinzani et al performed one of the only prospective studies of surveillance imaging, which included 78 patients with FLs in first CR following induction therapy (⁴⁶). Patients received PET-CT scans every 6 months for 2 years, with annual scans thereafter. The relapse rate was 8% to 10% as shown by scans performed until 36 months and decreased after that time. As the purpose of the study was to describe specificity of scans, the impact on management and subsequent outcome was not reported. Gerlinger et al performed surveillance with annual CT scans and bone marrow biopsies in 71 patients with FL in second or subsequent remission following SCT (⁴⁷). Although approximately half of relapses were CT detected, few such patients required immediate treatment; there was no difference in overall survival between patients in whom disease relapse

was detected by imaging compared with clinical presentation. Their conclusion was surveillance imaging was futile in this setting. Surveillance CT scans result in radiation exposure, patient anxiety, and significant health-care costs, which should be carefully weighed against any potential benefit. The National Comprehensive Cancer Network (NCCN) guidelines suggest “surveillance CT scan up to every 6 months for the first 2 years following completion of therapy, and not more than annually thereafter.” In contrast, the European Society for Medical Oncology (ESMO) guidelines are more conservative, suggesting minimal adequate radiological or ultrasound investigations every 6 months for 2 years and annually thereafter. Regular CT scans are not mandatory outside clinical trials, and PET-CT should not be used for surveillance (⁴⁸).

Treatment of Limited-Stage Follicular Lymphomas

At diagnosis, approximately 15% to 20% of patients with FL have limited-stage disease (stages I and II). This stage of disease is associated with a favorable outcome, and up to half of these patients may be cured. Consequently, seizing the opportunity for cure should be strongly considered, even though some advocate deferral of therapy (⁴⁹). Several series have reported long-term disease-free survival of approximately 35% to 50% for stage I to II patients treated with involved-field radiotherapy (RT), so it appears that many of these patients are cured (⁴⁹⁻⁵³). Studies with extended-field or total lymphoid RT, in an attempt to increase cure rates, have not shown convincing additional benefit.

The integration of chemotherapy with involved-field RT has shown promising results in some trials. Investigators at MD Anderson Cancer Center (MDACC) prospectively treated 85 patients with stage I or II FL with 10 cycles of COP-Bleo (cyclophosphamide, vincristine, prednisone, and bleomycin) or CHOP-Bleo (COP-Bleo plus doxorubicin) and involved-field RT “sandwiched” after the third cycle. The disease-free survival at 5 and 10 years was 80% and 72%, respectively—an apparent improvement over results with RT alone (⁵⁴). Analysis of the National LymphoCare Study also demonstrated improvement in progression free survival (PFS) in patients who received systemic therapy in combination with RT (⁵⁵). The role of rituximab in stage I or II disease is not clearly defined; efficacy has been extrapolated from the advanced-stage literature. A prospective, randomized study is being conducted here at MDACC to investigate the addition of rituximab to RT in limited stage, previously untreated patients with FL; results are yet to come.

In summary, patients with limited-stage FL appear to be potentially curable. The role of RT in these patients is well established, so involved-field RT remains the standard

treatment (see Table 7-2). Despite the established role of involved-field RT and its endorsement by experts, RT appears to be underutilized in practice^(55, 56). Total lymphoid RT and combined-modality therapy approaches remain controversial and are seldom used.

Management of Advanced-Stage Follicular Lymphomas

For decades, the treatment of patients with advanced stage FL has been built on two pillars that lean in opposite directions. First, there are numerous effective therapeutic options that can induce remission (Table 7-3); second, relapse appears to be inevitable. If and when therapeutic advances lead to more comprehensive control of FL, then there may be consensus about early intervention because a smaller tumor burden would presumably be more easily treatable, analogous to the stage I or II situation. Until then, it is still the case that deferral of therapy is a common consideration for many asymptomatic patients with low tumor burden.

When treatment is deemed appropriate, there are a number of considerations in choosing an initial management strategy. With advances in supportive care, we have seen improvement in the tolerability of chemotherapy and SCT. With a better understanding of B-cell lymphomagenesis and the role of the microenvironment, noncytotoxic therapeutic strategies are being incorporated into front-line clinical trials. The range of therapeutic options for patients with advanced-stage FL remains broad (see Table 7-3). The therapeutic goals continue to focus on minimizing toxicity, providing palliation, and attaining durable CR. Consideration of a clinical trial when available is advisable.

Table 7-3 Management Strategies for Follicular Lymphoma and Other Indolent Lymphomas

Stages I-II	IF RT RT and CT ^a
Stages III-IV	Deferral of therapy (if no threatening disease) Single-agent alkylators Single-agent MoAb COP and variants, with MoAb CHOP and variants, ^a with MoAb FND and variants, ^a with MoAb RT (stage III) CT and RT ^a (stage III) Consolidation (see text) Maintenance (see text)

^aMDACC protocol approaches over the years (see text).

Rituximab Monotherapy

For patients with asymptomatic FL with a low tumor burden, deferment of therapy until the development of symptoms or high tumor burden has been accepted based on three randomized trials demonstrating survival equivalent to that with immediate therapy in the prerituximab era⁽⁵⁷⁻⁵⁹⁾. With the long-term safety and efficacy of rituximab established, observation has been challenged in the modern era with rituximab monotherapy in patients with low tumor burden. The goal is to delay the first cytotoxic chemotherapy and to have an impact on health-related quality of life.

The findings of a randomized trial of rituximab versus a watch-and-wait approach in asymptomatic, nonbulky patients with FL suggested patients who received rituximab monotherapy had a delay in progression in comparison to those with an initial watch-and-wait approach⁽⁶⁰⁾. Those who received rituximab maintenance following rituximab induction also reported improved quality of life. No significant difference in overall survival was reported.

The RESORT study was a randomized cooperative group trial evaluating two dosing strategies of rituximab monotherapy in patients with untreated, grade I or II FL of low tumor burden⁽⁶¹⁾. There were 289 patients randomized to either rituximab maintenance or retreatment after responding to rituximab induction (4 weekly doses). The median time to treatment failure (FFS) was similar (3.9 vs 4.3 years), quality of life was similar, and significant toxicity was infrequent among both strategies. For patients with FL with a low tumor burden, rituximab monotherapy followed by a retreatment strategy was associated with less rituximab use while providing comparable disease control to that achieved with a maintenance strategy.

For patients with untreated FL of low tumor burden not eligible for a clinical trial or deemed appropriate for more intensive therapy, an initial management strategy of rituximab monotherapy was associated with a delay in the need for cytotoxic therapy, was well tolerated, and was perceived by some to enhance their health-related well-being. Hence, the decision between observation and rituximab monotherapy should be made following a detailed discussion about the goals of treatment.

Rituximab Plus Chemotherapy

Several trials have shown convincingly that the addition of rituximab to chemotherapy leads to improved outcomes (Table 7-4). Incorporation of rituximab (R) has become standard. Suitable partners for rituximab in induction regimens include cyclophosphamide, vincristine, and prednisone (CVP); cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP); bendamustine (B); and fludarabine-based regimens

Table 7-4 Front-Line Rituximab-Plus-Chemotherapy Trials in Indolent Lymphoma

Regimen	Trial Design	% CR	% PR	% FFS (@ Time)	% Survival @ Time
R-CVP ^a	Phase III	41 ^a	40	52 (3 years) ^a	89 (30 months)

^bComparator arm R-CHOP.

^cComparator arm FND, followed by rituximab (maintenance).

(such as FND [fludarabine, mitoxantrone, and dexamethasone]) (^{57, 60-66}). Few randomized studies have been conducted to inform selection of frontline chemoimmunotherapy. Bendamustine-rituximab (BR) has been compared with R-CHOP in a randomized trial; BR appeared to be better tolerated and modestly more effective than R-CHOP (⁶⁶). A randomized study comparing R-CVP versus R-CHOP versus R-FM (fludarabine and mitoxantrone) reported R-CHOP and R-FM were superior to R-CVP in regard to time to treatment failure and PFS; however, both, particularly R-FM, were associated with a higher rate of adverse events (⁶⁷). A global phase III study randomized patients with indolent or mantle cell lymphoma to either BR or the standard therapy of R-CHOP or R-CVP, finding BR was noninferior and associated with an acceptable safety profile (⁶⁸).

The most common initial management strategy in the United States is currently chemoimmunotherapy (⁵⁶). A phase II study conducted here at MDACC reported on the efficacy and safety of a novel, non-chemotherapeutic strategy of rituximab and lenalidomide in untreated FL with high response rates (overall response rate [ORR] 98%, CR 87%) and manageable

toxicity (⁶⁹). This study provided the rationale for conducting a large, global phase III, randomized study investigating rituximab chemotherapy (R-CVP, R-CHOP, or BR) versus rituximab-lenalidomide in patients with untreated FL. Enrollment has completed; results are yet to come. The findings of this study may lead to a change in the treatment paradigm of previously untreated FL.

Maintenance Therapy

Rituximab maintenance (Table 7-5) has been widely utilized after frontline chemoimmunotherapy with the goal of extending the disease-free interval after induction. A randomized study investigated the efficacy of 2 years of rituximab maintenance following rituximab chemotherapy in patients with previously untreated FL (⁷⁰). Rituximab maintenance after chemoimmunotherapy significantly improved PFS (HR [hazard ratio] = 0.55, 95% CI [confidence interval] 0.44-0.68) and was generally well tolerated but had no significant impact on overall survival. Factors influencing the decision to pursue a maintenance strategy should include

Table 7-5 Maintenance Rituximab

	Induction	Induction Response		↑ FFS With
		% CR	% PR	Maintenance ^a
A. Front-line trials	Rituximab	9	58	Yes
	CVP	13	60	Yes
	Various + R	–	–	Yes
B. Salvage	Rituximab	0	28	Yes ^b
	R-CHOP	30	55	Yes
	R-FCM	41	54	Yes

^aMaintenance schedules and duration variable (see text).

^bBenefit of maintenance was matched by re-treatment at time of progression.

consideration of the patient's risk of early relapse, the response to induction therapy, and the financial burden of extended dosing.

Consolidation Therapy

A large multicenter randomized trial of radioimmunotherapy (RIT) consolidation therapy has shown a significant failure-free survival benefit when used after a variety of induction therapy regimens (⁷¹). Notably, the induction therapy included rituximab in only a minority of the patients. Still, the feasibility and impact of such a strategy is noteworthy. Prolongation of disease control was significant in subset analyses of both complete and partial responders to the induction therapy. Patients who attained only partial remission after chemotherapy commonly attained CR after RIT (77%).

Other trials have also studied RIT consolidation. A Southwest Oncology Group trial compared CHOP followed by RIT versus R-CHOP in patients with advanced-stage FL (⁷²). With a follow-up of 4.9 years, there was no significant difference in the 2-year PFS (80% vs 76%) or OS (overall survival) (93% vs. 97%) rates. With the benefits and safety profile of rituximab as part of induction or as maintenance established, the role of RIT in the modern era is unclear.

Salvage Therapy

There are many effective therapeutic options for patients with relapsed disease. The efficacy of single-agent rituximab has been demonstrated reproducibly, although most responses to salvage rituximab are PR rather than CR. Attempts at improving the rate of CRs and enhancing the duration of response are evolving (Table 7-6).

Newer anti-CD20 MAbs are being investigated, with modifications that theoretically represent enhancements over rituximab, such as fully humanized

MAbs as opposed to a chimeric mouse-human construct; MAbs with enhanced capacity for mediation of complement-dependent cytotoxicity; MAbs with enhanced mediation of antibody-dependent cellular cytotoxicity; and other modifications. Monoclonal antibodies that target antigens other than CD20 have been developed. CD19 and CD22 are B-cell-specific antigens that internalize following antibody binding. The development of therapeutic antibodies against these targets has included their use both alone and as immunotoxins, that is, as delivery systems for toxins, analogous to the delivery of isotopes with RIT.

Many therapeutic options under study in the past decade have been developed against specific cell growth regulatory pathways. These include targets of the B-cell receptor pathway: Bruton tyrosine kinase (BTK) inhibitors (eg, ibrutinib) (⁷³), phosphatidylinositol-3-kinase delta (PI3K δ) inhibitors (eg, idelalisib) (⁷⁴), and inhibitors of the proteasome or nuclear factor kappa B (NF- κ B) pathway (eg, bortezomib) (⁷⁵). As previously discussed, immune modulation is an attractive approach particularly in indolent lymphoma. Rituximab in combination with lenalidomide in the relapsed setting has been reported to be an effective salvage and bridge to SCT (⁷⁶). Enhancement of the endogenous antitumor response by targeting the microenvironment may be achieved with immune checkpoint inhibitors such as anti-PD1 MAbs. A recent study investigated the activity of pidilizumab with rituximab in 32 patients with relapsed FL and reported an ORR of 66% and CR rate of 52% with no autoimmune or treatment-related grade 3 or 4 adverse events (⁷⁷). With some of these agents, their categorization as "biological" or "targeted" therapy, rather than conventional cytotoxic therapy, may be arguable. Some of these targeted therapies are associated with myelosuppressive toxicity, as is seen with conventional chemotherapy.

Numerous non-cross-resistant chemotherapeutic agents can be effective in indolent lymphomas (Table 7-7).

Table 7-6 Consolidation Therapy Approaches

Induction	Consolidation	% CR After Induction	% CR After Consolidation	% CR + PR	% FFS (@ Times)
CHOP	Rituximab ^a	57	^a	94	44 (3 years)
FN	Rituximab ^a	68	^a	96	63 (3 years)
CHOP	Tositumomab	39	69	98	67 (5 years)
Various	Ibritumomab/Y-90	51 ^b	87 ^b	100 ^b	53 (3 years ^a)
R-FND	Ibritumomab/Y-90	69	89	89	73 (3 years)
Fludarabine	Tositumomab/I-131	9	86	100	60 (5 years)

^aIn these trials, rituximab crossover only for subset who did not attain molecular response: conversion to molecular remission occurred in 74% and 61% in the two trials.

^bTrial design accepted only CR and PR patients for RIT. FFS measured from study entry, before RIT but after induction chemotherapy.

Typically, those not chosen for a patient's frontline treatment are candidates for salvage use. It is notable that retreatment of previously responsive patients is a legitimate option. Long-term follow-up studies have shown that second and later responses can be attained, even with the same agents, but the ensuing clinical remissions become progressively more brief. Because some physicians advocate the avoidance of the toxicities of certain agents (eg, doxorubicin or the nucleoside analogs) in the frontline setting, their role in the salvage setting is an important consideration. Selected salvage chemotherapy regimens are listed in Table 7-7.

Novel agents such as idelalisib (PI3K δ i) have demonstrated efficacy (ORR 57%, CR 6%) with a manageable safety profile (grade ≥ 3 neutropenia, 27%; transaminitis, 13%; pneumonia, 7%) in relapsed/refractory FL, leading to Food and Drug Administration approval for use in patients who have had at least two prior lines of systemic therapy (⁷⁴). As a result, a number of B-cell receptor pathway inhibitors and immune modulators are currently under investigation either as monotherapy or in combination with chemotherapy and MAbs. With minimal additive toxicity, combination approaches are under way in an attempt to obtain higher complete response rates and extend disease-free intervals. Consideration of a clinical trial in the setting of relapsed or refractory FL is strongly recommended given the vast trial options available and evolving management strategies.

Stem cell transplantation approaches can be arduous, but deserve strong consideration in patients with recurrent high-risk-FL. Autologous SCT strategies result in substantially more durable remissions than conventional-dose salvage therapy (⁷⁸). Allogeneic SCT is a strategy that is contingent on availability of a donor, and it is a complex undertaking that includes real risks

of treatment-related mortality. Nonetheless, allogeneic SCT not only can result in long-term remission but also can potentially lead to cure, presumably through its graft-versus-lymphoma effect. Data suggest that non-myeloablative allogeneic SCT is associated with less toxicity than conventional myeloablative allogeneic SCT, and augmentation of the conditioning regimen, including incorporation of bendamustine, has resulted in reduced myelosuppression and graft-versus-host disease (⁷⁹). With improved tolerance of SCT and the potential for cure, this remains a management strategy for eligible patients.

Palliative treatment for FL can include involved-field RT to sites of problematic disease (eg, for obstructive uropathy). Among chemotherapy options, one historically mild option is chlorambucil. Observation without therapy is of course also an option, even at the time of initial diagnosis, in patients with active disease but no threatening or symptomatic disease. The approach of deferral of therapy is common, but it should be done thoughtfully and with monitoring. Because elderly patients are often selected for the “watch-and-wait” strategy, that option should be weighed against the observation that elderly patients with FL have a 10-fold increased risk of dying within 1 year compared with age-matched controls (⁴¹).

SMALL LYMPHOCYTIC LYMPHOMA/CHRONIC LYMPHOCYTIC LEUKEMIA

Small lymphocytic lymphoma represents approximately 7% of all NHLs (^{1,2}). The WHO classification restricts SLL to tumors involving lymph nodes with the same B-cell immunophenotype as CLL without leukemic involvement and considers SLL to be the nodal or tissue counterpart of CLL (²). Cases of SLL and CLL, combined, represent about 12% of all B-cell NHLs.

Clinical Features and Management

Patients with SLL often present with asymptomatic lymphadenopathy. The B symptoms are uncommon and are observed in less than 10% of patients. Splenomegaly is common. Bone marrow is often involved, affecting approximately 70% of patients (^{1,2}). Although the traditional staging systems for SLL and CLL differ, these systems share common features, and the prognosis of patients with SLL is similar to that of patients with CLL.

Management strategies for patients with FL and CLL are often applicable to patients with SLL, but there are some caveats. For instance, as CD20 is usually dimly expressed by SLL/CLL, anti-CD20 antibody therapy for SLL may be better modeled on the results in the CLL literature rather than the results of patients with FL. Conversely, the response to anti-CD52 antibody

therapy (alemtuzumab) seems to depend greatly on tissue penetration, and response is often inadequate at sites of bulky disease in patients with SLL/CLL⁽⁸⁰⁾.

Histologic, Immunophenotypic, and Molecular Features

The lymph node architecture is diffusely and usually totally effaced by SLL/CLL⁽²⁾. The neoplastic cells are predominantly small, round lymphocytes. Vague pale areas composed of lymphocytes, prolymphocytes, and paraimmunoblasts, known as proliferation centers (or pseudofollicles), are usually present and are diagnostic of this neoplasm. In 5% to 10% of SLL/CLL cases, residual reactive lymphoid follicles are present, surrounded by neoplasm; this represents the so-called interfollicular pattern of SLL/CLL. In this morphologic variant, proliferation centers can surround benign follicles, mimicking nodal MZL.

The SLL/CLL cells express monotypic immunoglobulin light chain, IgM, usually IgD, pan-B-cell antigens, and Bcl-2. CD23 is usually positive in 90% to 95% of cases, and CD22, CD79B, and FMC7 are negative in most cases. The density of Ig and CD20 antigen expression on the surface of SLL/CLL cells is characteristically low ("dim" immunofluorescence by flow cytometry). These neoplasms almost invariably express the CD5 antigen, a pan-T-cell antigen that is not expressed on normal B cells. Other T-cell antigens are negative. CD38 and ZAP70 are expressed by a subset of cases, and expression correlates with unmutated Ig genes and poorer prognosis⁽⁸¹⁾. The neoplastic cells are negative for CD10 and Bcl-6⁽²⁾.

Conventional cytogenetic analysis has shown chromosomal abnormalities in 50% to 60% of SLL/CLL cases. This low frequency is partly attributable to poor cell growth in culture. Translocations involving the Ig genes are rare in SLL/CLL. The t(14;19)(q32;q13) involving the *bcl-3* gene at 19q13 is most common but is present in less than 5% of SLL/CLL cases. The t(14;19) is associated with atypical morphologic or immunophenotypic features and a poorer prognosis.

Fluorescence in situ hybridization (FISH) analysis has shown a higher frequency of abnormalities in SLL/CLL because this technique can assess interphase as well as metaphase nuclei and does not require cell growth in culture. At our center, SLL/CLL cases are routinely assessed by FISH with a panel of probes, including those specific for 6q, 11q (ATM), trisomy 12, 13q14, and 17p (*p53*). Deletion of the 13q14 locus is the most common abnormality in SLL/CLL. Trisomy 12 is detected in approximately 15% to 20% of cases and appears to be a secondary event, as it is usually found in only a subset of the neoplastic cells⁽⁸²⁾. Both del (11q) and trisomy 12 have been correlated with poorer prognosis. Abnormalities of the *p53* or *MYC*

genes correlate with increased risk of histologic transformation (Richter syndrome) and poorer prognosis.

Monoclonal B-Cell Lymphocytosis

Monoclonal B-cell lymphocytosis (MBL) is defined as a monotypic B-cell expansion in peripheral blood that is less than $5 \times 10^9/L$ in a patient with no evidence of other signs or symptoms of a lymphoproliferative disorder (eg, lymphadenopathy or related autoimmune disease)⁽⁸³⁾. An older name used for MBL was *monoclonal B-cell lymphocytosis of uncertain significance*. This term is analogous to monoclonal gammopathy of undetermined significance, an early precursor of plasma cell myeloma that is detected in the bone marrow.

Cases of MBL have been further subclassified into three categories: CLL-like immunophenotype (CD5⁺, CD20 dim positive), atypical CLL immunophenotype (CD5⁺, CD20 bright positive), and non-CLL (CD5⁻, CD20 bright positive) immunophenotype. The CLL-like category is most common, representing at least 75% of all cases of MBL, and the overall frequency of CLL-like MBL in the general population has ranged in various studies from 3.5% to 12%. The frequency of CLL-like MBL increases with age, and over half of all patients over 90 years of age have CLL-like MBL.

Monoclonal B-cell lymphocytosis is covered elsewhere in this volume. The concept of CLL-like MBL, however, is relevant to lymph node diagnosis because a small percentage of patients who undergo surgery for carcinoma (or other nonlymphoid tumors) can have an incidentally detected CD5⁺ B-cell lymphoproliferative disorder in a lymph node, usually removed for staging purposes. Typically, the lesions only partially replace the architecture of the lymph node biopsy specimen, and there is no evidence of other sites of lymphadenopathy, hepatosplenomegaly, or absolute lymphocytosis. In one study, approximately 10% of patients with these findings progressed to overt CLL/SLL. Gibson and colleagues⁽⁸⁴⁾ proposed that the concept of clinical CLL-like MBL can be extended to lymph node biopsy specimens. The authors suggested that a lymph node biopsy specimen involved (usually partially) by a B-cell infiltrate with a CLL immunophenotype, but without proliferation centers, is the tissue equivalent of clinical CLL-like MBL if the patient had a peripheral blood monoclonal B-cell count of less than $5 \times 10^9/L$ and lymph nodes were less than 1.5 cm as shown by imaging studies⁽⁸⁴⁾.

MARGINAL ZONE B-CELL LYMPHOMAS

Although their names are similar, the MZLs are not closely related to MBLs at the genetic level and have different pathogeneses. The MZLs include extranodal

MZL of mucosa-associated lymphoid tissue (MALT lymphoma), nodal marginal zone lymphoma, and splenic B-cell marginal zone lymphoma (SMZL). Prior to the advent of immunophenotypic and molecular methods, MALT lymphomas were often classified as *pseudolymphomas*. Immunophenotypic and gene rearrangement studies showed that most pseudolymphomas express monotypic immunoglobulin light chain or carry monoclonal Ig gene rearrangements.

The MALT lymphomas represent 7% to 8% of all NHLs (^{1,2}). Nodal marginal zone lymphomas represent approximately 2% of all NHLs. Splenic MZL is rare, representing less than 1% of all NHLs (¹). Splenic MZL can be associated with circulating lymphocytes with villous cytoplasmic projections. The entity previously described as splenic lymphoma with villous lymphocytes is, in most cases, SMZL.

Extranodal Marginal Zone B-Cell Lymphoma

Clinical Features

Patients with MALT lymphoma present with extranodal disease that is often localized (stage I-E or II-E). There may be a history of infection or autoimmune disease, and the disease is usually indolent. Peripheral lymph node involvement is uncommon in patients with MALT lymphoma. The most common site of involvement is the stomach, but numerous other extranodal locations can be involved, including lung, skin, orbit, salivary glands, other parts of the gastrointestinal tract, thyroid gland, and other rare sites. Dissemination occurs in up to 30% of cases, most often in patients with nongastric MALT lymphoma, often to other extranodal sites. In patients with nongastric MALT lymphomas, subclinical gastric involvement is not uncommon. The bone marrow is involved in only 10% to 20% of patients.

The stomach is the best-studied site of involvement. Patients often present with signs and symptoms suggestive of peptic ulcer disease, such as epigastric pain and dyspepsia. Anemia, weight loss, and gastrointestinal bleeding can be seen in patients with more advanced disease. *Helicobacter pylori* is present in the gastric mucosa of many patients with MALT lymphoma. Antibiotic eradication of *H. pylori* has resulted in regression of MALT lymphoma in over half of treated patients (^{85,86}). Thus, *H. pylori* is thought to be essential to lymphomagenesis in gastric MALT lymphoma.

In nongastric MALT lymphomas, symptoms are related to the anatomic site involved. Disseminated disease is generally more common in these patients than in patients with gastric MALT lymphoma. Despite the higher frequency of stage IV disease, the 5-year survival is 90% with a variety of therapies.

Histologic Features

Four findings are present in most MALT lymphomas: a population of neoplastic small lymphoid (centrocyte-like) cells that may have monocytoid features, occasional large lymphoid cells (blasts), lymphoepithelial lesions, and reactive lymphoid follicles (Figs. 7-3 to 7-5).

The neoplastic small lymphoid cells exhibit a range of cytologic appearances. In some cases, the cells resemble small lymphocytes with or without plasmacytoid differentiation. In other cases, the neoplasm appears biphasic: One component is a population of small lymphoid cells, and the other is a population of cells with extensive plasmacytoid differentiation, resembling mature plasma cells (see Fig. 7-5). In other cases, the cells have markedly irregular nuclear contours and resemble small-cleaved cells. All of these cell types may have abundant pale cytoplasm, imparting a monocytoid appearance. In most MALT lymphomas, occasional large lymphoid cells (blasts) are also present. However, when large cells are numerous and form confluent sheets, the neoplasm has evolved to DLBCL.

The small neoplastic cells have a marked tendency to infiltrate epithelium, forming so-called lymphoepithelial lesions (see Fig. 7-4). In well-formed lesions, aggregates of neoplastic cells are found within the epithelium. Reactive lymphoid follicles are also usually present in MALT lymphomas, generally surrounded by neoplastic small lymphoid cells. Neoplastic cells can also accumulate in these follicles (termed *colonization*), imparting a vaguely nodular appearance at low-power magnification.

Anatomic site-specific histologic findings are also observed in MALT lymphomas, involving chronic antigenic stimulation as a result of either an infectious organism or autoimmune disease. For example, normal

FIGURE 7-3 Extranodal marginal zone B-cell lymphoma of MALT (MALT lymphoma) involving the stomach. The neoplasm partially replaces gastric mucosa and infiltrates epithelium. A reactive follicle is present at the bottom left of the field.

FIGURE 7-4 A MALT lymphoma of a salivary gland. **A.** The neoplastic cells have a pale (monocytoid) low-power appearance and surround ducts. **B.** Lymphoepithelial lesions are prominent in this case (**A, B**, hematoxylin and eosin; **A**, $\times 20$; **B**, $\times 400$).

lymphoid tissue is not usually present in the stomach. However, more benign forms of MALT are likely acquired, probably in response to *H. pylori* infection. *Chlamydia psittaci*, *Borrelia burgdorferi*, and *Campylobacter jejuni* are other infectious agents that have been associated with orbital, skin, and small intestinal MALT lymphomas, respectively, although the data linking *B. burgdorferi* to skin lymphomas does not appear to be strong. Like the stomach, normal lymphoid tissue is also poorly developed in the lung. However, two inflammatory diseases are frequently associated with lung MALT lymphoma: Sjögren syndrome and lymphoid interstitial pneumonia. Similarly, MALT lymphomas of the salivary gland are usually associated with Sjögren syndrome, and Hashimoto's thyroiditis usually precedes MALT lymphoma of the thyroid gland.

FIGURE 7-5 A MALT lymphoma of the conjunctiva. In this field, the neoplasm has a biphasic pattern, with the subepithelial portion exhibiting extensive plasmacytoid differentiation (periodic acid–Schiff, $\times 400$).

Immunophenotypic, Cytogenetic, and Molecular Features

The MALT lymphomas express monotypic Ig light chain, pan B-cell antigens, and Bcl-2. These tumors typically do not express IgD, CD10, CD21, CD23, Bcl-6, cyclin D1, or T-cell antigens, including CD5. Four chromosomal translocations are well characterized in MALT lymphomas: t(11;18), t(14;18), t(1;14), and t(3;14).

Finally, t(11;18)(q21;q21) has been identified in approximately 20% to 30% of MALT lymphomas. In this translocation, the *birc3* (formerly known as *api2*) gene on 11q21 and the *malt1* gene on chromosome 18q21 are disrupted and recombine to form a novel *birc3-malt1* fusion gene. The *birc3* gene belongs to the inhibitor of apoptosis protein (IAP) gene family that is evolutionarily conserved and plays a role in regulating apoptosis. *Malt1* is a novel gene that is critical to the function of BIRC3-MALT1. The t(11;18) is most common in MALT lymphomas of the lung and stomach.

The t(14;18)(q32;q21) has been identified in approximately 10% to 20% of MALT lymphomas. In this translocation, the *Malt1* gene is juxtaposed next to the IgH gene on the derivative chromosome 14. As a result, MALT1 is overexpressed. The t(14;18) appears to be most common in MALT lymphomas, arising in the ocular adnexal region and liver.

The t(1;14)(p22;q32) is an uncommon translocation in MALT lymphomas, occurring in less than 5% of cases; it juxtaposes the *bcl-10* gene at 1p22 adjacent to the IgH gene. This translocation truncates *bcl-10*, and thus Bcl-10 protein loses its proapoptotic function. Mutations of the *bcl-10* gene also occur outside the context of the t(1;14) in 7% to 10% of MALT lymphomas. These mutations consist predominantly of deletions or insertions and are predicted to result in truncated proteins.

The t(3;14)(p14;q32) has also been described in MALT lymphomas. This translocation juxtaposes the

foxp1 gene at 3p14.1 with the IgH gene. The t(3;14) appears to be most common in MALT lymphomas arising in the thyroid gland, ocular adnexal region, and skin. Vinatzer et al identified additional chromosomal translocations or partner genes in MALT lymphomas, including t(1;14)/IgH-CNN3, t(5;14)/IgH-ODZ2, t(3;14)/IgH-Bcl6, t(9;14)/IgH-JMJD2C, and t(6;7)(q25;q11) (⁸⁷).

Activation of NF- κ B may be a final common pathway in MALT lymphomas. API2-MALT1 is known to activate NF- κ B. Similarly, overexpression of MALT1 or Bcl-10, by binding with each other, can form a complex in the cell and act to activate NF- κ B (⁸⁸).

Workup and Management

The diagnosis of gastric MALT lymphoma is established by endoscopy, with multiple biopsies obtained from abnormal and normal mucosa (⁸⁵). Endoscopic ultrasound may also be helpful in determining the depth of the lesion and for staging. Early-stage disease can be successfully treated initially with antibiotic therapy, with complete regression in 35% to 100% of patients and a low rate of recurrence (⁸⁶). Therefore, the recommended therapy for stage I or II disease is a standard regimen of antibiotic therapy for *H. pylori* with follow-up endoscopy 2 to 3 months later to document *H. pylori* eradication. If patients remain *H. pylori* positive, a second-line anti-*Helicobacter* regimen is administered until they are *H. pylori* negative. The time between *H. pylori* eradication and CR of gastric MALT lymphoma varies and can take longer than 1 year. More extensive disease, as documented by endoscopic ultrasound demonstrating lymphoma involvement beyond the mucosa and in regional nodes, is less likely to respond to antibiotic therapy (⁸⁵). Lack of response has been correlated with the presence of the t(11;18).

Surgery, RT, chemotherapy, and anti-CD20 MAbs therapy have been used for both MALT lymphomas and other MZLs. The treatment of choice is dependent on the site of disease, the stage, and the patient's clinical presentation. Surgery and RT are prime therapeutic approaches for localized MALT lymphoma, including gastric MALT lymphoma that does not respond adequately to antibiotic therapy. Chemotherapy and MAbs therapy are also options, especially for widespread disease. Conconi et al studied rituximab in patients with MALT lymphoma and found significant activity in both untreated and relapsed patients (⁸⁹). By extrapolation from SLL/CLL data, combinations that include nucleoside analogues have been explored (⁹⁰). The best systemic treatment option is not clear.

Nodal Marginal Zone Lymphoma

Clinical Features and Management

Patients with nodal MZL typically present with peripheral or para-aortic lymphadenopathy and bone

FIGURE 7-6 Nodal marginal zone lymphoma. In this field, the neoplastic cells have abundant pale cytoplasm and surround a reactive germinal center composed of large cells (center of field) (hematoxylin and eosin, $\times 400$).

marrow involvement. The 5-year overall and failure-free survival rates are lower for patients with nodal MZL compared to patients with MALT lymphoma (56% vs 81% and 28% vs 65%, respectively). The majority of effective treatment regimens and outcomes of patients with nodal MZL are similar to that of patients with advanced FL.

Histologic, Immunophenotypic, and Molecular Features

Nodal MZLs have a propensity to involve the marginal zones of a lymph node. In most cases, however, the neoplasm also expands into the perifollicular compartments with sparing of germinal centers, or it completely replaces lymph node architecture. The cytologic features of nodal MZL are the most distinctive aspect of this neoplasm. The tumor cell cytoplasm is relatively abundant and pale, with well-delineated cell borders (Fig. 7-6). The tumor cell nuclei are small, chromatin is relatively clumped, and mitotic figures are infrequent. Rare large cells are also present.

Nodal MZLs are mature B-cell neoplasms that express monotypic Ig, pan B-cell antigens, and Bcl-2. These tumors do not express CD10, CD21, CD23, Bcl-6, cyclin D1, or T-cell antigens, including CD5. Conventional cytogenetics and FISH studies have identified a variety of abnormalities, most often trisomy 3. However, there are no unique recurrent chromosomal abnormalities in nodal MZL. The t(11;18), t(14;18), and t(1;14) have not been identified.

Splenic Marginal Zone Lymphoma

Clinical Features and Management

Patients with SMZL usually present with splenomegaly, cytopenias, and circulating malignant lymphocytes.

They commonly have modest abdominal lymphadenopathy and bone marrow involvement. Monoclonal gammopathy, usually of IgM type, can be observed in 10% to 20% of patients. Peripheral lymphadenopathy and B-type symptoms are uncommon. The clinical course is indolent, with the 5-year overall survival rate ranging from 65% to 78%.

Approximately one-third of patients with SMZL will never require therapy. Splenectomy is indicated in patients with symptomatic splenomegaly or cytopenias secondary to hypersplenism. If splenectomy is contraindicated, splenic irradiation may be an alternative. Alkylating agents have been used, but responses are usually partial and not durable. Patients treated with fludarabine demonstrate a higher response rate and longer-lasting remission than those treated with alkylating agents. Rituximab has significant activity in SMZL.

Histologic, Immunophenotypic, and Molecular Features

In SMZL, the white pulp is expanded by a neoplasm that initially replaces the marginal and mantle zones and then eventually replaces the white pulp (Fig. 7-7). Lesser red pulp involvement is also usually present. At high-power magnification, the neoplastic cells are small lymphocytes with abundant pale (monocytoid) cytoplasm. The neoplastic cells may exhibit plasmacytoid differentiation. Occasional large lymphoid cells are present. In a peripheral blood smear, the neoplastic cells can have villous cytoplasmic projections.

Splenic MZL is a mature B-cell neoplasm that expresses monotypic immunoglobulin, pan B-cell antigens, and Bcl-2. A subset of cases is positive for IgD or CD5 (dim intensity by flow cytometry). These

neoplasms are negative for CD10, Bcl-6, cyclin D1, and T-cell antigens (other than CD5).

Conventional cytogenetics and FISH analysis have identified a variety of abnormalities, most often trisomy of chromosomes 3 and 7. Deletion of 7q is present in approximately 50% of cases. A recent study using array-based comparative genomic hybridization has shown del(7q36.2) involving the sonic hedgehog (SHH) gene and del(7q31.32) involving the protection of telomere 1 (POT1) genes in SMZL⁽⁹¹⁾. MYD88 L265P mutations have been identified in 10% to 20% of cases of SMZL and correlate with IgM gammopathy⁽⁹²⁾.

LYMPHOPLASMACYTIC LYMPHOMA AND WALDENSTRÖM MACROGLOBULINEMIA

In the current version of the WHO classification, LPL is defined as a neoplasm composed of small lymphocytes, plasmacytoid lymphocytes, and plasma cells and most often involves the bone marrow but can also involve lymph nodes and spleen. Often, LPL is associated with a serum IgM paraprotein, but this feature is *not* required for the diagnosis of LPL⁽²⁾. Patients with LPL also can have a serum paraprotein composed of IgA or IgG, and the relationship of these cases to WM is not clear. In contrast, patients with WM have LPL involving the bone marrow associated with a serum IgM paraprotein of any level^(93, 94). Using these definitions, all patients with WM have LPL, but not all patients with LPL have WM.

Patients with LPL not meeting the criteria for WM are rare, and there is poor characterization. Furthermore, a serum IgM paraprotein can be observed in

FIGURE 7-7 Splenic marginal zone lymphoma. **A.** At low power, the white pulp of the spleen is markedly expanded by lymphoma, which has a biphasic pattern. **B.** One white pulp nodule at higher magnification (**A, B**, hematoxylin and eosin; **A**, $\times 20$; **B**, $\times 200$).

patients with other types of indolent B-cell lymphoma⁽⁹⁵⁾, and there is morphologic and immunophenotypic overlap with MZLs. For these reasons, our focus here is on WM.

Clinical Features

Some patients with WM can be asymptomatic, but many have symptoms of anemia, which is a common presenting feature. Only about 15% of patients have splenomegaly, hepatomegaly, or lymphadenopathy^(2, 94). The hyperviscosity syndrome—characterized by mucosal hemorrhage, visual disturbances, neurologic changes, and cardiac failure—is dramatic and classic but occurs in only a minority of patients with WM. Other even less-common manifestations include cryoglobulinemia, cold-agglutinin hemolysis, autoimmune thrombocytopenia, amyloidosis, and light-chain nephropathy^(93, 94).

Histologic, Immunophenotypic, and Molecular Features

The bone marrow is always involved in WM⁽⁹³⁾. Bone marrow aspirate smears show increased small lymphocytes, plasmacytoid small lymphocytes, and mature plasma cells, in varying proportions. Mast cells are commonly increased (Fig. 7-8). In the so-called polymorphous type of WM, large lymphoid cells are increased, 5% to 10%. Although the large cells do not form sheets and thus the criteria for large B-cell lymphoma are not met, patients with the polymorphous type have a poorer prognosis, suggesting that this is may be an early stage of large-cell transformation⁽⁹⁶⁾.

The cells of WM are composed of essentially two immunophenotypically distinct cell populations

corresponding to lymphocytes and plasma cells. The lymphocytes cells express monotypic surface Ig light chain, IgM, and pan B-cell antigens such as CD19 and CD20 and are negative for CD3 and Bcl-6. In most cases, the lymphocytes are negative for CD5, CD10, and CD23 by immunohistochemical staining; however, dim expression of CD5 and CD23 is not uncommon when assessed by flow cytometry. The plasma cells express CD19, CD38, and CD138 and are negative for CD20.

Conventional cytogenetics has shown no characteristic chromosomal abnormalities in WM. The most common cytogenetic abnormality is deletion (6q). The t(9;14)(p13;q32) is a rare abnormality reported in a subset of nodal small B-cell lymphomas with plasmacytoid differentiation, previously presumed to be LPL/WM. However, studies using conventional cytogenetics or FISH have not detected the t(9;14) in any case of WM.

The MYD88 L265P mutation is commonly present in cases of WM, ranging from about 80% to up to 95% of cases^(92, 97). This finding is now considered a part of the definition of WM by many observers and may be included as part of the disease definition in future versions of the WHO classification. Other gene mutations have been reported in WM. Of these, CXCR4 mutations are most common and correlate with tumor burden⁽⁹⁸⁾. The MYD88 L265P mutations also occur, at low frequency, in other indolent B-cell lymphomas, including SLL/CLL and MZLs. The MYD88 L265P mutation also seems to correlate with the presence of IgM gammopathy in other indolent B-cell lymphomas.

Management

A prognostic scoring system for patients with WM based on age, albumin, and number of cytopenias has been developed that stratifies patients into low-,

FIGURE 7-8 Waldenström macroglobulinemia involving bone marrow. **A.** The bone marrow aspirate smear shows numerous small neoplastic lymphocytes with occasional benign mast cells. **B.** The bone marrow biopsy specimen shows an interstitial and diffuse pattern of involvement by the neoplasm. (A, Wright-Giemsa, $\times 1,000$; B, hematoxylin and eosin, $\times 400$).

intermediate-, and high-risk groups. Other prognostic variables include performance status and serum B2M level. Patients in the low-risk group can be observed.

Alkylating agents such as chlorambucil or bendamustine, nucleoside analogues such as cladribine or fludarabine, and the anti-CD20 antibody rituximab, either as single agents or in various combinations, have been used as initial therapy for the treatment of patients with WM. Important novel options include incorporation of the proteasome inhibitor bortezomib or monotherapy with ibrutinib. Individual patient characteristics need to be weighed in choosing therapy, including the age of the patient, the need for rapid disease control, and consideration of the patient's later candidacy for an autologous transplant approach. For patients with relapsed or refractory disease whose initial remission lasted more than 1 year, retreatment with the same therapy can be considered. Transplantation, both autologous and allogeneic, can be considered for patients with relapsed or primary refractory disease who have good performance status.

Plasmapheresis is indicated for the management of hyperviscosity syndrome and may be helpful for other IgM-related disorders, such as cryoglobulinemia, neuropathy, amyloidosis, and light-chain nephropathy. Plasmapheresis is typically used on a short-term basis until chemotherapy takes effect. In patients with autoimmune conditions or clinical symptoms from cryoglobulinemia, corticosteroids may be helpful.

CONCLUSIONS

To date, most advanced-stage indolent B-cell lymphomas remain incurable. Novel approaches to therapy are continuing to be explored, including next-generation MAbs, pathway inhibitors, and immune modulators. These approaches to therapy and novel combinations will likely play an increasingly important role in the management of patients with indolent B-cell lymphomas. Allogeneic transplantation in indolent B-cell lymphomas continues to be an area of heightened interest, especially with the development of the better tolerated miniallogeneic transplant strategies. The importance of the graft-versus-lymphoma effect reflects our growing knowledge that the host's immune response is a potentially powerful tool that we have not yet fully exploited. As emerging therapies become integrated with the best of conventional therapies, it is optimistic that a curative approach for more patients with indolent B-cell lymphomas is achievable. Equally promising is widespread use of well-tolerated therapy that is associated with durable disease control resulting in chronic management. Also worthwhile of clinical exploration is identifying the most effective sequencing of therapy over an individual's disease course. With so many

unanswered questions and emerging novel strategies, consideration of clinical trials for indolent lymphoma is strongly recommended to facilitate the translation of important scientific breakthroughs.

Aggressive B-Cell Lymphomas

Jason R. Westin
Sergej N. Konoplev
Luis E. Fayad
L. Jeffrey Medeiros

It is clinically useful to divide non-Hodgkin lymphomas (NHL) into indolent and aggressive based on their clinical behavior (¹). Patients with indolent NHL typically have a survival of many years, even if untreated, but paradoxically are usually incurable. Patients with aggressive NHL have a survival time measured in weeks to months if untreated yet are usually chemosensitive and frequently curable. In this chapter, we focus on the clinical characteristics, pathology, and treatment of aggressive NHL.

EPIDEMIOLOGY

The incidence of NHL has increased over the last five decades, as reported by US and international registries (²⁻⁴). During the years 1993 to 1995, the age-adjusted incidence increased 3% per year according to data from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute (²). Some of this increased incidence can be attributed to the acquired immunodeficiency syndrome (AIDS), but this epidemic does not explain the increase of NHL before 1980. In the elderly population, there has also been a marked increase of NHL, largely the indolent NHLs, which are discussed in Chapter 7.

An estimated 71,850 new cases of NHL will be diagnosed in the United States in 2015, and 19,790 NHL-related deaths will occur. In 2014, NHL was the ninth largest cause of death among men and the eighth largest cause in women (3% of all cancer-related deaths). Diffuse large B-cell lymphoma (DLBCL), the most common NHL subtype, has an aggressive behavior and

is more common in whites than African Americans in the United States; however, 5-year survival outcomes are worse in African Americans (⁵).

ETIOLOGY

Most cases of aggressive NHL do not have a well-defined cause. Recent work has shown that the lifetime risk for many cancers correlates with the total number of divisions of normal self-renewing cells (⁶). The implications of these findings suggest that many cancers may not be due to heritable genetic aberrancies, environmental exposures, infectious etiologies, or other known causes, but instead are attributable to a combination of factors that may include chance. For the NHLs that appear to have currently identifiable drivers, there are four groups of drivers: immune suppression (both acquired and primary), infectious agents, toxic exposure, and familial (Table 8-1).

The strongest association is with immune suppression, both primary and acquired (⁷). Examples of primary immunodeficiency include inherited immune disorders, such as Wiskott-Aldrich syndrome, severe combined immune deficiency, common variable immune deficiency, and ataxia-telangiectasia (⁸). These and other inherited disorders are associated with an increased lifetime risk of developing NHL, with aggressive B-cell NHL being most common.

Patients who are immunosuppressed for therapeutic reasons—for example, after transplantation—are also at increased risk of NHL, especially if treated with cyclosporine, azathioprine, prednisone, or monoclonal

Table 8-1 Risk Factors Associated With Aggressive Non-Hodgkin Lymphomas

Inherited and acquired immune deficiency
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
Chédiak-Higashi syndrome
X-linked immunoproliferative disorder
Severe combined immunodeficiency
Common variable immune deficiency
Iatrogenic immune suppression
Solid organ or bone marrow transplant
Toxic exposures
Prior chemotherapy
Phenoxyherbicides
Dioxin
Radiation or radiation therapy
Infectious exposures
Epstein-Barr virus
Human T-cell leukemia/lymphoma virus
Human herpesvirus type 8 (HHV-8)
Human immunodeficiency virus (HIV)
Autoimmune disorders
Sjögren syndrome
Celiac sprue
Systemic lupus erythematosus
Rheumatoid arthritis

antibodies for the removal of T cells (⁹). A loose association can be drawn between the level of immune suppression and lymphoma risk. Transplant patients treated with the highest doses of immunosuppressive agents, such as heart transplant recipients, are at greater risk of developing lymphomas. These lesions are also more likely to be aggressive, extranodal forms. Individuals treated with pharmacologic immune suppression for autoimmune disorders—such as systemic lupus erythematosus, Sjögren syndrome, or rheumatoid arthritis—are also at increased risk for NHL, including the tumor necrosis factor antagonists (¹⁰). A subset of these NHLs is histologically aggressive and associated with Epstein-Barr virus (EBV). These lesions may regress following withdrawal of the immunosuppressive agent, speaking to the complex interaction between the immune system and an immune clonal population (¹¹).

Infectious agents associated with development of aggressive NHL include human immunodeficiency virus (HIV), EBV, human herpesvirus type 8, and human T-cell lymphotropic virus type 1 (¹²). The greatest factor involved in the worldwide increase in NHL, although lessened with the advent of highly active antiretroviral therapy (HAART), is HIV infection (¹³). The risk of NHL is increased by up to 300% in untreated HIV-infected patients, rising in proportion to the duration of the HIV infection. Although

the risk of NHL in HIV-infected patients appears to be decreased by HAART, the relative risk of NHL remains much higher than that for those not infected with HIV. Aggressive NHL can occur in HIV-infected patients at any stage of infection, but the risk increases as CD4 counts drop to $<100 \times 10^3/\mu\text{L}$, and NHL is considered an AIDS-defining illness.

EBV also plays a role in lymphomagenesis, due in part to chronic antigenic stimulation (¹⁴). EBV is virtually always associated with certain types of NHL, such as endemic (African) Burkitt lymphoma (BL) and extranodal T-cell/natural killer (NK)-cell lymphoma of nasal type, with many other NHL subtypes occasionally involved. Many patients with HIV-related lymphomas are co-infected by EBV, including HIV-associated primary central nervous system (CNS) lymphoma, which is infected in essentially 100% of cases (¹⁵). Human herpesvirus type 8 is associated with primary effusion lymphoma (PEL), which tends to occur in HIV-infected patients. Human T-cell lymphotropic virus type 1 is associated with adult T-cell lymphoma/leukemia.

Environmental and occupational exposures to toxins are associated with an increased risk of NHL (¹⁶). Herbicides, especially phenoxyacetic acid derivatives, are associated with NHL, especially in the farming belts of the United States. Occupations held by individuals reported to be at increased risk for NHL include farming, metalworking, forestry, aircraft maintenance, woodworking, and dry cleaning. One of the common exposures in these industries is the use of organic solvents.

Family history of NHL is also a potential risk factor for some lymphomas. Individuals who have relatives with NHL may have a slightly higher risk of developing NHL, but data are inconclusive and mechanisms are unclear (¹⁷).

CLINICAL PRESENTATION

The clinical presentation of patients with aggressive NHL varies substantially based on histologic type and anatomic site of disease. The likelihood of B symptoms, including fever greater than 38°C, night sweats, or weight loss greater than 10% of body weight in the preceding 6 months, increases with NHL aggressiveness. Approximately 50% of patients present with these B symptoms, often with fatigue, malaise, and pruritus, although these are less common initially.

Most patients present with painless lymphadenopathy, which is often first treated with antibiotics for presumed infection and eventually biopsied when lymph nodes fail to regress. The most common scenario involves a diagnosis based on examination of peripheral lymph nodes, which may be detectable prior to internal lymph nodes becoming enlarged and causing

symptoms. Peripheral lymph nodes are not usually painful, unless they are rapidly enlarging or are massive. Symptoms vary with the anatomic site of internal lymphadenopathy. Patients with mediastinal lymphadenopathy frequently experience cough, chest pain, and less commonly superior vena cava syndrome. Patients with large nodal masses in the abdomen or retroperitoneum frequently experience pain, abdominal fullness, or early satiety. Retroperitoneal lymphadenopathy can cause back pain and discomfort.

Extranodal disease is common in patients with aggressive NHL. The most common extranodal sites are the intestines, tonsils, and skin, although the frequency of involvement of these sites varies across reports. Disease in the gastrointestinal (GI) tract can present with nonspecific symptoms, including obstruction, blood loss with subsequent anemia, or diarrhea. Other extranodal sites include liver, lung, testis, bones, CNS, and spleen; however, aggressive extranodal NHL may involve nearly any organ system.

CLINICOPATHOLOGIC CHARACTERISTICS

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Diffuse large B-cell lymphoma is the most common type of NHL (^{1, 18}). It occurs mainly in adults, with a median age in the sixth decade. Men are affected slightly more often than women. B-type symptoms or bulky disease occurs in one-third of patients. Nodal presentation is most common, but extranodal sites are involved in approximately 40% of patients (Figs. 8-1 and 8-2), and more than one-third of patients have more than one extranodal site of disease. Slightly more than half of patients have stage III or IV disease (¹⁹). Bone marrow involvement occurs in approximately 10% to 20% of patients. Diffuse large B-cell lymphoma uncommonly involves privileged sites, such as the testis and CNS, of which the latter portends a poor prognosis.

If untreated, DLBCL is invariably fatal, but DLBCL is generally sensitive to chemotherapy, at least initially. With current immune-chemotherapy approaches, a slight majority of patients will be cured of their disease, with 2-year event-free survival of approximately 70% (²⁰). The International Prognostic Index (IPI) score remains a widely used prognostic model, despite not accounting for any tumor-specific biologic features. With rituximab plus chemotherapy-based disease management, the 4-year progression-free and overall survival rates for DLBCL patients with a Revised IPI (R-IPI) of 0, 1 to 2, and 3 to 5 are as shown in Table 8-2 (²¹).

FIGURE 8-1 Computed tomography scan showing diffuse large B-cell lymphoma with extensive lymph node involvement in the neck.

These data are generally useful but unfortunately are not predictive of outcomes for an individual patient. Nearly half of patients will have a poor-risk R-IPI, and of these patients, approximately half will be cured and half will die of disease. Few patients with relapsed disease are cured.

The diagnosis of DLBCL is based on its diffuse growth pattern and large neoplastic cells, with frequent

FIGURE 8-2 Computed tomography scan showing diffuse large B-cell lymphoma as a periorbital mass.

Table 8-2 Survival Rates for Diffuse Large B-Cell Lymphoma Patients

Revised IPI	No. of Factors Present	% of Patients	4-Year PFS	4-Year OS
Very good	0	10	94	94
Good	1-2	45	80	79
Poor	3-5	45	53	55

IPI, International Prognostic Index; OS, overall survival; PFS, progression-free survival.

mitotic figures (¹). Cytologically, the neoplastic cells can be subdivided as large centrocytes, centroblasts, or immunoblasts. Large centrocytes range from 13 to 30 mm in size and have irregular or cleaved nuclear contours, relatively small, indistinct nucleoli, and a thin rim of eosinophilic cytoplasm. Centroblasts are 20 to 30 mm in size and have round or oval vesicular nuclei with two or three nucleoli and more abundant amphophilic cytoplasm (Figs. 8-3 and 8-4). Immunoblasts are larger than centroblasts, with an eccentrically located vesicular round or oval nucleus containing a prominent target-like central nucleolus and relatively abundant amphophilic, often plasmacytoid cytoplasm (Fig. 8-5). Elevated proliferation (Ki-67) rates and immunoblastic features appear to correlate with *MYC* rearrangements (²²).

Immunophenotypic studies have shown that DLBCLs are of mature B-cell lineage. Approximately two-thirds of cases express monotypic immunoglobulin (Ig). These tumors express pan-B-cell antigens, 60% to 70% express *BCL2*, and a subset is positive for CD10 and *BCL6*.

Diffuse large B-cell lymphomas are heterogeneous at the molecular level. A subset of cases carries the

FIGURE 8-4 Diffuse large B-cell lymphoma. Fine-needle aspiration of cervical lymph node. The neoplastic cells are large (compared with neutrophils in field) with abundant basophilic cytoplasm (Wright-Giemsa, 1,000×).

t(14;18) involving *BCL2*, as shown by conventional cytogenetic or molecular studies (^{23,24}). Another subset of DLBCLs has translocations or other abnormalities involving *BCL6* at chromosome 3q27. *BCL6* is rearranged in approximately 20% to 40% of DLBCLs, more often in tumors arising at extranodal sites (²⁵). Recently, DLBCLs with translocations involving both *MYC* and *BCL2* or *BCL6*, representing approximately 5% to 10% of DLBCL, have been shown to have an extremely aggressive behavior and are commonly referred to as “double-hit” DLBCL (²⁶). Diffuse large B-cell lymphomas with overexpression of *MYC* and *BCL2* or *BCL6* protein levels are more common and are designated double-positive DLBCLs. These tumors are still adverse compared to DLBCLs without protein overexpression but less so than translocation-defined double-hit DLBCLs (²⁷⁻²⁹).

FIGURE 8-3 Diffuse large B-cell lymphoma. A. The neoplastic cells are large with vesicular chromatin and are arranged in a diffuse pattern. B. The neoplastic cells are positive for CD20. (A, hematoxylin-eosin, 1,000×; B, immunohistochemistry, 400×.)

FIGURE 8-5 Diffuse large B-cell lymphoma, immunoblastic variant. The neoplastic cells are large with prominent central nucleoli imparting a “target-like” appearance (hematoxylin-eosin, 1,000×).

Gene expression profiling (GEP) can molecularly divide DLBCL into three groups: germinal center B-cell like (GCB), activated B-cell like (ABC), and a third noncharacteristic group. Patients with the GCB type of DLBCL have a better prognosis independent of the IPI^(30, 31). Despite the initial GEP studies of DLBCL occurring approximately 15 years ago, this technology is not routinely used in clinical practice due to logistical issues and need for significant bioinformatic analysis. Fortunately, new technologies may allow these issues to finally be overcome by limiting the number of genes analyzed, such as in the Lymph-2Cx Nanostring assay (Nanostring, Seattle, WA)⁽³²⁾. In lieu of GEP, a limited number of immunohistochemical markers, including CD10, MUM-1, BCL6, GCET1, and FOXP1, can subclassify DLBCL into GCB and non-GCB with relatively good concordance with GEP^(33, 34).

Diffuse Large B-Cell Lymphoma Clinicopathologic Subtypes

T-Cell/Histiocyte-Rich B-Cell Lymphoma

T-cell/histiocyte-rich (TCHR) DLBCL is a diffuse neoplasm in which most of the cells are reactive T cells and histiocytes and the large, neoplastic B cells represent <10% of all cells in the infiltrate (Fig. 8-6). Patients with TCHR-DLBCL commonly have a history of nodular lymphocyte-predominant Hodgkin lymphoma, and TCHR-DLBCL may represent a transformation event in some patients.

Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System

This entity includes all primary intracerebral or intra-ocular lymphomas. Although these lymphomas are remarkable for their unique clinical presentation, histologically and at the immunophenotypic level, these neoplasms closely resemble other cases of systemic DLBCL. In HIV-positive patients, the neoplastic cells commonly have immunoblastic features and are positive for EBV. Approximately, one-third of the cases demonstrate translocations involving the *BCL6* gene.

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

As the name suggests, DLBCL, leg type, presents as cutaneous lesions originally described in the lower extremities, although all skin sites may be affected. Lesions often are initially confused with an insect bite, but eventually become diffuse and ulcerated, and the clinical course is aggressive. Histologic sections show diffuse sheets of monotonous neoplastic cells with centroblastic or immunoblastic morphology with frequent mitotic figures⁽³⁶⁾. The neoplastic cells have a non-germinal center B-cell immunophenotype, and

FIGURE 8-6 T-cell/histiocyte-rich large B-cell lymphoma. A. Scattered large neoplastic lymphoid cells in a background of numerous small lymphocytes. B. The large neoplastic cells are positive for CD20, and the small lymphocytes are T cells (immunostain not shown [A, hematoxylin-eosin, 630×; B, immunohistochemistry, 200×]).

fluorescence in situ hybridization studies often detect rearrangements of *BCL6*, *IGH*, and/or *MYC* ⁽³⁷⁾.

Epstein-Barr Virus–Positive Diffuse Large B-Cell Lymphoma of the Elderly

This DLBCL is most common in the elderly, defined arbitrarily as >50 years of age but can occur in younger patients and often presents at an advanced stage. Epstein-Barr virus is a defining feature. Histologically, these neoplasms have a diffuse pattern and show a spectrum of features, and two morphologic variants are recognized: polymorphous, with a broad range of B-cell maturation in the reactive background, and monomorphous, which contains mostly large cells ⁽¹⁾. Geographic necrosis is common, and the neoplastic cells usually have a non-germinal center B-cell immunophenotype.

Intravascular Large B-Cell Lymphomas

These are rare neoplasms in which the lymphoma cells are confined to intravascular spaces ⁽¹⁾. The histologic diagnosis can be subtle, and therefore, diagnosis can be delayed. The neoplastic cells are large, express B-cell antigens, and usually have a non-germinal center B-cell immunophenotype. The molecular basis of intravascular large B-cell lymphoma is unknown (Fig. 8-7).

Primary Effusion Lymphoma

Primary effusion lymphoma, also known as body cavity–based lymphoma, is a very rare neoplasm of large B cells that involves a body cavity and is almost always associated with AIDS ⁽³⁸⁾. The prognosis for patients with PEL is poor. Human herpesvirus type 8 (also known as Kaposi sarcoma–associated herpesvirus) is present in virtually all cases of PEL, and its presence selects for a distinct cellular gene expression profile ⁽¹⁾.

EBV is also present in most cases of PEL. An extra-cavitary (solid) variant of PEL also can occur, involving lymph nodes or extranodal sites ⁽³⁹⁾.

Primary Mediastinal (Thymic) B-Cell Lymphoma

These neoplasms are thought to arise in the thymus, are usually localized to the thoracic cavity, and occur more frequently in young women, with a female-to-male ratio of 2:1 ⁽¹⁾. Patients with primary mediastinal B-cell lymphoma (PMBL) present frequently with cough and dyspnea mimicking a respiratory infection or, rarely, superior vena cava syndrome. Histologically, PMBL has a diffuse pattern and is composed of large lymphoid cells that exhibit a spectrum of cytologic appearances: centroblastic, immunoblastic, or a mixture. Sclerosis is common, mitotic figures are usually numerous, and the tumor cells can have clear or pale cytoplasm. Immunophenotypic studies have shown that PMBLs are frequently Ig negative and commonly lack major histocompatibility complex class II antigens. Gene expression profiling analysis of PMBL has shown significant overlap with classical Hodgkin lymphoma ⁽⁴⁰⁾. Rearrangements of *CIITA* occur in about 40% of PMBLs, and amplification of the chromosome 9p24.1 locus (site of programmed death ligands) and mutations of *PTPN1* have been reported in about 25% of cases ⁽⁴¹⁾. These molecular abnormalities highlight the interaction between the immune system and PMBL in pathogenesis and suggest potential therapeutic targets.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) represents approximately 6% of all NHLs ⁽¹⁹⁾. Patients with MCL have a median age in the seventh decade, and MCL has a male-to-female ratio of approximately 3:1 ⁽⁴²⁾. Most

FIGURE 8-7 Intravascular large B-cell lymphoma involving bone marrow. A. Large neoplastic cells are present with a small blood vessel. B. The anti-CD20 antibody highlights numerous large neoplastic cells within many blood vessels. (A, hematoxylin-eosin, 1,000 \times ; B, immunohistochemistry, 400 \times .)

FIGURE 8-8 Mantle cell lymphoma, nodular pattern (hematoxylin-eosin, 50 \times).

patients present with advanced-stage disease, with bone marrow involvement in approximately 60% of patients, and most patients have low-level involvement of the peripheral blood. Overt leukemia may be associated with a poorer prognosis. Although GI symptoms are uncommon, 85% to 90% of MCL patients have GI involvement (⁴³). Blastoid MCLs have a more aggressive clinical course and often have occult CNS involvement. In the peripheral blood, MCL can sometimes resemble B-cell prolymphocytic leukemia.

Histologically, in classical MCL, the lymph node architecture is replaced by a diffuse or vaguely nodular neoplasm (Fig. 8-8) (¹). In a subset of cases, a mantle zone pattern results when the neoplasm selectively involves the follicular mantle zones surrounding normal or reactive germinal centers (Fig. 8-9). Cytologically, MCL is composed of a monotonous population of small lymphoid cells with slightly or clearly irregular

FIGURE 8-9 Mantle cell lymphoma, mantle zone pattern (hematoxylin-eosin, 50 \times).

FIGURE 8-10 Mantle cell lymphoma. In this field, a uniform population of small, irregular lymphoid cells can be seen (hematoxylin-eosin, 400 \times).

nuclear contours (Fig. 8-10). In about 15% of cases, MCL may show blastoid (lymphoblastic-like) or pleomorphic (large cell-like) features. These neoplasms are associated with a poorer prognosis and have a high frequency of *TP53* or *TP16* mutations.

Mantle cell lymphomas express monotypic Ig light chain IgM, IgD, pan-B-cell antigens, BCL2, SOX11, alkaline phosphatase, and CD5 (²¹). A high proliferation rate, most often assessed by Ki-67 immunohistochemical analysis, predicts a poorer prognosis. *t*(11;14) (q13;q32) is present in virtually all cases of MCL (⁴⁴). In this translocation, *CCND1* on 11q13 is juxtaposed with *IGH* on 14q32, resulting in overexpression of cyclin D1 (Fig. 8-11). Cyclin D1 facilitates cell cycle transition from G₁ to S phase (⁴⁵). Although *t*(11;14) is central to the pathogenesis of MCL, *t*(11;14) is insufficient

FIGURE 8-11 Mantle cell lymphoma, blastoid variant. The neoplastic cells are large and pleomorphic and were cyclin D1 positive (immunostain not shown) (hematoxylin-eosin, 1,000 \times).

to cause lymphomagenesis. Conventional cytogenetic studies have shown a number of additional abnormalities^(46,47), and a number of gene mutations have been reported.

Burkitt Lymphoma

There are three variants of BL: endemic (African), sporadic (nonendemic), and AIDS-associated^(21,48). Endemic BL was first described in equatorial Africa and is associated with EBV infection in 95% of patients⁽⁴⁸⁾. The median age of patients is approximately 7 years, with a 3:1 male-to-female ratio⁽⁴⁹⁾. Abdominal and retroperitoneal lymph nodes, the GI tract, and the gonads can be involved.

Sporadic BL occurs in industrialized nations and is associated with EBV infection in approximately 25% of patients. Patients are usually in the second or third decade of life, with a male-to-female ratio of 3:1. Involvement of the jaw is uncommon, and patients may present with large masses in the abdomen, peripheral lymph nodes, pleura, or pharynx⁽¹⁹⁾. In endemic or sporadic BL, bone marrow and CNS involvement are uncommon at presentation, but they are frequent sites of subsequent dissemination.

Burkitt lymphoma can also occur in the clinical setting of immunosuppression, including HIV infection, posttransplant, or congenital immune deficiency setting⁽¹⁹⁾. Epstein-Barr virus infection occurs in 30% to 40% of cases.

Morphologically, all variants are similar. The relatively clear histiocytes in a background of blue lymphoma cells imparts a “starry sky” appearance (Fig. 8-12A). This pattern results from rapid cell turnover with individual cell necrosis and scavenging of debris by macrophages. The neoplastic cells are round to ovoid, uniform in shape, and approximately the size of benign histiocyte nuclei. The chromatin is coarse, with two to five prominent basophilic nucleoli. Mitotic figures are numerous.

Burkitt lymphomas of endemic, sporadic, and AIDS-associated types are of mature B-cell lineage and express Ig, pan-B-cell antigens, CD10, and BCL6⁽²³⁾. Burkitt lymphomas have a very high proliferation rate (>99%) using an antibody specific for Ki-67 (Fig. 8-12B and C) and are negative for BCL2. *MYC* translocations are characteristic of BL. Approximately, 80% of cases carry the t(8;14)(q24;q32), with the remaining cases having one of two variant translocations, t(2;8)(p11;q24) or t(8;22)(q24;q11)⁽⁵⁰⁻⁵²⁾. Common to each of these translocations is involvement of chromosome region 8q24, the site of the *MYC*, which is deregulated. Via these translocations, *MYC* is juxtaposed with the IgH or the Ig light chain genes.

B-Cell Lymphoma With Features Intermediate Between Diffuse Large B-Cell Lymphoma and Burkitt Lymphoma

This entity in the 2008 edition of the World Health Organization (WHO) classification of hematopoietic neoplasms is designed for cases that do not fit either DLBCL or BL⁽¹⁾. In the past, these cases were designated as atypical Burkitt/Burkitt-like lymphoma or as high-grade B-cell lymphoma or B-cell lymphoma with high-grade features. This group often exhibits morphologic and immunophenotypic deviation from typical cases of BL and DLBCL. These neoplasms have a diffuse pattern, often with a starry sky appearance, and a high proliferation rate (Fig. 8-13)^(53,54). A significant number of cases demonstrate *MYC* rearrangement, although in some of the cases, *MYC* rearrangement involves one of the non-Ig partners⁽⁵⁵⁾. Many cases of so-called double-hit lymphoma fit within this category. These cases commonly demonstrate strong BCL2 expression and a complex karyotype⁽⁵⁶⁾. The algorithm for diagnosis of high-grade B-cell lymphoma is illustrated in Fig. 8-14.

FIGURE 8-12 Burkitt lymphoma. A. The neoplastic cells are intermediate in size, similar to that of benign histiocyte nuclei, with multiple small nucleoli. A starry sky pattern is also seen in this field. B and C. The neoplastic cells are negative for BCL-2 (B) and are >99% positive for Ki-67 (C). (A, hematoxylin-eosin, 1,000 \times ; B, C, immunohistochemistry, 400 \times .)

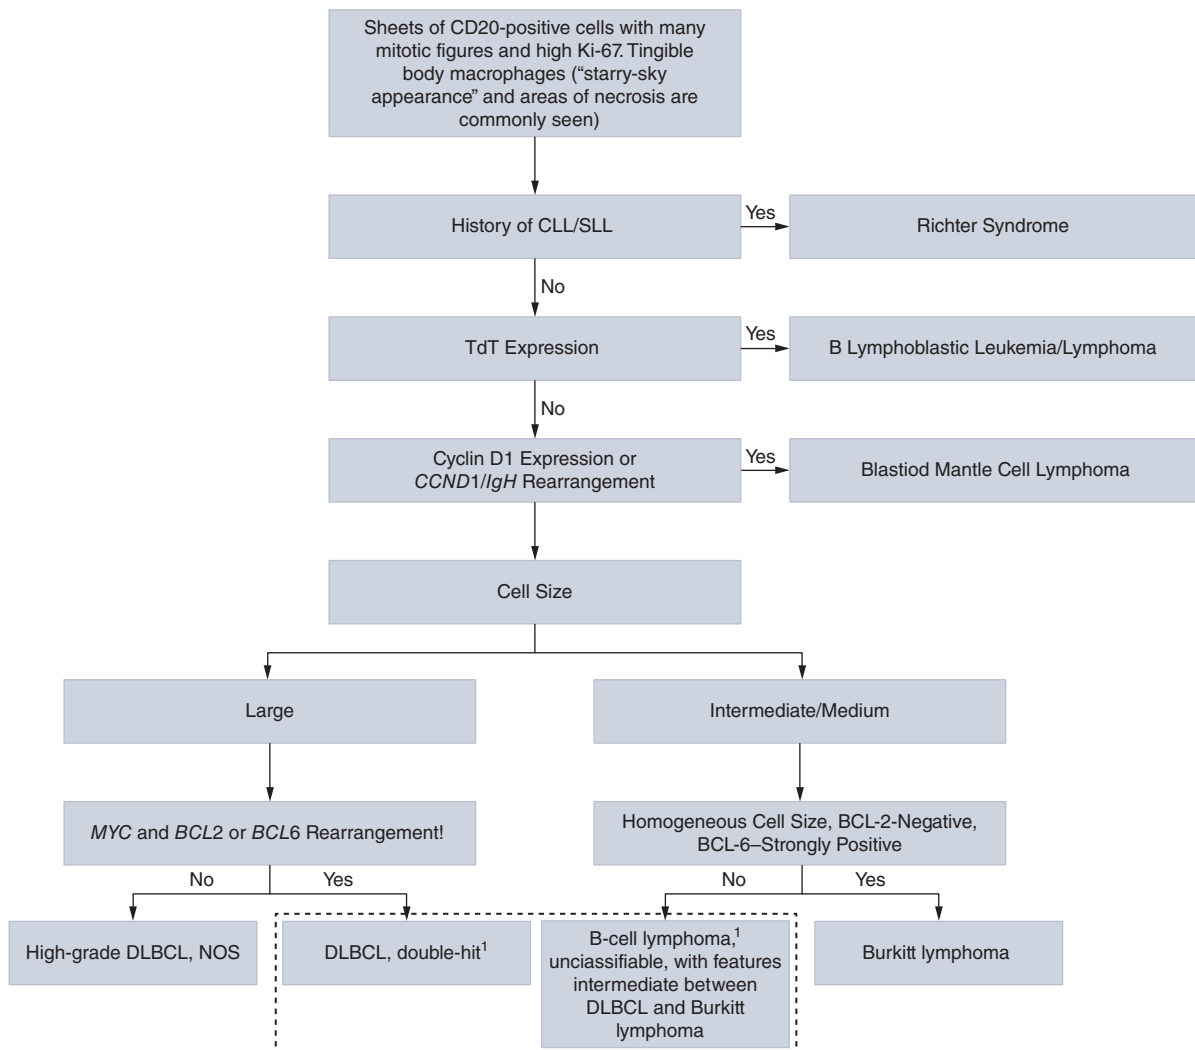

FIGURE 8-13 B-cell lymphomas with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma. Similar to Burkitt lymphoma, the neoplastic cells are intermediate-sized and demonstrate brisk mitotic activity, but unlike Burkitt lymphoma, cells have prominent single nucleoli (A). While the proliferative rate is similar to Burkitt lymphoma (B), the neoplastic cells strongly express Bcl-2 (C). In this case, fluorescence in situ hybridization detected both translocations t(8;14) and t(14;18), so-called double-hit lymphoma (Lymph node, A, hematoxylin-eosin, 1,000×; B, Ki-67 (Mib-1), 400×; C, Bcl-2, 400×).

The Diagnostic Approach to High-Grade B-cell Lymphoma

¹In the current WHO classification, B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma, also includes DLBCL, double-hit.

FIGURE 8-14 Algorithm for diagnosis of high-grade B-cell lymphoma. CLL, chronic lymphocytic leukemia; DLBCL, diffuse large B-cell lymphoma; NOS, not otherwise specified; SLL, small lymphocytic lymphoma; WHO, World Health Organization.

STAGING AND INITIAL EVALUATION

The Ann Arbor Staging system, developed in 1971 for Hodgkin lymphoma, is used to stage NHL (Table 8-3) ⁽¹⁹⁾. NHLs are often disseminated at diagnosis, unlike Hodgkin lymphoma. Of interest, there does not appear to be any meaningful difference in the outcomes of patients with stage III or IV disease, and thus the purpose of staging is to identify the patients with localized NHL who may benefit from additional local therapy.

A careful history and physical examination, including the presence of systemic symptoms, is essential. Performance status and comorbid conditions should be assessed. Physical examination should include a complete survey of all external lymph node groups including cervical, supraclavicular, axillary, epitrochlear, inguinal, and popliteal areas. Examination of abdomen for organomegaly is necessary, and in men, the testes should be examined. A complete neurologic examination must also be performed. Laboratory evaluation includes a complete blood count with differential, lactate dehydrogenase (LDH), β_2 -microglobulin, kidney and liver function tests, albumin, calcium, and uric acid. Testing for hepatitis B is indicated prior to rituximab therapy, as the virus may reactivate during or after treatment. Testing for HIV should always be performed, as should bone marrow aspiration and biopsy (bilateral biopsies for certain NHL types; also see comments on fluorodeoxyglucose [FDG] positron emission tomography [PET] and bone marrow findings below). Examination of the cerebrospinal fluid (CSF) should be strongly considered for patients with highly aggressive NHL; DLBCL associated with spinal

or paraspinal masses; renal or adrenal, ovarian, breast, or skull lesions; bone marrow involvement; testicular lymphoma; or nasal or sinus lymphomas; or any patient with clinical symptoms leading to suspicion of CNS involvement ⁽⁵⁷⁾.

Additional clinical evaluation is guided by the histologic type of NHL, symptoms, and anatomic sites involved by NHL. Lymphomas of the GI tract, especially in the stomach, require endoscopy for diagnosis unless other disease sites can be found to biopsy. It is especially important that multiple biopsies of different areas of the stomach be obtained because sampling error is frequent. There is no utility to gastrectomy or other surgical management for extranodal disease. Other types of aggressive NHL can involve the GI tract, especially MCL ⁽⁴³⁾. Evaluation of primary CNS lymphoma requires biopsy of the lesion, but a vigorous search for additional disease sites should be undertaken concurrently, because therapy for CNS and systemic disease will need to account directly for both.

Imaging Studies for Initial Staging

The use of imaging studies for evaluating lymphoma patients has evolved greatly. In 2014, FDG-PET-computed tomography (CT) scans were named the preferred imaging technique for FDG-avid lymphomas (essentially all aggressive NHLs) ⁽⁵⁸⁾. Based on these new guidelines, referred to as the Lugano criteria, a routine chest x-ray is no longer required. These guidelines also recommend that bone marrow biopsy could be omitted if the bone or marrow is FDG-avid on initial PET/CT scans. There still is significant controversy regarding the opposite situation: If the PET/CT scan does not show bone or marrow involvement, what is the utility of a bone marrow biopsy? Scant infiltration of DLBCL in the bone marrow (10%) may be missed with lack of FDG avidity, and thus, routine bone marrow biopsy may still be required for staging DLBCL patients (Figs. 8-15 and 8-16).

Limitations of PET/CT scan for staging of aggressive lymphoma include the fact that uptake of FDG is not specific to tumors and that infection and inflammatory processes are common false-positive findings on PET. As a result, an unexpected FDG-avid lesion that will result in a significant change in management should be confirmed by biopsy. The presence of high normal background activity in an organ, for example, in the kidneys or testes, may also make it difficult to identify abnormal FDG sites in that region. Although there is usually high normal metabolic activity within the brain, CNS lymphomas are often positive on FDG-PET scans, showing greater metabolic activity than the adjacent brain. However, additional imaging with magnetic resonance imaging (MRI) may be indicated for confirmation.

Table 8-3 ANN ARBOR Staging System for Non-Hodgkin Lymphomas^a

Stage I	Involvement of a single nodal group or extranodal site (I _E)
Stage II	Involvement of two or more nodal groups on the same side of the diaphragm or localized involvement of an extranodal site or organ (II _E) and one or more nodal groups on the same side of the diaphragm
Stage III	Involvement of nodal groups on both sides of the diaphragm, which may be accompanied by localized involvement of an extranodal region or site (III _E) of spleen (III _S) or both (III _{SE})
Stage IV	Diffuse or disseminated involvement of one or more distant extranodal sites

^aTemperature >38°C, weight loss >10% of body weight in the last 6 months, night sweats preceding diagnosis are defined as "B" symptoms and designated by the suffix B. Others are designated by the suffix A.

FIGURE 8-15 Positron emission tomography (PET) scan showing right cervical lymph nodes involved by diffuse large B-cell lymphoma.

Bone Marrow Evaluation

Bone marrow aspiration and biopsy should be performed as part of the initial staging evaluation because involvement suggests widespread disease (stage IV) that affects treatment and prognosis, with the caveat mentioned above (see previous section). Bilateral iliac crest assessment is preferred because sensitivity of detection is higher than unilateral biopsy⁽⁵⁹⁾. Although several studies found high accuracy of FDG-PET for predicting bone marrow involvement, a recent analysis concluded that the positive predictive value is high, but a negative FDG-PET is not completely concordant with the results of bone marrow biopsy⁽⁶⁰⁾. Of note, the pattern of uptake within the bone marrow spaces on FDG-PET is important, because a diffuse pattern is commonly seen with activation (eg, with underlying anemia or infection, or after chemotherapy or growth factor treatment), and caution should be taken in interpreting this as diffuse bone marrow involvement by tumor. In contrast, focal or nodular uptake within osseous structures is suspicious (Fig. 8-17).

FIGURE 8-16 Extranodal lymphoma on fluorodeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT). The patient presented with mediastinal lymphoma; this is easily seen on a maximum intensity projection (MIP) image from FDG-PET/CT. However, an additional focus is present in the right kidney; although not confirmed by biopsy, the renal lesion disappeared after chemotherapy, and the stage was changed from stage I to stage IV.

PROGNOSTIC FACTORS

Pretreatment

Prognostic factors in patients with aggressive NHL can be broadly grouped into pretreatment (tumor-related) and treatment-related characteristics. Tumor-related genetic characteristics of importance, as noted earlier, include germinal (GCB) or non-GCB origin genetic profile and presence of *MYC* and *BCL2* translocations (“double-hit”). Other tumor-related characteristics reported to be of prognostic value include a complex karyotype shown by conventional cytogenetics, high proliferation rate (high Ki-67 expression), and *BCL2* and/or *MYC* expression shown by immunohistochemical staining⁽¹⁾.

High serum LDH level is a measure of anaerobic metabolism and/or cell turnover and tumor bulk and is

FIGURE 8-17 Bone and bone marrow uptake on fluorodeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT). **A.** Typical pattern of marrow activation, commonly seen after chemotherapy or with growth factor treatment. This is diffuse but homogenous. In contrast (**B**), another patient had negative bilateral iliac crest biopsies but had focal activity in a destructive lesion involving the right humerus. Directed biopsy of this site was positive for bone involvement.

associated with a lower probability of complete remission and poorer long-term survival in patients with aggressive NHL. Other pretreatment prognostic factors include serum β_2 -microglobulin level, stage, number of disease sites, bulky disease, presence of bone marrow involvement, poor performance status, and age (⁶¹). Of these pretreatment factors, age appears to be the most important, with patients over the age of 60 having lower response rates and a higher rate of relapse (⁶²).

The most commonly used system to provide pretreatment prognostic information in patients with aggressive NHL is the IPI, first developed in 1993 (Table 8-4) (⁶³). These initial data resulted from a cohort of 2,031 patients treated with doxorubicin-containing regimens analyzed for the presence of factors that independently predicted survival. The most commonly used doxorubicin-based regimen at that time was CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) (Table 8-5). Significant prognostic factors were serum LDH (abnormal vs normal), age (<60 vs >60), number of extranodal sites (<2 vs >2), performance status (Eastern Cooperative Oncology

Group [ECOG] 0-1 vs 2-4), and stage (I and II vs III and IV). Each of the five factors had an equal impact on survival. Risk groups identified were low (zero to one factor), low/intermediate (two factors), high/intermediate (three factors), and high (four to five factors), with 5-year survival rates of 73%, 51%, 43%, and 26%, respectively. Stage, serum LDH level, and performance status were independent predictive prognostic factors in a simplified subanalysis of 1,274 subjects ≤60 years of age in the same study. In this subgroup, the 5-year survival rate was 83% for zero risk factors, 69% for one risk factor, 46% for two risk factors, and 32% for three risk factors. In patients over 60 years of age, the 5-year survival rates were 56%, 44%, 37%, and 21%, respectively. These data highlight the prognostic significance of age on the survival of patients with aggressive NHL.

The IPI has been broadly applied as the standard for prognosis in patients with aggressive NHL, although corrections or changes to the IPI have been proposed including the National Comprehensive Cancer Network IPI (⁶⁴), the IPI24 (⁶⁵), and the R-IPI, which accounts for the addition of rituximab to the frontline

Table 8-4 International Prognostic Index With Age-Adjusted Index

FACTORS					
Age	≤60 versus >60				
Serum LDH	Normal versus high				
Performance status	0 or 1 versus 2-4				
Extranodal disease	≤1 or less versus >1				
Stage	I or II versus III or IV

Table 8-5 Most Commonly Used Chemotherapeutic Regimens in Diffuse Large B-Cell Lymphomas

Regimen	Dose/Route	Days	Interval
FRONTLINE			
R-CHOP			
Cyclophosphamide	750 mg/m ² IV	1	21 days
Doxorubicin	50 mg/m ² IV	1	
Prednisone	100 mg PO	1-5	
Vincristine	1.4 mg/m ² IV	1	
Rituximab	375 mg/m ² IV	1	
SALVAGE (first salvage, preautologous SCT)			
RICE			
Rituximab	375 mg/m ² IV	1	14-21 days
Ifosfamide	5 g/m ² IV CI	2	
Mesna concurrent with Ifosfamide	5 g/m ² IVCI 2 over 24 h, then 2 g/m ² over 12 h	2-3	
Carboplatin ^a	Maximum 800 mg	2	
Etoposide	100 mg/m ² IV	2-4	
GCSF	5 mcg/kg/day SC	7-14	

^aCalculate Carboplatin dose using Calvert equation: AUC = 5 g/mL/min; dose = 5 × [25+Cl_{cr}] capped at 800 mg.

treatment of DLBCL (²¹). In the R-IPI, there are only three groups—low risk with zero risk factors, intermediate risk with one or two risk factors, and high risk with three or more factors—with 4-year progression-free survival (PFS) rates of 94%, 80%, and 53%, respectively.

Prognostic Factors in Mantle Cell Lymphoma

The same prognostic factors in the IPI for aggressive lymphomas are of utility in patients with MCL. Other adverse prognostic factors include *p53* mutations or deletion, elevated Ki-67, and blastoid histology. A prognostic model for MCL patients treated with chemotherapy followed by high-dose chemotherapy followed by autologous stem cell transplantation (Mantle Cell International Prognostic Index) was proposed using age, performance status, LDH, and leukocyte count (⁶⁶). Patients were divided in low-, intermediate-, and high-risk groups, with overall survival (OS) times of not reached, 51 months, and 29 months, respectively. In patients receiving rituximab plus hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone (R-hyper-CVAD), alternating with rituximab-methotrexate and cytarabine, this model could not be reproduced (⁶⁷). However, it was reproducible in patients treated with CHOP-rituximab-like regimens consolidated with high-dose chemotherapy with stem cell transplantation (⁶⁸).

Prognostic Factors in Primary Central Nervous System Lymphoma

Age and LDH are important prognostic factors in patients with HIV-negative primary CNS lymphoma; however, the most important factor is performance status at the time of treatment. Elevated LDH, CSF protein, and tumor mass location(s) are also contributors to prognosis (⁶⁹). Many patients can improve their condition by use of corticosteroids and thus be candidates for intensive chemotherapy-based regimens that are potentially curative.

Therapy-Associated Prognostic Factors

An important posttreatment prognostic indicator is tumor response to induction chemotherapy. In patients with aggressive NHL, dramatic response to induction with early complete remission (by the third cycle of therapy) is associated with a superior outcome (⁷⁰). Fluorodeoxyglucose PET has been found to be highly sensitive for the detection of aggressive NHL in posttreatment residual masses, but its ability to detect interim therapy response is controversial. Moskowitz et al found that DLBCL patients with persistent FDG avidity after four cycles of rituximab plus

CHOP (R-CHOP) had an 86% false-positive rate (PET/CT positive, biopsy negative for persistent disease) (⁷¹). Similar data have been shown by many others, highlighting the need for biopsy confirmation of a positive PET/CT scan prior to therapeutic decisions.

Patients who fail to achieve at least a good partial response to induction chemotherapy have primary refractory disease and short survival despite all efforts. Another important indicator of prognosis is duration of remission obtained after induction chemotherapy, because patients with relapses occurring at <1 year have a worse outcome (⁷²).

APPROACH TO THERAPY

Early-Stage Aggressive Non-Hodgkin Lymphoma

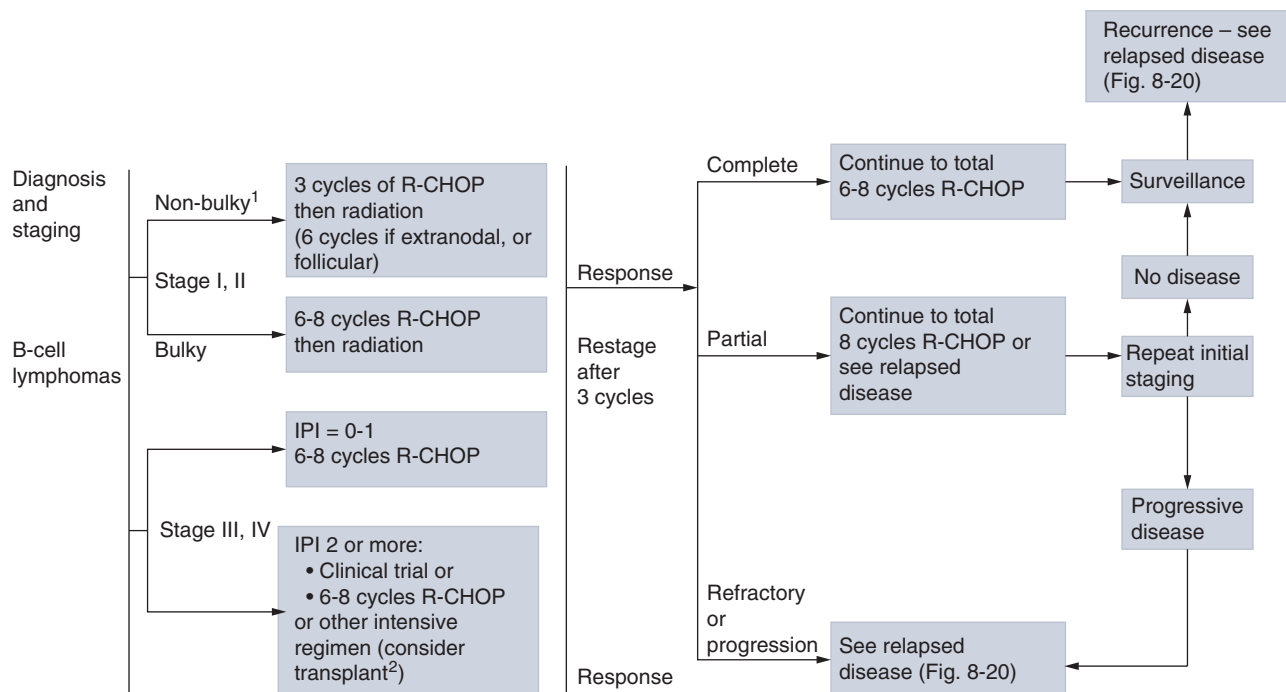

Early-stage (localized) aggressive NHLs (stages I and contiguous II) were historically treated with radiation therapy (RT) alone, and the results were highly variable (⁷³). The 5-year survival with involved-field RT for stage I/II disease was approximately 50%. Patients with bulky disease (>5 cm) suffered a higher relapse rate. Although many studies were undertaken to improve results by adjusting dosages and field coverage, it was the addition of combination chemotherapy to RT regimens that improved outcome most dramatically. Four randomized trials were conducted in patients with early-stage aggressive NHL before rituximab therapy was incorporated into the CHOP regimen. The first study was by the Southwest Oncology Group (SWOG); eight cycles of CHOP were compared to three cycles of CHOP followed by involved-field RT (40-55 Gy) in limited-stage DLBCL (⁷⁴). The combined-modality arm achieved an OS of 82%, versus 72% for the CHOP alone arm. The ECOG randomized patients with bulky stage I or II disease to eight cycles of CHOP with or without involved-field RT. Patients achieving a complete remission were randomized to involved-field RT (30 Gy) or no further therapy. Patients achieving partial remission received involved-field RT at a higher dose (40 Gy). Disease-free survival at 5 years was higher in patients who received radiation (73% vs 58%) after achieving complete remission (⁷⁵). The Groupe d'Etude des Lymphomes de l'Adulte (GELA) conducted a similar study comparing aggressive chemotherapy (dose-intensified doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone [ACVBP]) alone versus abbreviated chemotherapy (three cycles of CHOP) followed by involved-field RT for stage I or II mostly low-risk aggressive lymphoma. All patients in this study were younger than age 60 years. Both the 5-year event-free survival (82%) and OS (90%) rates were significantly better in the chemotherapy group

than in the combined-modality group (74% and 81%, respectively); however, the chemotherapy group had significant toxicity and ACVBP is not available in the United States. Although the addition of RT reduced relapses at the initial disease sites, this was not enough to overcome the excessive number of relapses in the abbreviated chemotherapy group (⁷⁶). Despite these results indicating the inability of abbreviated chemotherapy plus RT to prevent out-of-field relapses, the GELA group conducted another trial, GELA LNH 93-4, comparing CHOP with CHOP plus involved-field RT to 40 Gy, this time for patients older than 60 years (⁷⁷). The use of ACVBP had been dropped by the time this trial was undertaken because of excessive toxicity. At a median follow-up time of 7 years, no significant differences were evident in 5-year event-free survival rates (61% for chemotherapy alone vs 64% for chemoradiation) or OS rates (72% vs 68%, respectively). The results in the chemotherapy-only group were similar to the results from the group that received eight cycles of CHOP in the SWOG trial discussed earlier. However, because relapses could appear beyond 5 years, another 5 to 10 years should be allowed to elapse before any approach is widely adopted. A SWOG trial evaluated the addition of rituximab to three cycles of CHOP, followed by involved field RT, for localized DLBCL and found favorable comparisons to nonrituximab historical controls (⁷⁸). The MD Anderson Cancer Center (MDACC) approach to the treatment of DLBCL is shown in Fig. 8-18.

Localized MCL in general has been treated in the same way as extensive disease, but the use of RT with or without chemotherapy has been reported by investigators in British Columbia to be effective as well (⁷⁹).

Advanced-Stage Aggressive Non-Hodgkin Lymphoma

Initial cures using chemotherapy for patients with large-cell lymphoma were reported in the 1970s (^{80, 81}). The SWOG initially reported that CHOP induced complete response in 50% of patients, with long-term disease-free survival in 35%, and CHOP has since represented the standard of care in the treatment of patients with aggressive NHL despite intensive research into newer regimens. Subsequent trials of combination chemotherapy over the last 25 years can be thought of as “generations” (⁸²). The initial generation included CHOP, M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, etoposide, and leucovorin), BACOD, ProMACE-MOPP (addition of etoposide), ProMACE-CytaBOM (addition of cytarabine), and MACOP-B (methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin). These regimens showed an increased rate of complete remission of nearly 80% in early studies with greater than 60% long-term disease-free survival. The SWOG undertook a landmark phase III trial comparing CHOP, MACOP-B, M-BACOD, and ProMACE-CytaBOM, which showed

¹Bulky disease is >5 cm by definition at MD Anderson Cancer Center. ²Especially if bone marrow disease is present.

FIGURE 8-18 Algorithm for treatment of diffuse large B-cell lymphoma.

that, despite early reports of improved response, OS at 3 years varied from 50% to 54%, with disease-free survival ranging from 41% to 46%. In this trial, there was no apparent advantage to increased intensity of therapy. Another finding noted in the 1980s was that inclusion of an anthracycline in the chemotherapy regimen was important to long-term disease-free survival. Other approaches have included alternating regimens, higher dose therapy, and dose-dense therapy. The first two have not been shown to have a survival benefit, whereas the third is still under scrutiny.

Dose-dense therapy was reported to be feasible in 2003 by the German High-Grade NHL Study Group (DSHNHL) ⁽⁸³⁾. Three variants of CHOP-like therapy were evaluated, including CHOP-14, CHOEP-14 (addition of etoposide 100 mg/m² on days 1-3), and CHOP-21, each with hematopoietic growth factor support. An interim analysis of 959 patients showed that adherence to the dose-dense regimens was excellent, although dose reductions were more frequently required for the addition of etoposide. To evaluate younger patients, 710 patients with good-prognosis aggressive NHL age 18 to 60 years were randomized to receive six cycles of CHOP-21, CHOP-14, CHOEP-21, or CHOEP-14 ⁽⁸⁴⁾. Patients in the 2-week regimens received granulocyte colony-stimulating factor (G-CSF) from day 4. Initial sites of bulky or extranodal disease were treated with 36 Gy of RT. Patients receiving CHOEP achieved a higher complete response rate (87.6% vs 79.4%) and 5-year event-free survival (69.2% vs 57.6%) than patients treated with CHOP. Dose density (the 2-week regimens) improved OS in a multivariate analysis. Patients receiving CHOEP had a higher rate of myelosuppression, but generally, the regimen was well tolerated.

While the German group was exploring dose density, GELA reported their results of trial LNH98-5 in which 399 patients with DLBCL were randomized to receive either R-CHOP every 21 days or standard CHOP alone for a total of eight cycles. Patients with stage II to IV DLBCL who were between 60 and 80 years old were eligible for this trial. No RT or intrathecal chemotherapy was administered. The complete response rate (76% vs 63%) and the 5-year PFS, disease-free survival, and OS rates were better in the rituximab arm ⁽⁸⁵⁾.

Based on the GELA LNH98-5 results and their own data, the DSHNHL designed a four-arm randomized study in patients older than 60 years (RICOVER-60) that compared CHOP-14 with or without rituximab for six cycles versus CHOP-14 for eight cycles with or without rituximab (in the six-cycle R-CHOP arm, the patients received a total of eight doses of rituximab) ⁽⁸⁶⁾. The CHOP alone group was inferior, and six cycles of R-CHOP plus two cycles of rituximab were as effective as eight cycles of R-CHOP. Of note, this

trial also found that patients who achieved a partial response after four cycles received no additional benefit from receiving a total of eight cycles, as compared to the standard six cycles. Subsequent to this study, two other studies addressing the question of R-CHOP every 21 days versus every 14 days in DLBCL, one from the United Kingdom and the other from GELA, have not shown any benefit in the dose-dense group compared to standard R-CHOP every 21 days ^(87, 88).

An ongoing trial is directly comparing rituximab plus etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin (R-EPOCH) versus R-CHOP in patients with DLBCL, with highly anticipated results expected in 2016. In addition, there are numerous phase II and III trials evaluating the effect of novel agents, including lenalidomide and ibrutinib, when added to standard-of-care therapies. At MDACC, our preference is that all patients with DLBCL be evaluated for a clinical trial at each treatment stage.

Special Types and Situations in Diffuse Large B-Cell Lymphoma

Primary Central Nervous System and Ocular Lymphoma

The treatment of patients with primary CNS lymphoma is limited to drugs that can cross the blood-brain barrier. Standard chemotherapies such as R-CHOP do not cross to the brain, and they have limited activity in this condition. The initial evaluation must include slit-lamp evaluation of the eyes, MRI of the brain and spine, lumbar puncture, and the standard studies for any other lymphoma to exclude systemic disease. The most common histology in primary CNS lymphoma is DLBCL, and the most important drug is high-dose methotrexate, in general at doses higher than 3.0 g/m². The combination of chemoimmunotherapy using rituximab, high-dose methotrexate, procarbazine, and vincristine is generally considered the standard of care ⁽⁸⁹⁾. In this approach, patients have historically received consolidation with low-dose RT if in complete remission, although there is controversy regarding the role of RT. Lower doses of radiation have decreased the long-term neurotoxicity seen in prior studies ⁽⁹⁰⁾. In the most widely used approach, patients receive consolidation with high-dose cytarabine after completion of RT. Recent studies have shown promising results without the use of RT, although larger studies are required to evaluate whether omitting RT due to concerns about neurotoxicity is viable ⁽⁹¹⁾. The use of intrathecal chemotherapy is controversial in patients with no evidence of leptomeningeal involvement, but it is used in patients with CSF disease. Radiation fields should include the eyes if those are thought to be involved.

Testicular Lymphomas

Most patients with testicular lymphoma have DLBCL, but other lymphoma types can be seen. Patients with testicular lymphoma often have a worse prognosis compared to other DLBCL patients without testicular involvement. The treatment in this group of patients should include prophylaxis of CNS relapses with intrathecal chemotherapy and RT to the contralateral testicle to decrease the risk for localized relapses (¹⁹).

Intravascular Lymphomas

These lymphomas are traditionally considered to have poor prognosis. They have better outcomes with the addition of rituximab to the standard chemotherapy regimen. They have a high incidence of CNS relapse, but there are no standard CNS prophylaxis recommendations in this group of patients (¹⁹).

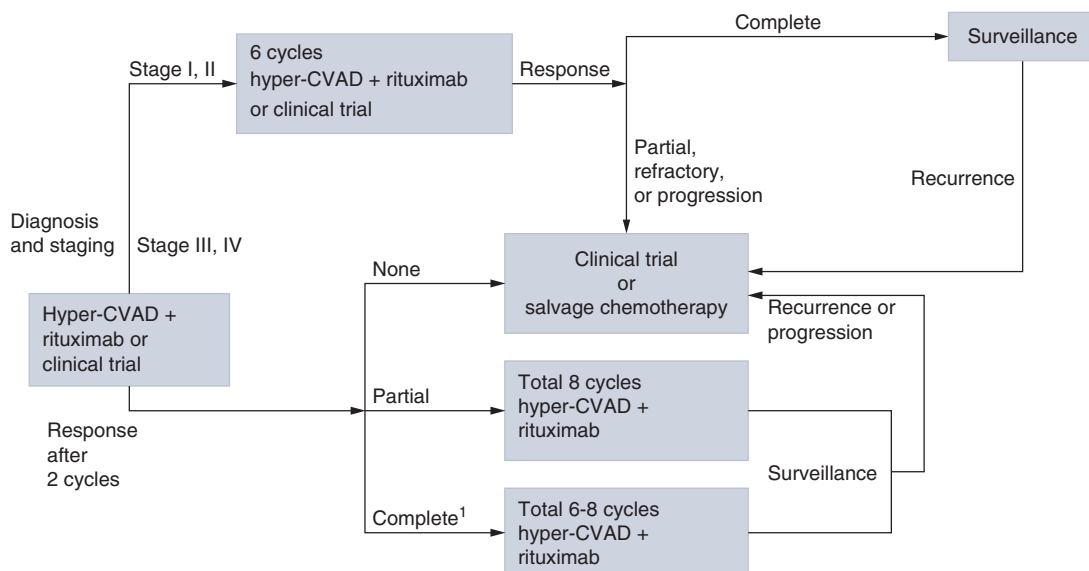

Primary Mediastinal B-Cell Lymphoma

Historically, PMBL had been an NHL subtype with a poor prognosis, despite intensive therapy and young fit patients (⁹²). These tumors are usually CD20⁺, and thus rituximab is now incorporated with standard-of-care chemotherapy. Consolidation with RT after chemotherapy has been a standard practice, but investigators from the National Institutes of Health have shown that dose-adjusted R-EPOCH without radiotherapy can achieve excellent results (⁹³). These data have not yet been confirmed in a multicenter trial, and thus controversy exists regarding whether RT can be omitted in all patients or may still play a role in patients with a residual large non-FDG-avid mass. At MDACC,

our current practice is treat PMBL patients with dose-adjusted R-EPOCH and omit RT for all patients who achieve a complete response.

Treatment of Advanced Mantle Cell Lymphoma

Mantle cell lymphoma is considered a special case because of its recognized aggressiveness and frequent refractory behavior (Fig. 8-19). In many studies of patients with MCL, the disease has been shown to be the NHL type with the poorest prognosis overall, with complete and partial response rates of 29% and 45%, respectively, when treated with a CHOP-like regimen. Investigators at MDACC have investigated hyper-CVAD, a regimen of fractionated cyclophosphamide and continuous infusion doxorubicin, vincristine, and dexamethasone alternating with methotrexate and cytarabine, which had previously been used for patients with acute lymphoblastic leukemia (Table 8-6) (⁹⁴). In long-term follow-up of R-hyper-CVAD alternating with rituximab plus methotrexate and cytarabine in untreated MCL, Romaguera and colleagues reported a 97% response rate, 87% complete response rate, and median time to treatment failure of 4.6 years (⁹⁴). The median OS had not been reached at a median follow-up of 8 years. Because the most toxic portion of this treatment is the high-dose methotrexate-cytarabine cycle, Kahl et al used a modified R-hyper-CVAD with maintenance rituximab for 2 years, obtaining a 77% overall response rate, a complete response rate of 64%, and a median PFS of 37 months (⁹⁵). Many other groups have incorporated a consolidation phase with autologous stem cell transplantation after induction

¹Confirm complete response by bone marrow biopsies, upper endoscopy, and colonoscopy (with biopsies).

FIGURE 8-19 Algorithm for treatment of mantle cell lymphoma.

Table 8-6 R-Hyper-CVAD Regimen Used in Mantle Cell Lymphoma and Highly Aggressive Lymphomas^a

Regimen	Dose/Route	Days	Interval
Hyper-CVAD/Methotrexate/ Ara-C			21-28 days
Cycles 1,3,5,7			
Rituxan	375 mg/m ² IV by slow infusion	1	
Cyclophosphamide	300 mg/m ² /dose over 3 h q 12 h × 6 doses	1-3	
Mesna	600 mg/m ² /day CIV over 24 h daily (Start 1 h prior to cyclophosphamide and complete by 12 h after last dose of cyclophosphamide)	1-3	
Doxorubicin	25 mg/m ² /day CIV over 24 h daily (Begin at 12 h after last dose of cyclophosphamide)	4-5	
Vincristine	1.4 mg/m ² IV (max 2 mg) (Give 12 h after last dose of cyclophosphamide and on day 11)	4 and 11	
Dexamethasone	40 mg PO daily	1-4 and 11-14	
Cycles 2, 4, 6, 8			
Methotrexate	200 mg/m ² IV over 2 h then 800 mg/m ² IV over 22 h	1	
Solumedrol	50 mg IV q 12 h × 6 doses	1-3	
Ara-C	3 g/m ² IV over 2 h every 12 h × 4 doses	2-3	
Leucovorin	50 mg IV followed by 15 mg IV q 6 h × 8 doses (Start 12 h after completion of methotrexate)		
Intrathecal therapy ^b			
Ara-C	100 mg	2	
Methotrexate	12 mg (6 mg if Ommaya reservoir)	7	

^aDose reductions for renal insufficiency, age, and previous toxicity are required. Intrathecal chemotherapy is more frequent for proven CNS disease.

^bMantle cell lymphoma is not typically treated with intrathecal therapy.

chemotherapy with various regimens with remarkable results⁽⁹⁶⁾. Bendamustine with rituximab, in comparison to R-CHOP, achieved a statistically significant prolongation in PFS and thus has become a new standard-of-care option for patients unfit to undergo more intensive approaches⁽⁹⁷⁾.

Special Considerations

Patients with double-hit lymphomas, defined as the presence of *MYC* translocation with *BCL2* or *BCL6* or another oncogene, have a very poor outcome even with aggressive treatments⁽²⁹⁾. Consolidation with transplant in first response should be considered, even though transplant outcome data have not shown clear benefit due to small sample sizes in the largest retrospective series^(98, 99). At MDACC, our approach to double-hit DLBCL currently includes dose-adjusted R-EPOCH and consideration of autologous stem cell transplantation consolidation if the patient is fit, but clinical trials are always preferred. The best treatment approach for patients with DLBCL with double protein

expression is unclear⁽¹⁰⁰⁾, and additional clinical trials are needed.

Central nervous system prophylaxis remains controversial. However, it is recommended in patients with high-grade lymphomas or BL, bone marrow involvement with DLBCL, renal or adrenal involvement, two or more extranodal sites, testicular involvement, and disease involvement in areas close to the CNS^(19, 57).

With the widespread use of effective antiretroviral therapy, patients with HIV-associated lymphomas have an improved prognosis and should be treated with curative intent⁽¹⁰¹⁾. Standard treatments with rituximab-containing regimens, such as R-CHOP, dose-adjusted R-EPOCH, or continuous infusion cyclophosphamide, doxorubicin, and etoposide, reported acceptable results, especially in the era of the HAART. In HIV-associated BL, investigators from the National Cancer Institute (NCI) have shown that a short course of R-EPOCH can be highly effective⁽¹⁰²⁾. It is important to note, however, that when EPOCH-based treatments are used, it is often recommended that HAART be stopped while on treatment.

REFRACTORY OR RELAPSED AGGRESSIVE NON-HODGKIN LYMPHOMA

Treatment of Recurrent/Refractory Diffuse Large B-Cell Lymphoma

Approximately 10% of patients treated for aggressive NHL fail to achieve a complete remission after induction therapy; their disease is termed *primary refractory* (Fig. 8-20). A larger portion of patients with aggressive NHL, up to a third of all patients, will relapse after initially responding to chemotherapy. Although these patients may be sensitive to a second chemotherapy regimen, most patients with refractory and relapsed aggressive NHL have a poor prognosis. Conventional salvage therapy includes rituximab combined with standard chemotherapeutics such as ifosfamide, etoposide, taxanes, and platinum compounds. Among the most commonly used are DHAP (dexamethasone, cytarabine, and cisplatin), ICE (carboplatin replacing cisplatin), GDP (gemcitabine, dexamethasone, and cisplatin), TTR (paclitaxel, topotecan, and rituximab) and ESHAP (etoposide, methylprednisolone, cytarabine, and cisplatin) (¹⁰³⁻¹⁰⁵). The salvage regimens tend to have higher toxicity and require greater support for administration, often including hospitalization.

Because of the poor prognosis in patients with relapsed disease, the purpose of many of the chemotherapy regimens offered in this clinical setting is to attain remission followed by high-dose chemotherapy

with stem cell support. The Parma trial examined autologous bone marrow transplantation versus salvage chemotherapy in patients with relapsed, chemotherapy-sensitive NHL (¹⁰⁶). Patients were randomized to four more cycles of DHAP versus high-dose therapy with stem cell support, showing an event-free survival rate of 46% in the high-dose arm but only 12% in the DHAP alone arm. This is considered strong evidence that high-dose therapy with stem cell support is the treatment of choice for patients with chemosensitive relapsed or primary refractory aggressive NHL.

Gisselbrecht et al reported a GELA study known as the CORAL trial for second-line treatment for 400 recurrent/refractory CD20⁺ DLBCL patients randomized to receive rituximab plus DHAP (R-DHAP) versus rituximab plus ICE (R-ICE); responding patients received autologous stem cell transplantation. No difference in the response rates (~50% in prior rituximab-exposed patients), PFS, and OS were noted between the R-ICE and R-DHAP groups (¹⁰³).

Patients who do not respond to a second-line treatment or are unfit for an aggressive approach should be evaluated for a clinical trial. If not eligible for a trial, they should then be considered for a palliative treatment that may provide meaningful transient benefit or palliative care. Patients who are responding to second-line treatment, but who are unable to mobilize stem cell treatment, should be considered for alternative donor transplant. Treatment response failure beyond second relapse indicates an incurable disease. A small portion of patients, however, may be rescued with

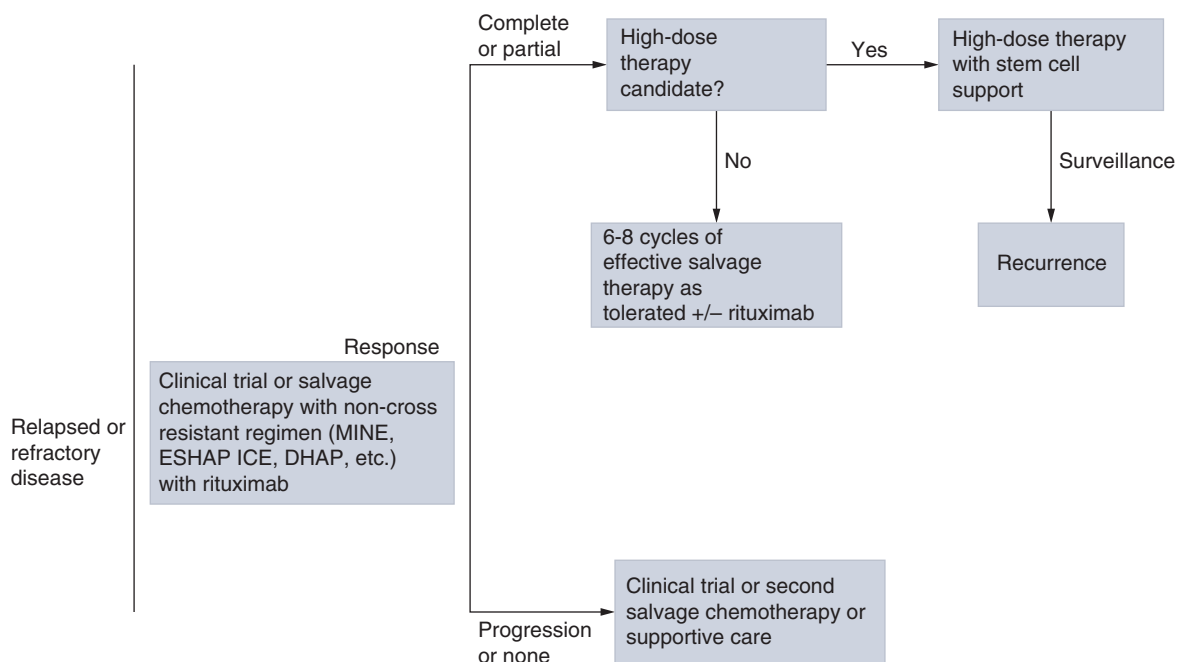

FIGURE 8-20 Algorithm for treatment of relapsed aggressive lymphomas (except high-grade or mantle cell lymphoma). MINE, mesna, ifosfamide, mitoxantrone, etoposide.

salvage chemotherapy and a second stem cell transplantation, often of allogeneic donor origin; however, this is unlikely, and investigational agents should be prioritized over further chemotherapy. At MDACC, our priority for patients who are either unfit for aggressive therapy or resistant to second-line chemotherapy is to aggressively pursue a clinical trial.

Patients with a history of follicular lymphoma with subsequent transformation to DLBCL, who had prior doxorubicin-based treatment, should be treated with salvage therapy for recurrent DLBCL.

Treatment of Recurrent Mantle Cell Lymphoma

Decisions regarding salvage therapy for patients with recurrent MCL should be individualized, depending on their candidacy for stem cell transplantation. Aside from aggressive combination chemotherapy, targeted therapy agents are active against MCL, and bortezomib, lenalidomide, and ibrutinib have each been approved by the US Food and Drug Administration (FDA) for relapsed MCL.

Recurrent Primary Central Nervous System and Ocular Lymphoma

The treatment of recurrent primary CNS lymphoma is limited because of the inability of many drugs to penetrate into the CNS. Retreatment with high-dose methotrexate can be attempted if there was a long duration of the first remission. Patients with recent prior whole-brain RT may be at high risk for methotrexate-induced encephalopathy. Reports using temozolomide in combination with rituximab have been encouraging. Responding patients may benefit with consolidation with high-dose chemotherapy (especially with

preparative regimens including thiotepe), followed by autologous stem cell transplantation.

HIGHLY AGGRESSIVE (HIGH-GRADE) NON-HODGKIN LYMPHOMA

Patients with highly aggressive NHL have largely benefited from the successful application of pediatric therapy regimens to the adult population, with long-term remissions approaching 80% to 90% in some series (Fig. 8-21). The most important principle for treating patients with highly aggressive NHL is prompt systemic therapy, as these are medical emergencies. Attempts should be made to maintain dose intensity and density using supportive therapies, such as growth factor support, prophylaxis for tumor lysis syndrome, and CNS prophylaxis.

Patients with BL should not be treated with CHOP or CHOP-like regimens due to poor long-term disease-free survival (¹⁹). Combined-modality therapy appears to add toxicity without any proven benefit. Patients at MDACC have been treated with the hyper-CVAD/methotrexate/cytarabine regimen, with intrathecal methotrexate/cytarabine CNS prophylaxis with some success (¹⁰⁷) (see Table 8-6). The NCI has developed an alternating regimen of cyclophosphamide, doxorubicin, vincristine, methotrexate, leucovorin, and ifosfamide, etoposide, and cytarabine with intrathecal cytarabine and methotrexate called CODOX-M/IVAC (¹⁰⁸). This is administered for four cycles, with CODOX-M as cycles 1 and 3 and IVAC as cycles 2 and 4. A complete remission rate of 92% was reported, with a 3-year event-free survival rate of 85%. At MDACC, rituximab was added to standard hyper-CVAD alternating with methotrexate-cytarabine

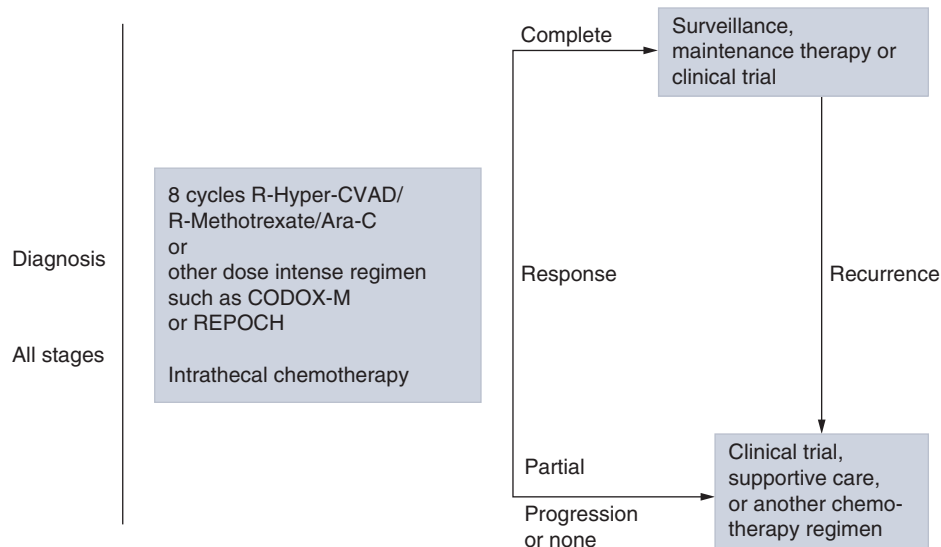

FIGURE 8-21 Algorithm for treatment of Burkitt and Burkitt-like lymphoma. Ara-C, cytarabine.

(see Table 8-6), resulting in impressive long term outcomes. Adverse risk factors for these patients include elevated LDH, age, and leukemic presentation ⁽¹⁰⁹⁾. Finally, the EPOCH chemotherapy regimen developed at the NCI has recently shown great promise in a small phase II trial, in both HIV-positive and HIV-negative BL, with freedom from progression rates in excess of 90% with 5 years of follow-up ⁽¹⁰²⁾.

THERAPY IN ELDERLY PATIENTS

As has been repeatedly shown, patients with aggressive NHL over the age of 60 years have a worse prognosis ^(21, 110). Unfortunately, more than 50% of patients with aggressive NHL are over 60 years old, and most of these patients do not experience extended long-term survival. Treatment of older patients is complicated by higher overall toxicity rates and lower tolerance of aggressive therapies. At MDACC, our practice is to screen older patients with DLBCL for clinical trials with novel therapies.

Although it is sometimes necessary to reduce the doses of chemotherapeutic regimens to treat elderly patients with comorbid conditions, CHOP is generally well tolerated by patients without contraindications to doxorubicin. Growth factor support should be used. Unfortunately, patients with a contraindication to doxorubicin also frequently have contraindications to other therapies, such as platinum-containing regimens. The substitution of etoposide for doxorubicin in patients who have contraindications to anthracyclines appears to be highly effective in a population-based retrospective review ⁽¹¹¹⁾. A multicenter trial found that R-mini-CHOP, a significantly reduced dosing of conventional R-CHOP, resulted in an acceptable compromise between efficacy and toxicity in patients age 80 years and older ⁽¹¹²⁾.

NEW DRUGS

The field of new cancer drugs has evolved rapidly and is difficult to adequately capture in a book chapter. Since 2000, there has been an incredible number of new drugs evaluated in clinical trials for patients with aggressive lymphomas. The typical pattern of drug development includes an evaluation of toxicity and dosing in the relapsed/refractory setting. If tolerable and an early signal of efficacy is found, drugs are then evaluated in larger phase II trials, often in a population enriched for likely responders. The authors of this chapter believe that the evaluation of efficacy in heavily pretreated, refractory aggressive NHL may actually underestimate the true response rate of targeted therapies ⁽¹¹³⁾.

The drugs listed here are not yet FDA approved for DLBCL, BL, or MCL, but appear promising thus far

in clinical trials ⁽⁶¹⁾. The goal of this section is not to recommend use of these nonapproved drugs off of a clinical trial but to serve as an indication of the large progress on the horizon. The Bruton tyrosine kinase inhibitor ibrutinib has now been approved for several B-cell malignancies, including MCL. Early trials confirmed a pathway-based prediction of increased efficacy in the non-GCB subtype of DLBCL ⁽¹¹⁴⁾. Based on promising efficacy and acceptable toxicity, ibrutinib is now being evaluated in a randomized clinical trial with R-CHOP (vs R-CHOP + placebo) ⁽¹¹⁵⁾.

Other inhibitors of the B-cell receptor pathway, including Syk, are ongoing but to date have demonstrated modest results in heavily pretreated patients. Inhibitors of the PI3K/Akt/mTOR pathway have shown significant promise across lymphoma subtypes, although as single agents, they have proven more effective in indolent lymphomas ⁽¹¹⁶⁾. Inhibitors of the various isoforms of PI3K are in numerous clinical trials in various B-cell malignancies, with idelalisib already being approved for some NHL subtypes. Inhibitors of TORC1 have shown response rates in the 30% response range across NHL subtypes, and temsirolimus has received an orphan drug approval for MCL in Europe. Newer inhibitors that block both TORC1 and TORC2 may prove more effective, but further trials are needed. Lenalidomide is a drug with a diverse impact on numerous targets and cell types but is often described as a potent immunomodulatory drug and recently was approved for relapsed MCL. In the ABC subtype of DLBCL, lenalidomide blocks expression of interferon regulatory factor 4 (IRF4 or MUM1) and leads to a synthetic lethal response ⁽¹¹⁷⁾. Based on these and other findings, two randomized phase III trials are planned to evaluate R-CHOP with lenalidomide or placebo ⁽¹¹⁸⁾. Other agents appear to have great promise but are at a very early stage of clinical trial development, including selinexor, BCL2 inhibitors including venetoclax, and immune checkpoint inhibitor therapies.

RESPONSE AND FOLLOW-UP

Definitions of Response

Response to therapy is assessed according to criteria based on the anatomic and metabolic changes that occur in disease-involved nodal and extranodal sites ⁽¹¹⁹⁾. A recent consensus statement was issued by leading clinical investigators to attempt standardization of response criteria to be used in clinical trials. There remains controversy about what constitutes an abnormal PET, and it is generally recommended that uptake be compared to the mediastinal blood pool and liver as internal controls and that the results be scored based on these results ⁽¹²⁰⁾ (Table 8-7).

Table 8-7 Response Definitions for Clinical Trials

Response	Definition	Nodal Masses	Spleen, Liver	Bone Marrow
CR	Disappearance of all evidence of disease	(a) FDG-avid or PET positive prior to therapy; mass of any size permitted if PET is negative (b) Variably FDG-avid or PET negative; regression to normal size on CT	Not palpable, nodules disappeared	Infiltrate cleared on repeat biopsy; if indeterminate by morphology, immunohistochemistry should be negative
PR	Regression of measurable disease and no new sites	≥50% decrease in SPD of up to six largest dominant masses; no increase in size of other nodes (a) FDG-avid or PET positive prior to therapy; one or more PET positive at previously involved site (b) Variably FDG-avid or PET negative; regression on CT	≥50% decrease in SPD of nodules (for single nodule in greatest transverse diameter); no increase in size of liver or spleen	Irrelevant if positive prior to therapy; cell type should be specified
SD	Failure to attain CR/PR or PD	(a) FDG-avid or PET positive prior to therapy; PET positive at prior sites of disease and no new sites on CT or PET (b) Variably FDG-avid or PET negative; no change in size of previous lesions on CT		
Relapsed disease or PD	Any new lesion or increase by ≥50% of previously involved sites from nadir	Appearance of a new lesion(s) >1.5 cm in any axis, ≥50% increase in longest diameter of a previously identified node >1 cm in short axis Lesions PET positive if FDG-avid lymphoma or PET positive prior to therapy	>50% increase from nadir in the SPD of any previous lesions	New or recurrent involvement

CR, complete remission; CT, computed tomography; FDG, [¹⁸F] fluorodeoxyglucose; PD, progressive disease; PET, positron emission tomography; PR, partial remission; SD, stable disease; SPD, sum of the product of the diameters.

Restaging

Fluorodeoxyglucose PET has proven very useful in assessing responses to therapy and is now considered standard of care for initial posttherapy restaging in FDG-avid lymphomas. Despite this recommendation, FDG-PET/CT should not be used for long-term follow-up imaging after initial response is confirmed (¹²¹) (Figure 8-22).

Surveillance

Follow-up of patients with aggressive NHL after complete remission and cessation of therapy is typically done every 3 to 6 months for 2 years, then annually until year 5, although there is significant controversy about optimal use of surveillance imaging (¹⁹). A large retrospective evaluation of the utility of surveillance imaging to detect recurrence, as compared to patient-reported complaints, found that most DLBCL recurrences were identified based on symptoms and

not imaging alone and that outcomes were not different between imaging and symptom-identified recurrences (¹²²). The emergence of blood-based minimal residual disease detection techniques may ultimately make the debate about the utility of imaging moot.

Relapse or Recurrence

The presence of a new lesion, either by anatomic criteria or on FDG-PET scan, is considered relapsed or progressive disease, but at MDACC, we view a biopsy to confirm imaging findings to be essential. Fluorodeoxyglucose PET is nonspecific, and uptake may occur in both benign and malignant tumors, in inflammatory or infectious lesions, and with normal physiologic processes. Sarcoidosis and fungal infections may mimic lymphoma, and biopsy is often necessary to exclude recurrence (Fig. 8-23). A single persistent or new focus of activity, with paradoxical response at other sites

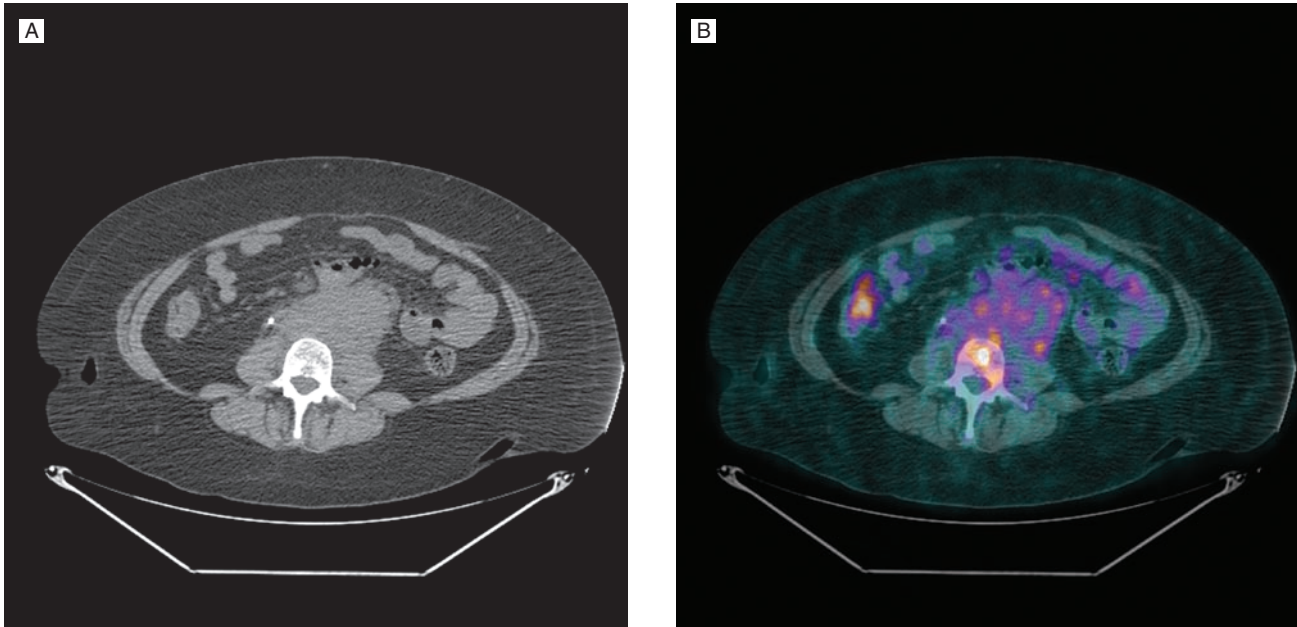

FIGURE 8-22 Residual mass, not residual lymphoma. After completing chemotherapy, this patient had a residual soft tissue abnormality in the retroperitoneum. **A.** This was previously positive on fluorodeoxyglucose positron emission tomography (FDG-PET) but now does not have activity above background levels and is considered negative. **B.** Biopsy of this mass was negative, and it was stable on follow-up studies. Previously, this would be considered a partial response (PR) or unconfirmed complete response (CRu). Under the revised criteria, taking into account the FDG-PET findings, this is considered a complete response (CR).

FIGURE 8-23 Examples of false-positive fluorodeoxyglucose positron emission tomography (FDG-PET). Restaging study is suspicious for recurrent lymphoma. **A.** With predominantly osseous involvement; however, biopsy revealed nonnecrotizing granulomas thought to be due to sarcoidosis. Two months later, nearly all of the FDG-avid sites resolved without any therapy. **B.** A second patient presented over 10 years after successful treatment for lymphoma, with new lymphadenopathy and lung opacities that were positive on FDG-PET. Biopsy revealed fungal lymphadenitis.

FIGURE 8-24 Incidental significant finding on fluorodeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT). An enlarging metabolically active lung nodule is seen. Biopsy revealed non-small-cell lung cancer, and the patient went on to have lobectomy for stage I lung cancer.

of disease, requires further evaluation with a biopsy, because findings may represent a premalignant lesion, such as a thyroid or colonic adenoma, or an incidental second malignant tumor (Fig. 8-24).

NEW DIRECTIONS

Over the last 20 years, remarkable advances have been made in the diagnosis, characterization, and treatment of patients with aggressive NHL. The molecular characterization of disease is finally gaining clinical traction, due in large part to efficacy in clinical trials being preferential for a particular disease subtype. The future is bright for basic science, translational, and clinical research for aggressive lymphomas with a multitude of new therapeutic agents. It is our strong recommendation that all patients be considered for clinical trials to move the field forward.

PERIPHERAL (MATURE) T-CELL LYMPHOMAS

Peripheral T-cell lymphoma (PTCL) is a heterogeneous group of lymphomas derived from a mature T cell (Fig. 9-1). Currently, the World Health Organization (WHO) classification combines mature T- and natural killer (NK)-cell neoplasms under the umbrella term PTCL, and the category is composed of 23 different entities (Table 9-1), based on the different morphologic, phenotypic, molecular, and clinical features, including disease site (¹). Most PTCLs lack distinct genetic or biologic alterations that are seen in B-cell lymphomas, such as t(14;18) in follicular lymphoma and t(11;14) in mantle cell lymphoma. Compared with B-cell lymphomas, many types of PTCL develop not in lymph nodes, but in specific extranodal sites such as extranodal NK/T-cell lymphoma, nasal type (ENKL) in the nasal cavity, enteropathy-associated T-cell lymphoma (EATL) in the small intestine, and hepatosplenic T-cell lymphoma (HSTL) in the liver and spleen.

EPIDEMIOLOGY

Peripheral T-cell lymphoma represents 5% to 10% of all lymphomas in the United States (²). The most common histologic subtype is PTCL, not otherwise specified (PTCL-NOS), followed by angioimmunoblastic T-cell lymphoma (AITL) or anaplastic large-cell lymphoma (ALCL), either ALK positive or ALK negative. The three types account for about 60% of all cases of PTCLs (³). The age-adjusted incidence in the United

States for PTCL-NOS, AITL, and ALCL is 0.30, 0.05, and 0.25 per 100,000 person-years, respectively (²). Previous studies have indicated that some Asian countries have a higher incidence of PTCL (³). However, age-adjusted incidence estimated by population-based cancer registry data showed a similar incidence of PTCL in the United States and Japan except for NK/T-cell lymphoma (NKTCL) and adult T-cell leukemia/lymphoma (ATLL) (⁴). The incidence of cutaneous T-cell lymphoma (CTCL) is higher in the United States, particularly in African Americans.

PRESENTATION AND HISTOPATHOLOGIC FINDINGS

The presentation of patients with T-cell lymphoma largely depends on the subtype. Peripheral T-cell lymphoma, not otherwise specified, AITL, and ALCL often present with generalized lymphadenopathy, and there is also frequent involvement of the skin, gastrointestinal tract, liver, spleen, and bone marrow. In contrast, a number of rare specific subtypes, such as NKTCL, HSTL, and EATL, present primarily with extranodal disease, and other subtypes, such as NKTCL and ATLL, may have a leukemic presentation. Advanced-stage disease (stages III and IV) is common: PTCL-NOS, 69%; AITL, 89%; ALK-positive ALCL, 65%; ALK-negative ALCL, 58%; EATL, 69%; and HSTL, 90%.

The histopathologic and immunophenotypic findings may vary within a given subtype. Therefore, the diagnosis should be made based on a combination of clinical presentation and histopathologic findings.

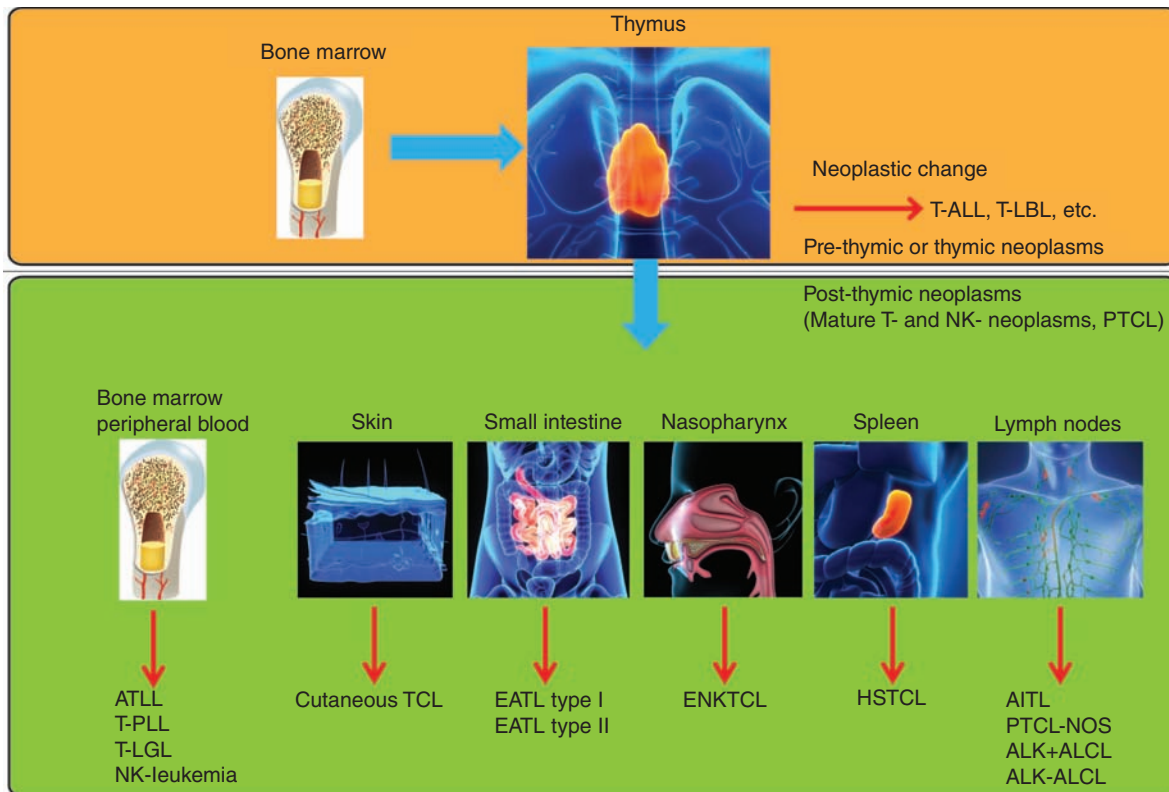

FIGURE 9-1 Peripheral T-cell lymphoma: T-cell maturation and organ of involvement. AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large T-cell lymphoma; ATLL, adult T-cell lymphoma/leukemia; EATL, enteropathy associated T-cell lymphoma; ENKTCL, extranodal NK/T-cell lymphoma; HSTCL, hepatosplenic T-cell lymphoma; NK, natural killer; PTCL, peripheral T-cell lymphoma; PTCL-NOS, PTCL, not otherwise specified; T-ALL, T-cell acute lymphoblastic leukemia; TCL, T-cell lymphoma; T-LBL, T-cell lymphoblastic lymphoma; T-LGL, T-cell large granular lymphocytic leukemia; T-PLL, T-cell prolymphocytic leukemia.

T-cell receptor rearrangements are found in most cases of PTCL, but a negative result does not necessarily exclude the disease.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphoma, not otherwise specified, represents the largest subtype and accounts for 25% to 30% of all PTCLs (^{1,3}). Its definition in the current WHO classification is a "mature T-cell lymphoma which does not correspond to any of the specifically defined entities." The diagnosis of PTCL-NOS should be made only when other specific entities have been excluded, and, therefore, it is a heterogeneous category at the genetic level.

There is male predominance (male-to-female ratio of approximately 2:1). Patients most often present with lymph node enlargement and with advanced-stage disease (60%-70%) with B symptoms. Extranodal presentation is also common (30%-40%), with the bone marrow, skin, and gastrointestinal tract being the most commonly affected sites (^{5,6}).

Histologically, the lymph node architecture is diffusely effaced (¹). The cytologic spectrum is extremely broad ranging from highly polymorphous to monomorphous presentations. Most cases exhibit a spectrum of cell sizes from medium to large and can have abundant clear cytoplasm with irregular, pleomorphic, and hyperchromatic nuclei and high mitotic figures (Figs. 9-2 and 9-3). Reed-Sternberg-like cells may also be found.

Immunophenotypic studies show aberrant T-cell phenotype, typically marked by downregulation of CD5 and CD7. Nodal cases most often show CD4⁺/CD8⁻ phenotype. T-cell receptor (TCR) β -chain (β F1) is usually expressed, allowing the distinction from $\gamma\delta$ T-cell lymphomas and NK-cell lymphomas. Cytotoxic molecules, such as TIA-1 and granzyme B, are expressed in 40% of nodal PTCL-NOS, and expression is associated with younger age at presentation, aggressive features, treatment resistance, and inferior survival (⁷). CD30 expression is observed in 3% to 50% of cases (^{5,8,9}). Lymphoma cells may occasionally express CD15, but the phenotypic profile and morphology allow the distinction from ALCL and Hodgkin

Table 9-1 Peripheral T-Cell Lymphomas in World Health Organization Classification, 4th Edition

Mature T-cell and NK-cell neoplasms
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK-cell lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Systemic EBV-positive T-cell lymphoproliferative disease of childhood
Hydroa vacciniforme-like lymphoma
Adult T-cell leukemia/lymphoma
Enteropathy-associated T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
Lymphomatoid papulosis
Primary cutaneous anaplastic large-cell lymphoma
Primary cutaneous gamma-delta T-cell lymphoma
Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4-positive small/medium T-cell lymphoma
Peripheral T-cell lymphoma, unspecified
Angioimmunoblastic T-cell lymphoma
Anaplastic large-cell lymphoma, ALK positive
Anaplastic large-cell lymphoma, ALK negative

EBV, Epstein-Barr virus; NK, natural killer.

**FIGURE 9-2** Peripheral T-cell lymphoma, not otherwise specified. The neoplastic cells in this case are predominantly small (hematoxylin-eosin, 1,000×).**FIGURE 9-3** Peripheral T-cell lymphoma, not otherwise specified. The neoplastic cells in this case are small and large (hematoxylin-eosin, 1,000×).

lymphoma⁽⁹⁾. Cytogenetic abnormalities in PTCLs are common, and karyotypes are often complex. Recurrent chromosomal gains have been observed in chromosomes 7q, 8q, 17q, and 22q, and recurrent losses in chromosomes 4q, 5q, 6q, 9p, 10q, 12q, and 13q, with del 5q, 10q, and 12q being associated with better outcome^(10,11).

Gene expression profiling analysis has confirmed the molecular heterogeneity of the PTCL-NOS category. Using expression signatures, about one-third of PTCL-NOS cases can be classified as other known T-cell entities, such as AITL. In addition, cases of PTCL-NOS that remain can be divided into two groups characterized by high expression of GATA3 or TBX21, with the GATA3 group having poor survival⁽¹²⁾.

Follicular T-Helper Cell Lymphoma

These tumors are currently considered a variant of PTCL-NOS, but they have a distinctive follicular pattern and are thought to be derived for follicular T-helper cells, a small T-cell population that is CD10⁺, BCL6⁺, and PD-1/CD279⁺ in normal follicles. A recurrent t(5;9)(q33;q22), resulting in the *ITK-SYK* fusion gene, has been described in a subset of patients with follicular histology⁽¹³⁾.

Anaplastic Large-Cell Lymphoma

In the current WHO classification, two types of systemic ALCL are recognized. One type associated with translocations involving the *ALK* gene and leading to ALK overexpression is well established. The other category, morphologically similar to ALK-positive ALCL but lacking ALK abnormalities of overexpression, is considered a provisional category and designated as ALK-negative ALCL. However, there are recent data

that show that the ALK-negative ALCL category is highly heterogeneous at the genetic level and that genetic abnormalities correlate with prognosis, calling into question the validity of the ALK-negative ALCL category.

ALK-Positive Anaplastic Large-Cell Lymphoma

Patients with ALK-positive ALCL are younger, with a median age in the low 30s, and children are commonly affected (^{14,15}). Anaplastic large-cell lymphoma accounts for 3% to 5% of all non-Hodgkin lymphomas (NHLs) and for 10% to 20% of childhood lymphomas (¹). Patients with ALK-positive ALCL generally present with lymph node enlargement and frequent extranodal involvement of skin, bone, soft tissue, lung, and liver. More than half present with B symptoms at diagnosis, particularly fever.

Histologically, ALK-positive ALCL exhibits a wide histologic spectrum (Fig. 9-4). A number of morphologic patterns have been recognized: common type, lymphohistiocytic, small cell, Hodgkin-like,

sarcoma-like, and others, as well as mixed or composite patterns. About 80% of cases exhibit the common pattern, characterized by large lymphoma cells infiltrating sinuses and/or showing cohesive features. The lymphohistiocytic and small-cell patterns each represent 5% to 10% of cases of ALK-positive ALCL. In all variants, the lymphoma cells have eccentric, horseshoe- or kidney-shaped nuclei, often with an eosinophilic region near the nucleus (so-called hallmark cells). The cytoplasm is abundant and usually basophilic (see Fig. 9-4).

ALK-positive ALCL is a lymphoma of T/null-cell lineage that is characterized by strong and diffuse CD30 and ALK expression. Most of cases are CD2⁺, CD4⁺, CD43⁺, CD3⁻, CD8⁻, and BCL2⁻. CD15 and PAX5 are negative (unlike classical Hodgkin lymphoma). The pattern of ALK expression, in part, can predict molecular abnormalities involving ALK. Cytoplasmic and nuclear expression correlates with the t(2;5)(p23;q35)/NPM1/ALK (¹⁶). Other cases with ALK abnormalities show a cytoplasmic restricted or, rarely, a membranous pattern of expression (¹⁷).

FIGURE 9-4 ALK-positive anaplastic large-cell lymphoma. **A.** In this field, the neoplasm is paracortical and spares a central lymphoid follicle. **B.** The neoplastic cells are large with horseshoe-shaped nuclei. **C, D.** The neoplastic cells express CD30 (**C**) and ALK (**D**). (**A, B**, hematoxylin-eosin; **A**, 100 \times ; **B**, 1,000 \times ; **C, D**, immunohistochemistry; **C**, 1,000 \times ; **D**, 400 \times).

ALK-Negative Anaplastic Large-Cell Lymphoma

Patients with ALK-negative ALCL are older, with a median age in the late 50s. Clinically patients present with aggressive disease, with lymph node enlargement, frequent extranodal involvement, and B symptoms. The morphologic spectrum of ALK-negative ALCL is similar to ALK-positive ALCL, except that the neoplastic cells may be more pleomorphic. The neoplastic cells have a T/null-cell immunophenotype and strongly and uniformly express CD30 but are negative for ALK.

A recent study has shown that ALK-negative ALCL is molecularly heterogeneous. Rearrangement of *DUSP22*, marked by t(6;7), was found in 30% of cases and is associated with excellent prognosis with 90% long-term survival, whereas *TP63* rearrangement, marked by inv(3), was seen in 8% of cases and is associated with poor prognosis with only 17% long-term survival. The remaining cases are still poorly characterized.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma was first described as angioimmunoblastic lymphadenopathy with dysproteinemia in 1974 and was thought to be a preneoplastic process. Evidence now indicates that AITL is a de novo PTCL. Angioimmunoblastic T-cell lymphoma represents the second most common subtype, accounting for 15% to 20% of PTCLs⁽³⁾.

The median age of patients with AITL is 65 years^(18, 19). Most patients present with advanced disease. Generalized lymphadenopathy and extranodal presentations, including hepatosplenomegaly, bone marrow involvement, rash with pruritus, ascites, and pleural effusion are frequent. B symptoms (fever, night sweats, weight loss) are common. Laboratory abnormalities include polyclonal hypergammaglobulinemia (sometimes with a positive direct Coombs test), anemia, hypereosinophilia, thrombocytopenia, and positive autoantibodies for cold agglutinin, rheumatoid factor, antinuclear factor, and anti-smooth muscle antibody are also common^(18, 19).

Histologically, the lymph node architecture is replaced by a diffuse, polymorphous population of cells associated with a proliferation of branching high endothelial venules. The neoplastic cells are small to medium in size, often with abundant clear cytoplasm, and can form small clusters surrounding the follicles and high endothelial venules (Fig. 9-5). Reactive cells are numerous in AITL, such as lymphocytes, eosinophils, plasma cells, histiocytes, and CD21⁺ follicular dendritic cell networks. Most cases also show expansion of B cells positive for Epstein-Barr virus (EBV), which is thought to be related to immune dysfunction.

In AITL, lymphoma cells usually express T-cell antigens such as CD3, CD2, and CD5, and have a T-helper cell immunophenotype characterized by expression of CD4, CD10, BCL6, CXCL13, and PD-1. Follicular dendritic cells (CD21⁺, CD23⁺) are expanded, usually surrounding high endothelial venules.

Chromosomal abnormalities have been identified in AITL, with trisomy 3 and trisomy 5 being most common⁽²⁰⁾. Recent studies have shown mutations in *TET2*, *IDH2*, *DNMT3A*, and *RHOA*⁽²¹⁾. Among 243 patients in the International T-Cell Lymphoma Project, 5-year failure-free survival and overall survival (OS) rates were 18% and 32%, respectively, which was very similar to the outcome of patients with PTCL-NOS⁽¹⁸⁾.

Rare Types of T-Cell Lymphoma

Adult T-Cell Lymphoma/Leukemia

Adult T-cell lymphoma/leukemia is a distinct clinicopathologic entity associated with infection by the human T-cell lymphotropic virus type-1 (HTLV-1)⁽¹⁾. The HTLV-1 is a single-stranded RNA retrovirus that is lymphotropic for T lymphocytes. Infection with HTLV-1 is endemic in Africa, Iran, the Caribbean islands, Central and South America, and the southern part of Japan⁽²²⁾. Approximately 10 to 20 million people are infected by HTLV-1 worldwide. Three major routes of HTLV-1 infection have been established: vertical transmission by breastfeeding, parental transmission, and sexual transmission. The lifetime cumulative incidence of ATLL in an HTLV-1 carrier is 2% to 3% for women and 6% to 7% for men⁽²³⁾. The median age at the time ATLL develops is the seventh decade of life. Risk factors for developing ATLL include high proviral load, advanced age, family history of ATLL, and types of human leukocyte antigen alleles⁽²⁴⁾. Individuals infected in adulthood rarely, if ever, develop ATLL, suggesting that the latency of infection is very long and age at the time of HTLV-1 infection is important⁽²⁵⁾. Adult T-cell lymphoma/leukemia accounts for less than 1% of NHL in the United States but accounts for around 35% to 40% of NHL in the endemic area in Japan⁽⁴⁾. However, there seems to be an increasing trend in the incidence of ATLL in the United States, possibly due to the emigration of people from endemic areas⁽²⁶⁾. The prognosis is extremely poor with conventional chemotherapy⁽²⁷⁾. Median OS is less than 1 year without allogeneic stem cell transplantation.

Adult T-cell lymphoma/leukemia is classified into four subtypes based on clinicopathologic features and prognosis: acute, lymphoma, chronic, and smoldering⁽²⁸⁾. Patients with acute ATLL, the most common form of the disease, have generalized

FIGURE 9-5 Angioimmunoblastic T-cell lymphoma. **A.** The neoplasm has a paracortical distribution. **B.** The neoplasm is composed of numerous cells with clear cytoplasm. **C.** In this field, arborizing blood vessels are shown. **D.** The neoplastic cells are positive for CD3. (**A–C**, hematoxylin-eosin; **A**, 100 \times ; **B**, 1,000 \times ; **C**, 200 \times ; **D**, immunohistochemistry, 400 \times).

lymphadenopathy, hepatosplenomegaly, skin lesions, peripheral blood involvement, lytic bone lesions, and hypercalcemia. Hypercalcemia may also develop in the absence of bone lesions, secondary to secretion of parathyroid hormone-related peptide by the neoplastic cells (Fig. 9-6).

In the peripheral blood, the neoplastic cells are medium-sized, with basophilic cytoplasm and markedly irregular, multilobulated nuclei, including cloverleaf shapes (also known as flower cells) (¹). The neoplastic cells in lymph nodes and viscera exhibit a spectrum of cell sizes, including small, medium, and large, with relatively round or markedly irregular nuclear contours. Histopathologic findings are not specific for ATLL, and testing for HTLV-1 antibody is needed for suspicious cases even in non-endemic areas.

Immunophenotypic studies show a mature T-cell immunophenotype. The neoplastic cells intensely express CD25 antigen. They also frequently express the chemokine receptor CCR4 and FOXP3, suggesting that regulatory T cells are the closest normal counterpart (²⁹).

Extranodal NK/T-Cell Lymphoma, Nasal Type

Extranodal NK/T-cell lymphoma is an aggressive lymphoma that can have an NK-cell or cytotoxic T-cell immunophenotype and may arise from a precursor cell of NK/T cells. It occurs predominantly in the nasal/paranasal area and much less often at nonnasal sites, such as skin/soft tissue and the gastrointestinal tract (¹). Extranodal NK/T-cell lymphoma is more prevalent in Asians and Native Americans in Central and South America (⁴). Its pathogenesis is unknown; however, the lymphoma cells in essentially all cases are positive for EBV-encoded RNA (EBER), suggesting a very strong association between EBV infection and oncogenesis. Patients with nasal involvement present with symptoms of nasal congestion or epistaxis. With locally advanced disease, the tumor erodes the palate and bone, causing pain, fistula, and infection. Some cases may be complicated by hemophagocytic syndrome (³⁰).

Histologically, ENKL shows a diffuse proliferation of lymphoma cells, often with an angiocentric

FIGURE 9-6 Adult T-cell leukemia/lymphoma involving bone. **A.** In this field, numerous osteoclasts are surrounding and resorbing bone. **B.** The neoplastic cells are large. (**A, B**, hematoxylin-eosin; **A**, 400 \times ; **B**, 1,000 \times).

or angiodestructive growth pattern, associated with a mixture of reactive lymphocytes and histiocytes. Fibrinoid change can be seen in the blood vessels. Granulocytes are rare unless associated with necrotic changes (Fig. 9-7).

Typically, the lymphoma cells express the NK-cell marker CD56, CD2, and cytoplasmic CD3 and are negative for surface CD3, CD5, and TCR. Cytotoxic molecules such as TIA-1, granzyme B, and perforin are also positive. Deletion of chromosome 6 is the most frequent cytogenetic aberration⁽³¹⁾. Chromosome 6 includes two genes named *PRDM1* and *FOXO3*, which may play a role in lymphomagenesis⁽³²⁾. Outcome with conventional chemotherapy is poor, with a median OS of 1 to 2 years⁽³³⁾. High EBV DNA load in plasma is associated with lower response rate to chemotherapy and worse outcome⁽³⁴⁾.

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma is a rare primary intestinal lymphoma often localized (but

FIGURE 9-7 Extranodal NK/T-cell lymphoma, nasal type, involving nasopharynx. Extensive necrosis (left of field) is common in these neoplasms (hematoxylin-eosin, 200 \times).

diffusely infiltrating) in the small intestine⁽¹⁾. Two types of EATL are recognized. Type I accounts for 80% to 90% of EATL, shows large lymphoid cells with an inflammatory background, and is strongly associated with celiac disease. Type II EATL accounts for 10% to 20% of EATL, shows monomorphic medium-sized lymphoma cells, and occurs sporadically, often without a history of celiac disease. Type I is predominant in Europe whereas type II is more common in Asia⁽³⁵⁾. Patients present frequently with abdominal pain, weight loss, and sometimes intestinal perforation⁽³⁶⁾.

Grossly, the involved intestine demonstrates multiple ulcers (Fig. 9-8), which may extend deeply into the bowel wall, often resulting in perforation; a distinct mass may not be found. The jejunum is the most common site of involvement. Histologically, the neoplasms are diffuse, and the neoplastic cells are a mixture of small, medium, and large lymphoid cells (see Fig. 9-8).

The intestine not involved by neoplasm may exhibit blunting of villi, as is seen in celiac disease.

Enteropathy-associated T-cell lymphoma expresses pan-T-cell antigens and usually has a cytotoxic profile positive for TIA-1, granzyme B, and perforin. Type II EATL expresses CD56 more often than type I EATL⁽³⁵⁾. Comparative genomic hybridization analysis often shows amplification of chromosome 9p31.3-qter and deletions of chromosome 16q12.1. The prognosis is poor, with a median OS of 10 months⁽³⁵⁾.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma accounts for less than 1% of all NHL and is derived from cytotoxic T cells. Most cases express the gamma-delta ($\gamma\delta$) TCR, but a minority of cases express the alpha-beta ($\alpha\beta$) TCR⁽¹⁾. Lymphoma cells predominantly involve the spleen, liver, and bone marrow. Peak incidence is in

FIGURE 9-8 Enteropathy-associated T-cell lymphoma. **A.** This field shows the transition from benign mucosa (left of field) to lymphoma and ulcer. **B.** The neoplastic cells are large. (A, B, hematoxylin-eosin; A, 20 \times ; B, 400 \times).

adolescents and young adults with a median age of 35 years. There is strong male predominance (^{1,37}).

Patients typically present with hepatosplenomegaly (abdominal pain) and B symptoms. Because of the hepatosplenomegaly and bone marrow involvement, patients often manifest marked cytopenia, most prominently thrombocytopenia. Chronic immune suppression seems to be associated with the risk of HSTL; up to 20% of patients develop the disease after solid organ transplantation or chronic antigenic stimulation.

Histologically, these neoplasms are composed of medium-sized lymphoid cells with slightly irregular nuclear contours, condensed chromatin, and small nucleoli (¹). In the liver, HSTL infiltrates sinusoids and spares portal tracts. In the spleen, the red pulp is involved and the white pulp spared (Fig. 9-9). In the bone marrow, the neoplastic cells can resemble blasts in aspirate smears and are commonly intrasinusoidal in core biopsy specimens.

Hepatosplenic T-cell lymphomas have a mature but aberrant T-cell immunophenotype. Most cases

FIGURE 9-9 Hepatosplenic T-cell lymphoma involving spleen (hematoxylin-eosin, 400 \times).

are positive for CD3 but negative for CD4 and CD8. CD56 is often positive, and most HSTLs are positive for TIA-1 but negative for granzyme B and perforin. Isochromosome (7q) and trisomy of chromosome 8 are common in HSTL (³⁸). Hepatosplenic T-cell lymphoma is extremely aggressive and chemoresistant. The median OS duration is less than 2 years (³⁷).

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is a rare cytotoxic T-cell lymphoma that arises in subcutaneous tissue. The previous WHO classification included both $\alpha\beta$ and $\gamma\delta$ type as SPTCL, but the recent WHO classification separated these diseases, and $\gamma\delta$ type is now classified as cutaneous $\gamma\delta$ T-cell lymphoma (¹). Cutaneous $\gamma\delta$ T-cell lymphoma is much more aggressive than SPTCL, which occurs in younger patients (median age of 35 years) (³⁹). Patients present with multiple subcutaneous nodules, most commonly in the extremities and trunk. Patients can develop a hemophagocytic syndrome, causing systemic symptoms with pancytopenia, fever, and hepatosplenomegaly (³⁹).

Histologically, SPTCLs involve subcutaneous tissue, without involvement of the overlying dermis. The neoplastic cells infiltrate fat lobules, usually sparing septa. Marked coagulative necrosis and fat necrosis are common, resembling panniculitis (Fig. 9-10). Lymphoma cells have irregular and hyperchromatic nuclei with pale-staining cytoplasm and can be surrounded by fat cells, often with some admixed histiocytes.

Subcutaneous panniculitis-like T-cell lymphoma has an $\alpha\beta$ T-cell phenotype, usually CD3⁺, CD8⁺, and CD4⁻ with expression of cytotoxic molecules, including TIA-1, granzyme B, and perforin (¹). Survival of patient is highly dependent on whether the patient has a hemophagocytic syndrome or not. The 5-year OS

FIGURE 9-10 Subcutaneous panniculitis-like T-cell lymphoma. **A.** The neoplasm involves adipose tissue and is associated with extensive fat necrosis in this field. **B.** The neoplastic lymphocytes surround fat spaces. (Hematoxylin-eosin; **A**, 100 \times ; **B**, 1,000 \times).

rates with and without a hemophagocytic syndrome were 46% and 91%, respectively (³⁹).

MOLECULAR ANALYSIS OF PERIPHERAL T-CELL LYMPHOMA

Gene expression profiling of PTCL has revealed that certain molecular signatures can discriminate histopathologic subtypes and, in addition, may divide cases into several subgroups based on genes that are found in clusters, including the follicular helper T-cell type of PTCL-NOS that has similarities to AITL (⁴⁰). In addition, next-generation sequencing and a comprehensive search for recurrent somatic mutations in PTCL have identified genes that are frequently mutated in PTCL, and the most highly mutated genes are responsible for epigenetic regulation, such as *TET2*, *IDH2*, and *DNMT3A* (¹²). Interestingly *IDH2* mutation seems particularly detected in cases of AITL. Such molecular

analysis may help to determine molecular targets of therapy in patients with PTCL.

PROGNOSTIC FACTORS

Prognosis varies according to the PTCL subtype. With the exception of patients with AL-positive ALCL, long-term survival is approximately 30% to 35% (³). The International Prognostic Index (IPI) provides a prognostic score based on clinical and laboratory factors but was developed for aggressive lymphomas and does not incorporate immunophenotypic results (⁴¹). Prognostic factors for T-cell lymphomas have been analyzed in a retrospective review of a large cohort of patients with PTCL-NOS, AITL, and ALCL. The prognostic index for PTCL-NOS (PIT) includes age >60 years, Eastern Cooperative Oncology Group performance status ≥ 2 , elevated lactate dehydrogenase (LDH), and bone marrow involvement, with each factor given a score of 1 (⁶). Five-year OS ranged from 62% (PIT = 0) to 18% (PIT = 3-4). The AITL prognostic index is calculated using aging >60 years, white blood cell (WBC) count $>10^4/\mu\text{L}$, anemia, platelet count $<15 \times 10^4/\mu\text{L}$, immunoglobulin (Ig) A level $>400 \text{ mg/dL}$, and extranodal involvement >1 (¹⁹). Three-year OS rates of low-risk patients (score 0-1) and high-risk patients (score 4-6) were 85% and 12%, respectively. ALK-positive ALCL is associated with generally good prognosis (³). However, the prognosis of patients with ALK-negative ALCL is worse than that of patients with ALK-positive ALCL, but seems better than those with other subtypes of PTCL (³). The Group d'Etude des Lymphomes de l'Adulte (GELA) group reported that age (<40 or ≥ 40) and β_2 -microglobulin were good prognostic indicators of ALK-negative ALCL (¹⁴). The 8-year OS rates of patients in group 1 (age <40 years and β_2 -microglobulin $<3 \text{ mg/L}$) and group 4 (age ≥ 40 years and β_2 -microglobulin $\geq 3 \text{ mg/L}$) were 84% and 22%, respectively. These prognostic models are clinically convenient and useful in estimating the prognosis of patients with PTCLs. However, there has not been an effective strategy to determine treatment approaches based on such prognostic indicators.

THERAPY

First-Line Therapy

CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) has been the most commonly used chemotherapy. The overall response rate (ORR) after CHOP is 70% to 80%, with complete response (CR) rates of 50%. Long-term progression-free survival (PFS) rate for PTCL-NOS, AITL, and ALK-negative ALCL

after CHOP is only 30% (^{3, 42, 43}). ALK-positive ALCL is an exception in PTCL and has a relatively favorable outcome, with 5-year PFS exceeding 60%. The benefit of anthracycline in the treatment of PTCLs has been questioned (³).

Given the poor outcome with conventional chemotherapy, more intensive approaches and/or upfront autologous stem cell transplantation (ASCT) were investigated. Retrospective study at the MD Anderson Cancer Center (MDACC) showed that patients treated with dose-intensified regimens (hyper-CHOP, hyper-CVAD [hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) had similar survival as those treated with CHOP (⁴⁴). Other studies showed a benefit from adding etoposide to CHOP (^{45, 46}). The German High-Grade Non-Hodgkin Lymphoma Study Group (DSHNHL) evaluated the outcome of 320 patients with T-cell lymphoma enrolled in clinical trials (⁴⁶). The addition of etoposide to CHOP improved response rates and was associated with longer event-free survival (EFS) in younger patients with normal LDH (18-60 years). The 3-year EFS rates with or without etoposide in the regimen were 75% and 51%, respectively. Ellin et al evaluated 755 patients with PTCL in the Swedish Lymphoma Registry and confirmed that the addition of etoposide to CHOP was associated with superior PFS in patients age ≤ 60 years (⁴⁵). Based on these studies, CHOEP (etoposide 100 mg/m² intravenously [IV] on days 1-3 in addition to standard CHOP) is now increasingly used as first-line treatment of PTCLs. The role of upfront ASCT is described later.

Salvage Chemotherapy

Commonly used traditional salvage chemotherapy regimens for relapsed/refractory PTCLs are platinum-containing regimens such as ICE (ifosfamide, carboplatin, and etoposide), GDP (gemcitabine, dexamethasone, and cisplatin), or GemOx (gemcitabine and oxaliplatin). The ORR with ICE ranges from 20% to 70%, with a median PFS of 6 months (⁴⁷). The ORR was 40% with GDP (⁴⁸) and 38% with GemOx with a median PFS of 10 months (⁴⁹). It should be noted that the outcome of patients with relapsed/refractory PTCLs is dismal if stem cell transplantation is not an option. In a study by the British Columbia Cancer Agency, the median durations of PFS and OS were 3.1 and 5.5 months, respectively, in patients with PTCLs who relapsed or progressed after first-line treatment and did not undergo stem cell transplantation (⁵⁰). Thus, previously mentioned combination salvage chemotherapy regimens are primarily offered for patients who are to undergo stem cell transplantation after such salvage therapy. For those who are not transplantation candidates, single-agent chemotherapy or other novel

therapeutic options are to be considered over combination chemotherapy, as detailed later in this chapter.

Hematopoietic Stem Cell Transplantation

Frontline Autologous Stem Cell Transplantation

The role of frontline ASCT in patients with PTCL who achieve CR after induction therapy has only been evaluated either in single-arm nonrandomized studies or in randomized studies including a minority of patients with PTCL (⁵¹). The German group evaluated CHOP followed by upfront ASCT in patients with newly diagnosed PTCLs (excluding ALK-positive ALCL) (⁴³). Among 83 patients treated, the ORR after high-dose chemotherapy was 66% with a CR rate of 56%. The 3-year OS and PFS rates were 48% and 36%, respectively. For patients who actually underwent transplant (66% of patients), the 3-year OS rate was 71% (⁴³). The Nordic group evaluated six cycles of CHOEP (etoposide was omitted for patients > 60 years old) followed by upfront ASCT in patients with PTCLs (excluding ALK-positive ALCL) (⁵²). Among 160 patients treated, the ORR after CHOEP was 82%, with a CR rate of 51%. The 5-year OS and PFS rates were 51% and 44%, respectively. By the subtype-stratified analysis, 5-year OS rates of PTCL-NOS, AITL, ALK-negative ALCL, and EATL were 47%, 52%, 70%, and 48%, respectively. These outcomes seem better than those of historical patients treated by conventional chemotherapy like CHOP (⁵³). Based on these studies, upfront ASCT in PTCLs other than ALK-positive ALCL is considered a reasonable option in clinical practice. For other subtypes of PTCL such as ATLL and HSTL, upfront ASCT is not associated with prolonged remission (⁵⁴).

Frontline Allogeneic Stem Cell Transplantation

A recent study demonstrated the potential benefit of upfront allogeneic stem cell transplantation (alloSCT) for PTCLs in first remission (⁵⁵). Among 49 patients (PTCL-NOS, $n = 33$; AITL, $n = 4$; ALK-negative ALCL, $n = 7$) who underwent upfront alloSCT, the 2-year OS was 72.5% and 1-year nonrelapse mortality (NRM) was 8.2%. Previous studies of alloSCT had generally shown NRM as high as 30%. Given this, the treatment is still considered investigational. In some subtypes of PTCL, such as ATLL, upfront alloSCT has been tested extensively, showing relatively good outcome (⁵⁶).

Autologous Stem Cell Transplantation for Relapsed or Refractory Disease

The benefit of ASCT is rather disappointing, with 5-year PFS $< 20\%$ (⁵⁷). Patients who experience excellent response to salvage chemotherapy may be considered for ASCT consolidation (⁵⁸), particularly if there

is no alloSCT option. Although the most commonly used regimen is BEAM (carmustine, etoposide, cytarabine, and melphalan), alternative conditioning regimens may improve outcome.

Allogeneic Stem Cell Transplantation for Relapsed or Refractory Disease

Likely due to the graft-versus-lymphoma effect, alloSCT may provide effective disease control in relapsed/refractory PTCLs⁽⁵⁹⁻⁶¹⁾. The French group has reported the outcome of 77 patients who received alloSCT. The 5-year NRM rate was 33%, and 5-year OS and EFS rates were 57% and 53%, respectively⁽⁶¹⁾. In a Japanese study, 354 patients (PTCL-NOS, *n* = 200; AITL, *n* = 77; ALCL, *n* = 77) who received alloSCT were analyzed⁽⁶²⁾. The 3-year NRM rates and the 3-year OS rates in younger patients (16-49 years old) who received myeloablative regimen versus a reduced-intensity conditioning regimen were 22% versus 14% and 43% versus 56%, respectively⁽⁶²⁾. We generally consider alloSCT for young patients achieving second remission.

NK/T-Cell Lymphoma

Historically, NKTCL is refractory to conventional treatment like CHOP. Combined-modality approach for early-stage disease (concurrent chemoradiation therapy) and different multiagent chemotherapy for advanced-stage disease have shown some success.

For limited-stage ENKL, platinum-containing chemotherapy given concurrently with high-dose radiation is promising. In a phase II Japanese study of concurrent DeVIC (dexamethasone, etoposide, ifosfamide, and carboplatin) therapy with 50 Gy of radiation, the 5-year OS rate was 70%⁽⁶³⁾. In a phase II study from Korea, patients first received concurrent radiation with weekly cisplatin and then received three cycles of VIPD (etoposide, ifosfamide, cisplatin, and dexamethasone). The ORR after concurrent therapy was 100%, with a CR rate of 73%, and the 3-year PFS and OS rates were 85% and 86%, respectively⁽⁶⁴⁾. Based on these studies, concurrent platinum-based chemotherapy and radiation therapy is an accepted standard approach for localized-stage ENKL.

For advanced-stage disease, there are no effective combination chemotherapies. Because ENKL highly expresses P-glycoprotein (multidrug-resistant protein), combination regimens using agents independent of P-glycoprotein were investigated. The most promising combination therapy is SMILE (methotrexate, ifosfamide, dexamethasone, etoposide, and L-asparaginase)⁽⁶⁵⁾, yielding an ORR of 79%, CR rate of 45%, and a 2-year OS rate of 50%. The French group treated 19 patients with L-asparaginase, methotrexate,

and dexamethasone (AspaMetDex). The ORR was 78%, with a CR rate of 61%, and the median survival was 12.2 months⁽⁶⁶⁾.

Novel Treatments

Table 9-2 shows the new agents used to treat peripheral T-cell lymphoma.

Brentuximab Vedotin

Brentuximab vedotin (BV) is an intravenously administered antibody-drug conjugate that consists of the CD30-specific monoclonal antibody conjugated with monomethyl auristatin E by linker peptide. Binding of the antibody-drug conjugate to CD30 on the cell surface causes internalization of the drug by endocytosis. The drug subsequently travels to the lysosome, causing cell cycle arrest and apoptotic death. Brentuximab vedotin was studied for the treatment of relapsed/refractory systemic ALCL, which uniformly expresses CD30. In a pivotal phase II study in patients with relapsed/refractory systemic ALCL, the ORR was 86%, and the CR rate was 57%. The median PFS was 26.3 months in patients who achieved CR⁽⁶⁷⁾. Grade ≥ 3 adverse events included neutropenia (21%), thrombocytopenia (14%), peripheral sensory neuropathy (12%), and anemia (7%). The US Food and Drug Administration (FDA) approved BV for the treatment of patients with ALCL in whom at least one prior multidrug chemotherapy regimen had failed.

Brentuximab vedotin was also investigated in rather small number of patients with other PTCLs expressing CD30⁽⁶⁸⁾. In PTCL-NOS, ORR was 33%, with a CR rate of 14%, and median PFS was 7.6 months. The ORR in patients with AITL was 54%, with a CR rate of 38%, and median PFS was 5.5 months.

Interestingly, there was no correlation between immunohistochemical CD30 expression and clinical response. A multicenter double-blind phase III study of CHP (CHOP without vincristine) plus BV (A+CHP) versus standard CHOP for CD30⁺ PTCLs (10% or higher) is ongoing (ClinicalTrials.gov identifier: NCT01777152).

Pralatrexate

Pralatrexate, an inhibitor of dihydrofolate reductase, is more than 10-fold more cytotoxic than methotrexate. A pivotal phase II study (PROPEL trial) enrolled 115 patients with relapsed or refractory PTCL. The ORR was 29%, with a CR rate of 11%⁽⁶⁹⁾. When response rates are analyzed based on histology, the ORRs of patients with PTCL-NOS (*n* = 59), AITL (*n* = 13), and ALCL (*n* = 17) were 31%, 8%, and 29%, respectively. The median PFS was 3.5 months in all patients and

Table 9-2 New Agents in Peripheral T-Cell Lymphoma

Agent	Dose/Schedule	No.	ORR (%)	CR (%)	Median DOR (months)	Median PFS (months)	Reference
Brentuximab vedotin	1.8 mg/kg, IV, day 1, every 21 d						
ALCL		58	86	57	12.6	13.3	67
PTCL-NOS		21	33	14	7.6	1.6	68
AITL		13	54	38	5.5	6.7	68
Pralatrexate	30 mg/m ² , IV, weekly x 6, every 49 d	111	29	11	10.1	3.5	69
Romidepsin	14 mg/m ² , IV, weekly x 3, every 28 d	131	25	15	17.0	4.0	70
Belinostat	1,000 mg/m ² , IV, d 1-5, every 21 d	129	26	10	8.3		71
Bendamustine	120 mg/m ² , IV, d 1-2, every 21 d	60	50	28	3.5	3.6	72
Mogamulizumab	1.0 mg/kg, IV, weekly x 8	37	35	14		3.0	74
Alisertib	50 mg, PO BID, 7 d, every 21 d	8	57	43			75

AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; BID, twice a day; CR, complete response rate; d, day; DOR, duration of response; IV, intravenous; ORR, overall response rate; PFS, progression-free survival; PO, oral; PTCL-NOS, peripheral T-cell lymphoma, not otherwise specified.

10.1 months in responding patients. Severe mucositis (grade 3-4 in 22%) often leads to dose delays or interruption.

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors are considered epigenetic modulating agents that induce accumulation of acetylated nucleosomal histones and induce differentiation and/or apoptosis in transformed cells. Two FDA-approved HDAC inhibitors for relapsed PTCLs are romidepsin and belinostat.

Romidepsin was approved for the treatment of CTCL in 2009 and for the treatment of recurrent PTCLs in 2011. A phase II study (n = 130) in relapsed/refractory PTCLs showed ORR of 25%, with a CR rate of 15% (⁷⁰). The median PFS was 4 months overall. It should be noted, however, that responses were frequently durable, with a median duration of response of 28 months. The most common grade 3 or 4 adverse events were thrombocytopenia, neutropenia, and infections. A multicenter phase III study of CHOP with or without romidepsin in patients with previously untreated PTCLs is ongoing (NCT01796002).

Belinostat was approved in 2014 by the FDA for the treatment of recurrent or refractory PTCL, based on the result of a phase II study (BELIEF trial) (⁷¹). This study enrolled patients with PTCLs after a failure of one or more prior systemic therapies. Among 129 patients enrolled, the ORR was 26%, with a CR rate of 10%.

The median response duration was 8.3 months. Grade 3 or 4 toxicity included thrombocytopenia (13%), neutropenia (13%), and anemia (10%). This drug is also being tested in combination with standard CHOP therapy in the frontline settings (NCT01839097).

Other Agents

Bendamustine is nitrogen mustard, consisting of chloroethylamine, an alkylating group, attached to a benzimidazole ring, a purine analog. In a phase II study (BENTLY trial) of 60 patients with relapsed PTCL or CTCL, the ORR was 50%, with a CR rate of 28% (⁷²). Median PFS was 3.6 months. The dose used in the trial for PTCLs was 120 mg/m² every 21 days, which is more intensive than the dose used in low-grade B-cell lymphoma (90 mg/m² every 28 days in combination with rituximab).

Mogamulizumab is a defucosylated anti-CC chemokine receptor 4 (CCR4) antibody that was initially developed for the treatment of ATLL. In a phase II study (n = 28) of patients with relapsed CCR4-positive ATLL, single-agent mogamulizumab showed an ORR of 50%, with a CR rate of 31%. Median PFS was 5.2 months (⁷³). Because CCR4 is also expressed in various proportions of PTCLs, mogamulizumab was evaluated in patients with CCR4-positive relapsed PTCL or CTCL. Of the 38 patient treated, ORR was 35%, with a CR rate of 14%. Median PFS of responders was 5.5 months (⁷⁴).

Alisertib is an aurora A kinase inhibitor. In a phase II study of 48 patients with relapsed/refractory NHL treated with alisertib, 8 had PTCL. The ORR was 57%, with a CR rate of 14% (⁷⁵). A phase III study comparing alisertib to investigator's choice single-agent drug (pralatrexate, gemcitabine, or romidepsin) in relapsed/refractory PTCL is ongoing (NCT01482962).

CUTANEOUS T-CELL LYMPHOMAS

Cutaneous T-cell lymphomas are a clinically heterogeneous group of mature T-cell lymphomas, accounting for most lymphomas arising in skin. Mycosis fungoides (MF) and Sézary syndrome (SS) are defined by their cutaneous lesions that result from the accumulation of a T-helper memory/effector subset with a CD4⁺, CD8⁻, CD45RO⁺CLA⁺ phenotype in skin and blood (¹). Most commonly, MF starts as an indolent and chronic dermatitis in the sun-shielded areas. A diagnostic biopsy specimen is difficult to obtain in early MF because of similarities with eczema and contact dermatitis.

CLASSIFICATION

Mycosis fungoides is staged using the tumor-node-metastasis (TNM) classification schema for the purpose of predicting disease prognosis (Fig. 9-11). Mycosis fungoides

and SS, the most common variants, are still rare with an annual incidence of 3 to 4 new cases per million individuals, or 1,200 new cases per year in the United States (⁷⁶). The next most common entities are the CD30⁺ lymphoproliferative disorders: lymphomatoid papulosis (LyP) and primary cutaneous anaplastic large-cell lymphoma (pcALCL). Subcutaneous panniculitic T-cell lymphoma, cutaneous γ/δ T-cell lymphoma, and NK/T-cell lymphomas are rare and more aggressive (see Table 9-1).

PRESENTATION AND DIAGNOSIS

The International Society for Cutaneous Lymphomas (ISCL) has developed an algorithm to diagnose early-stage MF. The clinical diagnosis is based on a scoring system consisting of clinical, histopathologic, molecular, and immunopathologic criteria. A score of 4 is needed to make the diagnosis (⁷⁷).

Clinically, patients have persistent or progressive patches and thin plaques on sun-shielded areas. Lesion morphology is variable, and patients can also exhibit poikiloderma. Histologically, MF is characterized by an atypical lymphocytic infiltrate in the superficial dermis and epidermis (epidermotropism). Epidermotropism is not always seen, especially in folliculotropic mycosis fungoides and SS. There is a predominance of CD4⁺CD8⁻ cells evidenced by an increased CD4:8

FIGURE 9-11 Mycosis fungoides (MF) and Sézary syndrome: disease-specific survival by clinical stage. Disease-specific survival of 1263 patients with MF and Sézary syndrome was measured according to clinical stage at diagnosis. (Reproduced, with permission, from Talpur R, Singh L, Daulat S, et al. Long-term outcomes of 1263 patients with mycosis fungoides and Sézary syndrome from 1982 to 2009. *Clin Cancer Res*. 2012;18(18):5051-5060.)

ratio and reduced CD7 expression. The finding of clonality with *TCR* gene rearrangement is not diagnostic but helps to support the diagnosis of lymphoma over a reactive process and is given 1 point under the ISCL algorithm. Mycosis fungoides may progress to a leukemic and erythrodermic condition called SS. Sézary syndrome is defined by erythroderma involving >80% of the body and the presence of >1,000/mL of atypical cells in the peripheral blood. By flow cytometry, most patients have increased numbers of CD4⁺CD26⁺ “Sézary cells.” In the skin, the atypical cells have lost epidermotropism and are found around the dermal vessels rather than in the epidermis. Sézary cells secrete Th2 cytokines, interleukin (IL)-4, and IL-10, causing loss of cellular immunity due to decreased production of Th1 cytokines, interferon- γ , and IL-2⁽⁷⁸⁾. This results in atopy characterized by erythroderma, peripheral eosinophilia, increased IgE production, and intractable pruritus. *Staphylococcus aureus* colonization can worsen erythroderma and pruritus. Molecular studies in MF show emergence of one or more clones of skin-homing CD4⁺ T cells with progression to SS; these appear in the blood and can be detected by flow cytometry⁽⁷⁹⁾.

PROGNOSIS

The predictive factors for survival are the T classification, presence of extracutaneous manifestations, and patient age⁽⁸⁰⁾. Independent adverse prognostic factors are large-cell transformation, follicular mucinosis, thickness of the tumor infiltrate, and elevated LDH

and β_2 -microglobulin⁽⁸¹⁾. Patients with SS have worse prognosis. A high Sézary cell count, loss of T-cell subset markers such as CD5 and CD7, and chromosomal abnormalities in T cells are also associated with poor outcome⁽⁸²⁾.

THERAPY

Figure 9-12 summarizes the primary treatment map for CTCL.

Treatment of Early Mycosis Fungoides

A number of FDA-approved therapies are available to treat MF/SS. Therapies are divided into skin-directed and systemic categories. Many of these agents are also used for eczema, psoriasis, and other forms of lymphoma.

Early MF (stages IA, IB, and IIA) is characterized by eczematous or psoriasiform dermatitis covering <80% body surface area without evidence of blood or visceral involvement. Early MF is treated with combination skin-directed therapy. The first therapy is topical steroids. For hypertrophic plaque lesions, the topical retinoid gels or creams may help restore normal epidermal differentiation and reduce the time of clearing when used in combination with phototherapy. The response rate for 1% bexarotene (Targretin) gel was 76% in patients not previously treated; this agent is the only topical therapy approved for MF⁽⁸³⁾. We have also found this gel to be useful for MF on the hands or feet⁽⁸⁴⁾ and for aborting LyP lesions⁽⁸⁵⁾ or MF tumors.

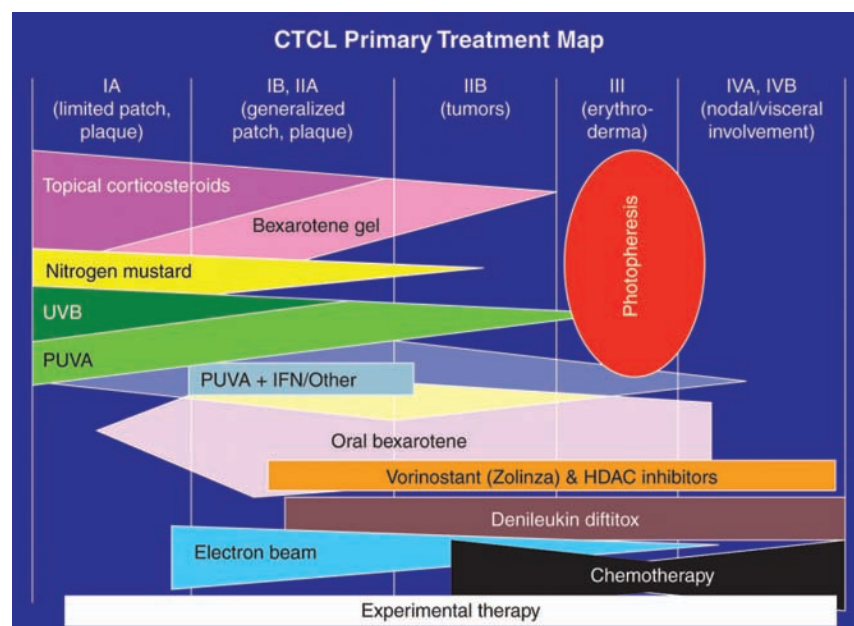

FIGURE 9-12 Cutaneous T-cell lymphoma (CTCL) primary treatment map. HDAC, histone deacetylase; IFN, interferon; PUVA, psoralen plus ultraviolet A; UVB, ultraviolet B.

Mechlorethamine (Valchlor) is a topical nitrogen mustard compound widely used for early-stage MF. Mechlorethamine gel and ointment have response rates of 46.9% and 46.2%, respectively, in stage IA to IIA MF. Faster responses are seen with the gel formulation⁽⁸⁶⁾.

Treatment of Intermediate-Stage, Refractory, or Transformed Mycosis Fungoides and Sézary Syndrome

Patients with MF who do not respond to first-line single-agent topical treatment need more potent therapy such as combinations of skin-directed and systemic therapy. These can include topical steroids, topical and systemic retinoids, topical nitrogen mustard, interferon- α , and chemotherapies (Table 9-3). For patch disease, narrow-band ultraviolet B is effective and can be combined with topical steroids, retinoids, or interferon- α or - γ . Thick plaque lesions or folliculotropic MF lesions are more difficult to clear and are treated with psoralen-ultraviolet A (PUVA) plus interferon or an oral retinoid (bexarotene,

acitretin, or isotretinoin) but often require radiation. Total skin electron beam radiation (TSEB) is effective against plaque and tumor lesions but is reserved for patients with extensive skin involvement who have failed to respond to skin-directed therapies or are planning to undergo stem cell transplantation⁽⁸⁷⁾. Low-dose TSEB of 10 to 20 Gy has good efficacy compared to the standard dose of 30 to 36 Gy⁽⁸⁸⁾. After TSEB, patients use a form of maintenance therapy such as Mustargen, PUVA, or oral bexarotene.

Intravenous denileukin diftitox (Ontak) and oral bexarotene have received FDA approval in 1998 and 1999, respectively, for the treatment of MF. Both are used in the setting of more advanced skin disease. Denileukin diftitox received FDA approval for treatment of all states of CTCL based on a randomized two-dose arm trial showing a response rate of 30%. Complete responses were seen in 10% of patients⁽⁸⁹⁾. Capillary leak syndrome is a side effect seen in 20% to 30% of patients treated with denileukin diftitox and may be prevented with hydration. Acute infusion reactions are blocked by steroid premedication. High expression of CD25⁺ in >20% of tumor cells is associated with a higher response rate of 60% compared to 20% with low expression. However, denileukin diftitox is currently unavailable; it was taken off the market recently by the FDA for inconsistent batches. E7777, a new fusion protein of human interleukin-2 and diphtheria toxin fragments, is undergoing clinical trials. Bexarotene and steroids may increase T-cell CD25 expression and could suggest synergism⁽⁹⁰⁾. Bexarotene monotherapy has a response rate of 54% at a dose of 300 mg/m² in early-stage disease and a response rate of 45% in more advanced stages. Its dose-limiting toxicity is hypertriglyceridemia, which can be controlled with the addition of an 3-hydroxy-3-methylglutaryl-coenzyme A reductase and/or a statin⁽⁹¹⁾.

Patients with transformed MF, tumors, or nodal disease respond to local radiation, denileukin diftitox, nucleoside analogues (gemcitabine, pentostatin), doxorubicin, HDAC inhibitors, or combination chemotherapy. Often, the duration of response is limited. Multiagent chemotherapy combinations, although effective for a limited time, can also induce immunosuppression, leading to line-induced sepsis or opportunistic infections.

Generalized exfoliative erythroderma (EE) is found in patients with blood involvement (SS). Extracorporeal photopheresis was approved in 1987 for the treatment of CTCL, and significant responses were seen in erythrodermic patients⁽⁹²⁾. Extracorporeal photopheresis is usually combined with biologic response modifiers, especially interferon- α or - γ , and retinoids. Responses approach 60% to 70% in SS⁽⁹³⁾. Extracorporeal photopheresis is also effective in early MF when used alone or in combination with biologic response modifiers (interferon- α or oral bexarotene)⁽⁹⁴⁾.

Table 9-3 Overview of Current Therapeutic Options for MF/SS

Skin-Directed Therapy
<ul style="list-style-type: none"> • Topical corticosteroids • Topical chemotherapy (eg, nitrogen mustard, carmustine) • Topical retinoids (bexarotene, tazarotene) • Topical imiquimod • Phototherapy (UVB, NbUVB, PUVA) • Electron beam therapy
Biological Therapy
<ul style="list-style-type: none"> • RXR retinoid (bexarotene) • RAR retinoid (isotretinoin) • Interferons • Granulocyte-macrophage colony-stimulating factor • Extracorporeal photopheresis • Fusion protein/toxin (denileukin diftitox)

NOVEL TREATMENTS

The recently FDA-approved HDAC inhibitors, vorinostat (Zolinza) in 2006, depsipeptide (Romidepsin) in 2009, and belinostat (Beleodaq) in 2014, represent a new strategy for targeted therapy of CTCL and are effective in patients highly refractory to chemotherapy and other agents. Their mechanism of action, like retinoids, involves inducing transcription of genes that control differentiation and apoptosis selectively in malignant cells. Oral vorinostat is well tolerated at a dose of 400 mg daily and has a rapid onset of action. Vorinostat yields a response rate of 30%. The response rate is higher (36%) in patients with SS compared to other stages. The drug improves skin, nodal, and blood involvement and reduces pruritus⁽⁹⁵⁾. Romidepsin (previously known as depsipeptide or FK228) is approved for the treatment of CTCL after at least one prior systemic therapy. The response rate is 34% (CR, 6%) in MF⁽⁹⁶⁾. The recommended dose and schedule of romidepsin is 14 mg/m² intravenously over 4 hours on days 1, 8, and 15 of a 28-day cycle. Most patients (63%) with moderate or severe pruritus experienced significant relief, which significantly impacted quality of life in SS and MF patients^(97,98).

Gemcitabine therapy yields a response rate of 70%, and doxorubicin has a response rate of 80%^(99,100). A phase II study of gemcitabine and bexarotene showed a lower response rate than gemcitabine alone⁽¹⁰¹⁾.

Pralatrexate was used at a lower dose of 15 mg/m² in MF and produced a response rate of 57%⁽¹⁰²⁾. Pralatrexate in combination with bexarotene achieved similar efficacy⁽¹⁰³⁾.

Targeted therapy with monoclonal antibodies against T-cell molecules is under investigation. Zanolimumab (HuMax-CD4) induced responses in 24% of patients and had an acceptable safety profile at a dose of 980 mg weekly⁽¹⁰⁴⁾. Alemtuzumab (Campath-H), targeting CD52, is useful in SS, especially in the elderly. It can be given subcutaneously but is extremely immunosuppressive, because it depletes T cells, B cells, and NK cells for years. Diphtheria fusion protein coupled to CD3 is under investigation. Forodesine is a nucleoside analogue that inhibits purine nucleoside phosphorylase and deoxyguanosine triphosphate buildup, causing T-cell apoptosis. A randomized phase II trial showed oral forodesine to achieve partial response in 11% of 144 patients at a daily dose of 200 mg⁽¹⁰⁵⁾. Intravenous forodesine also showed activity in relapsed-refractory NKTCL⁽¹⁰⁶⁾.

Other agents in trials for MF include CpG (activate Toll-like receptors), lenalidomide, sapacitabine (oral nucleoside inhibitor), and enzastaurin (PKC/AKT inhibitor). Lenalidomide 25 mg daily for 21 days every month produces a response rate of 28%⁽¹⁰⁷⁾.

FUTURE DIRECTIONS

T-cell lymphomas are rare and represent a heterogeneous group of diseases with poor prognosis. It is strongly recommended that patients with non-ALK-positive ALCL PTCLs and CTCLs receive treatment on clinical trials so that progress can be made in the management of these rare neoplasms. Targeted therapies may offer more selective activity with reduced immunosuppression.

Hodgkin Lymphoma

Dai Chihara
Fredrick B. Hagemeister
L. Jeffrey Medeiros
Michelle A. Fanale

INTRODUCTION

Hodgkin lymphoma (HL) was recognized in the first half of the nineteenth century by Thomas Hodgkin and Samuel Wilks (¹). HL usually arises in lymph nodes, preferentially in the cervical area, and the majority of HLs manifest clinically in young adults in their third and fourth decades of life. The incidence of HL is 3.0 per 100,000 person-year in the United States; it is higher in the Western countries than Asian countries (^{2, 3}). Biological and clinical studies have shown that HLs are comprised of two disease entities: nodular lymphocyte-predominant HL (NLP HL) and classical HL (cHL) (¹). The two entities differ in their clinical features and behavior. Within cHL, four subtypes have been described: nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted. These four subtypes differ in their clinical features, growth pattern, presence of fibrosis, and frequency of Epstein-Barr virus infection but share the immunophenotype of tumor cells.

The management of HL continues to evolve. Before the widespread use of modern polychemotherapy, large-field radiation therapy was able to cure cHL patients. However, reliance on radiation alone required extensive radiation portals to treat nearly the entire lymphatic system with radiation doses up to 44 Gy. With long-term follow-up, many patients developed heart toxicity and second malignancies. Therefore, efforts have been made to reduce the long-term toxicities of treatment for HL while maintaining excellent cure rates. With modern chemotherapy, multiple randomized studies have shown that radiation portals

can be safely reduced from extended-field radiation to involved-field radiation and, now, even smaller fields of radiation, including involved-node radiation.

Currently, the treatment of cHL is stratified by risk groups—early-stage favorable, early-stage unfavorable, and advanced-stage disease—according to the clinical stage and the presence or absence of adverse clinical features. In this chapter, we will review advances in the management of HL, including recent publications about strategies of management of the rarer diagnosis of NLP HL.

TYPES OF HODGKIN LYMPHOMA

Over the past decade, investigators have made significant progress in the diagnosis, classification, staging, prognosis, and treatment of HL. In past years, the true lineage of the neoplastic cells in HL was unknown; hence, the term *Hodgkin disease* was used. It is now recognized that almost all cases of HL are of B-cell lineage; hence, the name changed to Hodgkin lymphoma.

The classification of HL has remained relatively stable over the past 40 years, and the World Health Organization (WHO) classification of lymphoid neoplasms was updated in 2008 (¹) (Table 10-1). The current WHO classification recognizes that NLP HL is distinct from the other types that can be grouped together under the rubric of cHL (¹).

In 2015, it was estimated that 9,050 Americans would be diagnosed with HL, with a median age at diagnosis of 39 years (⁴). Hodgkin lymphoma has been traditionally defined as a hematopoietic neoplasm

Mixed cellularity
Lymphocyte depleted

composed of diagnostic Hodgkin and Reed-Sternberg (HRS) cells within a reactive cell background. An HRS cell is large, 30 to 60 μm, containing a bilobed vesicular nucleus, with each lobe containing a prominent round eosinophilic nucleolus surrounded by a clear zone or halo; it also has abundant cytoplasm. However, HRS cells often comprise less than 1% of the involved tumor tissue and are absent in NLPHL. Hodgkin and Reed-Sternberg cells are believed to be derived from germinal center (GC) B cells that have unfavorable immunoglobulin V gene mutations, whereas lymphocyte-predominant (LP) cells, which were previously termed lymphocytic and histiocytic (LH) cells, are thought to originate from antigen-selected GC B cells (6).

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Clinical Features

Approximately 5% of patients with HL have NLPHL. This disease is usually localized and most often involves cervical or axillary lymph nodes (1, 6). The disease affects patients of all ages, males more often than females, and is clinically indolent (Table 10-2). Systemic symptoms—such as fever, weight loss, and night sweats (also known as B symptoms)—are infrequent. Patients with NLPHL are characterized as having a more indolent course with delayed relapse compared with cHL, analogous to low-grade non-HL (6). Patients with NLPHL are at 5% to 6% risk for developing diffuse large B-cell lymphoma (DLBCL) or T-cell/histiocyte-rich large B-cell lymphoma (1).

The German Hodgkin Lymphoma Study Group (GHSG) has reported a large retrospective study of 394 patients with NLPHL. Patients were predominantly men (75%), only 9% had B symptoms, and 79% had early-stage disease (7). With a median follow-up of 50 months, tumor control (freedom from treatment failure) and overall survival were 88% and 96%, respectively, slightly better than in cHL (82% and 92%, respectively).

Histologic Features

Nodular lymphocyte-predominant Hodgkin lymphoma is characterized by effacement of nodal architecture by

Table 10-2 Comparison of Clinical Features of Nodular Lymphocyte-Predominant (NLPHL) and Classical Hodgkin Lymphoma (HL)

Clinical Feature	NLPHL	Classical HL
Frequency	5%	95%
Age distribution	Unimodal: equal in children and adults	Bimodal: peak in second and third decades
Male	70%	50%
Sites involved	Lymph nodes with sparing mediastinum	Mediastinum, cervical lymph nodes
Stage at diagnosis ^a	I	II or III
B symptoms	<20%	40%
Clinical course	Indolent, late relapses	Aggressive, curable

^aMost common stage at time of diagnosis.

variably sized, vague nodules composed of numerous small lymphocytes, histiocytes, and characteristic neoplastic LP cells (Fig. 10-1A) (1, 8). These cells are typically large, with pale cytoplasm and polyploid vesicular nuclei containing inconspicuous nucleoli resembling kernels of popped corn, hence the nickname popcorn cells (Fig. 10-1B). However, LP cells can exhibit a range of cytologic appearances. These cells can be round and/or have relatively prominent nucleoli. Eosinophils, neutrophils, and plasma cells are usually absent in NLPHL, and there is no associated necrosis or fibrosis.

Cases of NLPHL can also have diffuse areas. When diffuse areas are large, their presence often correlates with more aggressive disease. To reflect this change in clinical behavior, many pathologists diagnose such cases as NLPHL with progression to T-cell/histiocyte-rich large B-cell lymphoma, also described as T-cell-rich B-cell lymphoma (TCRBCL). Other pathologists use the term *NLPHL with large diffuse areas* and suggest that the diffuse areas may represent the beginning stages of progression to DLBCL. The boundary between NLPHL with diffuse areas and TCRBCL remains blurred. Most cases previously designated as diffuse LPHL, as defined previously (9), are now classified differently. With appropriate workup, these cases are usually classified as NLPHL with large diffuse areas, lymphocyte-rich cHL, or TCRBCL.

Gene expression profiling of NLPHL to determine the origin and pathogenesis of LP cells found significant similarities between NLPHL, TCRBCL, and cHL (10). Overall, LP cells are thought to derive from antigen-selected GC B cells (5). LP cells also demonstrate deregulation of numerous apoptosis regulators and putative oncogenes and a partial loss of their B-cell phenotype.

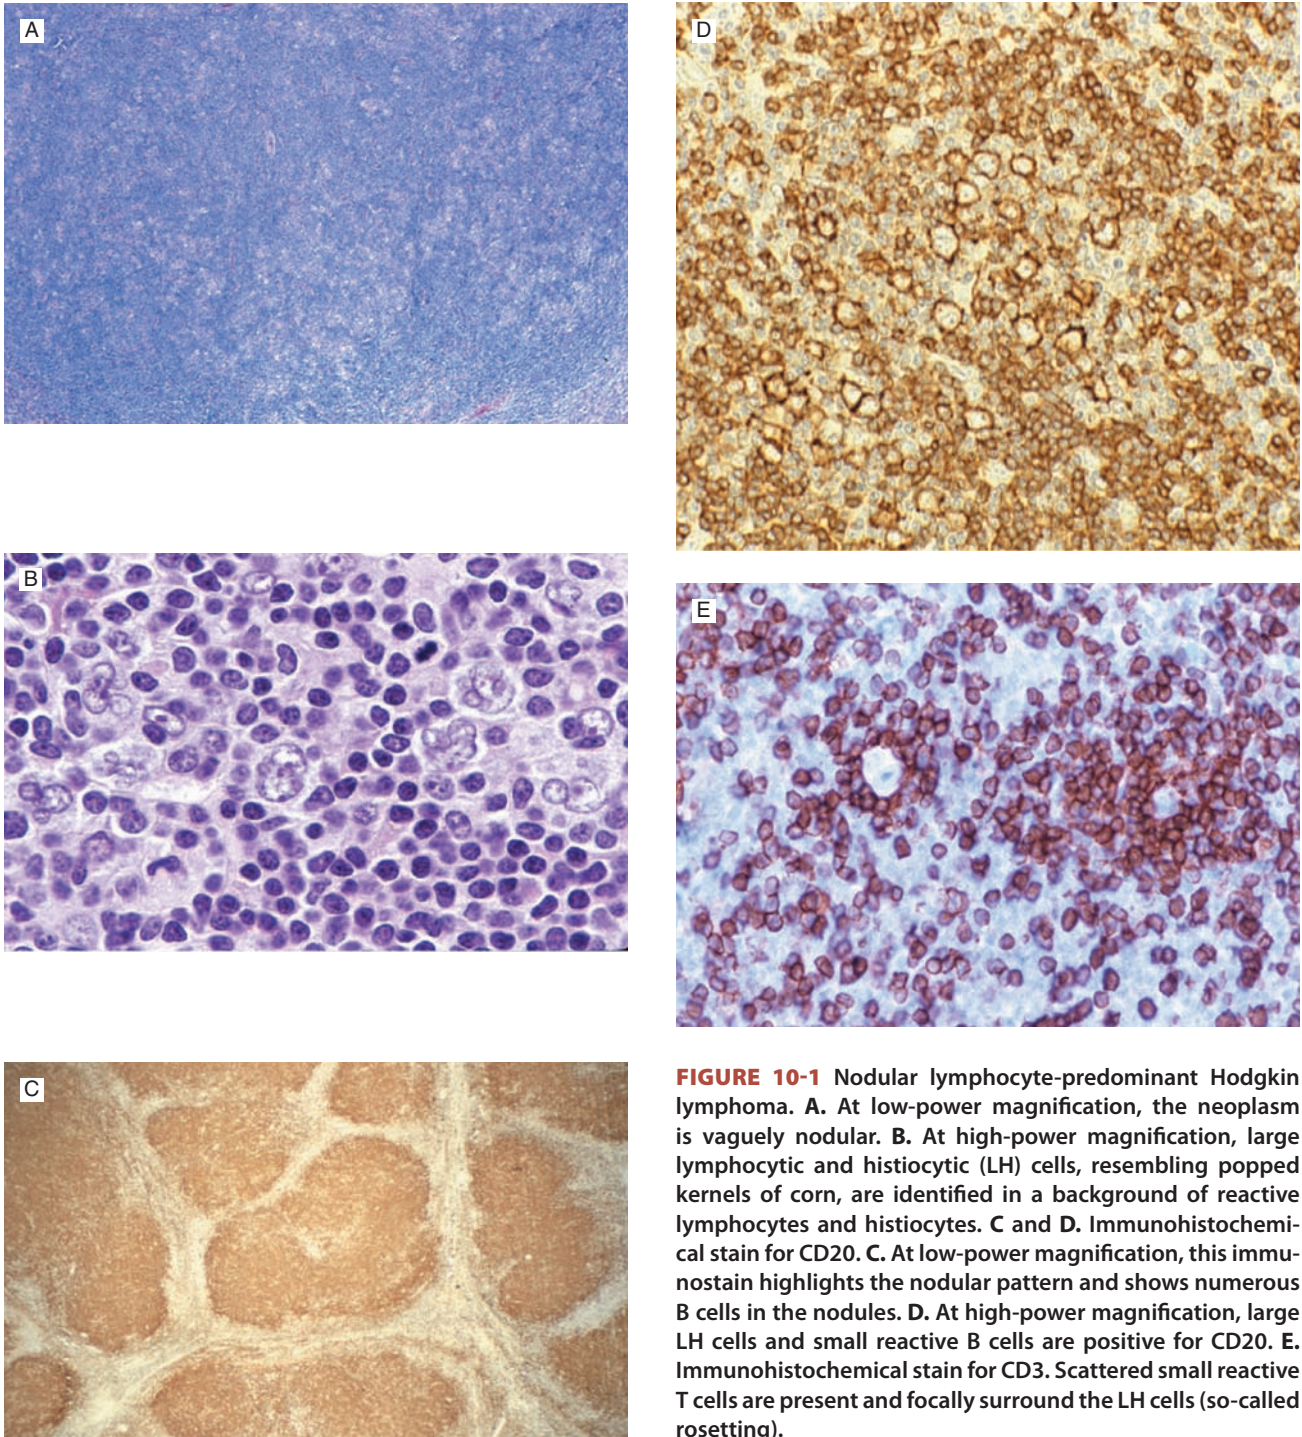

FIGURE 10-1 Nodular lymphocyte-predominant Hodgkin lymphoma. **A.** At low-power magnification, the neoplasm is vaguely nodular. **B.** At high-power magnification, large lymphocytic and histiocytic (LH) cells, resembling popped kernels of corn, are identified in a background of reactive lymphocytes and histiocytes. **C and D.** Immunohistochemical stain for CD20. **C.** At low-power magnification, this immunostain highlights the nodular pattern and shows numerous B cells in the nodules. **D.** At high-power magnification, large LH cells and small reactive B cells are positive for CD20. **E.** Immunohistochemical stain for CD3. Scattered small reactive T cells are present and focally surround the LH cells (so-called rosetting).

In addition, there is constitutive activation of nuclear factor- κ B (NF- κ B), Janus kinases/signal transducers and activator of transcription (JAK/STAT) pathway, and aberrant extracellular-regulated kinase signaling.

Immunophenotypic Findings

Nodular lymphocyte-predominant Hodgkin lymphoma is immunophenotypically distinct from other types of HL. The LP cells usually express leukocyte common

antigen (LCA; CD45), immunoglobulin J chain, B-cell antigens (CD19, CD20, CD22, CD79A, and BCL-6), and epithelial membrane antigen (EMA) and are negative for CD15 and CD30 (Figs. 10-1C and D). These results suggest that the LP cells are B cells that arise from the GC. The LP cells are negative for T-cell antigens but are often surrounded by a rosette of small, reactive T cells that may be positive for pan-T-cell antigens and CD57 (Fig. 10-1E). Epstein-Barr virus is almost always absent in the LP cells of NLP HL.

Lymphocyte-Rich Classical Hodgkin Lymphoma

Lymphocyte-rich cHLs (LRHLs) have been recognized that resemble NLPHL histologically but are cHL immunophenotypically (^{1,6,8}). The frequency of this type of HL is not well known but is most likely low (<5%). Clinically, patients with LRHL are similar to patients with other subtypes of cHL or have clinical findings intermediate between NLPHL and cHL. Unlike

patients with NLPHL, late relapse is uncommon in patients with LRHL.

Histologically, these tumors are rich in small lymphocytes and histiocytes. Granulocytes and plasma cells are usually infrequent. Necrosis is usually not present. Lymphocyte-rich cHL may be either nodular or diffuse. The nodular type closely resembles NLPHL. Vague nodules of numerous small lymphocytes are present, and the nodules may have a small compressed GC (Figs. 10-2A and B). The neoplastic cells

FIGURE 10-2 Lymphocyte-rich classical Hodgkin lymphoma, nodular variant. **A.** At low-power magnification, the neoplasm has a nodular pattern and is rich in reactive small lymphocytes (resembling nodular lymphocyte-predominant Hodgkin lymphoma). **B.** At high-power magnification, large neoplastic cells (so-called Hodgkin cells) are identified in the mantle zone of the follicle (note reactive germinal center to left of field). **C and D.** Immunohistochemical stain for CD20. **C.** The nodules contain numerous small reactive B cells. **D.** The Hodgkin cells are negative for CD20. **E.** Immunohistochemical stain for CD30. The Hodgkin cells are positive.

are present in the mantle zones of the nodules. These neoplastic cells usually resemble Reed-Sternberg and typical mononuclear variant cells (so-called Hodgkin cells) rather than LP cells. The cell composition is similar in diffuse cases of LRHL, but nodularity is minimal or absent. Immunohistochemical studies of LRHL show that the large neoplastic cells have an immunophenotype similar to that of all cHL cases, positive for CD15 and CD30 and negative for LCA (CD45) (Figs. 10-2C to E).

In a study of NLPHL by the European Task Force on Lymphoma⁽⁸⁾, a large number of tumors that had been classified as NLPHL were reviewed; the diagnosis was confirmed in only half of these cases. Most of those excluded were reclassified as LRHL.

Nodular Sclerosis Hodgkin Lymphoma

Clinical Features

Nodular sclerosis (NS) is the most common form of cHL, representing 60% to 70% of all cases in Western countries; it is also the most common type of cHL in patients younger than age 50 years. Whites are affected more often than others, and nodular sclerosis HL (NSHL) is much less frequent in Asian countries^(2, 3). The age-adjusted incidence rate of NSHL has been stable since 1993 to 2008 in the United States according to the National Cancer Institute (NCI) Surveillance, Epidemiology, and End Results (SEER) data⁽²⁾. The male-to-female ratio is approximately equal. Nodular sclerosis HL has a marked predilection for involving mediastinal, supraclavicular, and cervical lymph nodes. A mediastinal mass is very common, and the thymus may be involved.

Histologic Features

Nodular sclerosis HL is characterized by a triad of findings: (1) a nodular pattern, (2) broad bands of fibrosis that outline the nodules, and (3) characteristic mononuclear cell variants known as lacunar cells (Fig. 10-3). A lacunar cell has abundant clear cytoplasm with a sharply demarcated cell membrane. In formalin-fixed tissue, a characteristic artifact occurs. The cell cytoplasm retracts, leaving a clear space or lacuna surrounding the cell, hence the origin of the name. The typical lacunar cell has a polylobulated nucleus with one or multiple small nucleoli. However, lacunar cells can show great morphologic variability and can be round with prominent nucleoli, or they may resemble large noncleaved cells. A heterogeneous mixture of reactive cells may be seen in HL, including small lymphocytes, histiocytes, eosinophils, neutrophils, and plasma cells in variable numbers.

Nodular sclerosis HL has been graded (as 1 or 2) by the British National Lymphoma Investigation (BNLI)

FIGURE 10-3 Nodular sclerosis Hodgkin lymphoma. **A.** The neoplasm is nodular, and the nodules are surrounded by dense fibrous bands. **B.** The large neoplastic cells (lacunar cells) lie within lacunar spaces, and many are multinucleated in this field. Reactive cells are present in the background.

group⁽¹¹⁾ according to the numbers of neoplastic cells and reactive cells present, and this grading system has been adopted by the WHO classification⁽¹⁾. Grade 2 cases of NSHL show numerous neoplastic (lacunar) cells and depletion of reactive lymphocytes. Lymphocyte-depleted and syncytial variants (Fig. 10-4) of NSHL have been described; these cases are the outermost examples of grade 2 NSHL. The syncytial variant of NSHL is composed of sheets of neoplastic cells and necrosis.

Mixed Cellularity Hodgkin Lymphoma

Clinical Features

The mixed cellularity variant of HL (MCHL), the second most common type, affects 15% to 25% of all patients with the disease and is the most common form in patients older than age 50 years^(1, 12). Males are affected more often than females. According to NCI SEER data, MCHL is relatively more common in African Americans and Hispanic Americans than in whites in the United States. A substantial percentage

FIGURE 10-4 Syncytial variant of nodular sclerosis Hodgkin lymphoma. **A.** Nodularity and a fibrous band can be appreciated in this field. **B.** The nodules are composed of many neoplastic cells with depletion of small lymphocytes.

of patients with MCHL have clinical stage III or stage IV disease and B symptoms.

Histologic Features

Mixed cellularity HL is characterized by a large number of Reed-Sternberg cells and Hodgkin cells in a background of numerous eosinophils, plasma cells, histiocytes, and granulocytes in varying proportions (¹) (Fig. 10-5). The lymph node architecture is usually diffusely replaced. Partially involved lymph nodes show selective paracortical infiltration. Disorderly fibrosis may be seen, but the broad fibrous bands and capsular fibrosis characteristic of NSHL are absent.

Two variants of MCHL can be relatively more difficult to diagnose. In the interfollicular variant, which most likely represents partial involvement of lymph nodes by HL, the tumor is located in the interfollicular region and is often associated with reactive follicular hyperplasia and marked plasmacytosis. In the epithelioid histiocyte-rich variant, numerous epithelioid histiocytes and granulomas are present; these can be so numerous as to obscure the neoplastic cells. The

FIGURE 10-5 Mixed cellularity Hodgkin lymphoma. **A.** Classic Reed-Sternberg cell (center of field) and mononuclear Hodgkin cells can be appreciated in a background of reactive lymphocytes, histiocytes, and eosinophils. **B.** Immunostain for Epstein-Barr virus latent membrane protein type 1. The neoplastic cells are positive.

importance of these variants of MCHL lies in their unusual histologic findings.

Lymphocyte-Depleted Hodgkin Lymphoma

Clinical Features

Lymphocyte-depleted HL (LDHL) is the least common type, representing 1% of all cases (¹²). In the NCI SEER study, it was shown that the age-adjusted incidence rate for LDHL has decreased. This decrease is most likely explained by the recognition by pathologists that many tumors previously classified as LDHL are, in fact, non-HLs (such as anaplastic large-cell lymphoma). Improved classification is the result of application of immunohistochemical and molecular methods to the study of these tumors.

FIGURE 10-6 Lymphocyte-depleted Hodgkin lymphoma. Large neoplastic cells in the background of loose, nonpolarized fibrosis and lymphocyte depletion.

Patients with LDHL are usually elderly, and LDHL is rare in individuals younger than 40 years old. There is a slight male predominance. Whites and African Americans are equally affected. Most patients have advanced clinical stage and B symptoms. Patients commonly have a large contiguous mass of matted lymph nodes or diffuse visceral involvement. The diffuse fibrosis type of LDHL commonly has a subdiaphragmatic distribution. Lymphocyte-depleted HL has the poorest prognosis of all types of HL ⁽¹²⁾.

Histologic Features

The LDHL category includes two variants originally recognized by Lukes and Butler: diffuse fibrosis and reticular (Fig. 10-6). The diffuse fibrosis variant of LDHL is characterized by an extensive proliferation of disordered, hypocellular fibrosis. Diagnostic HRS cells can be difficult to find and may be spindled within dense collagen. Reactive inflammatory cells are relatively few. The reticular variant of LDHL has numerous HRS cells and bizarre variants that have been termed pleomorphic variants. These cells may exhibit marked variations in nuclear number and shape, often with giant nucleoli. Normal small lymphocytes are infrequent compared with the other subtypes of HL. Necrosis is common and may be extensive. The HRS cells and pleomorphic variants may be found in sheets. Mitotic figures are usually numerous.

Immunophenotypic Findings in Classical Hodgkin Lymphoma

Overall the mature B-cell origin of the HRS cells is not readily apparent because HRS cells have a very unusual

phenotype and have expression of genes that are seen on many hematopoietic cell types. The neoplastic cells are positive for CD15 and CD30 and negative for LCA (CD45) (Fig. 10-7) and EMA ⁽¹⁾. B-cell antigens, such as CD20, CD79A, PAX-5/BSAP, and MUM1/IRF4, are

FIGURE 10-7 Typical immunohistochemical findings in classical Hodgkin lymphoma. The Hodgkin cells are positive for CD15 (A) and CD30 (B). The Hodgkin cells in (C) are negative for LCA (CD45RB).

expressed in a subset of cases. CD20 expression is often weak. T-cell antigens are usually not expressed by the neoplastic cells. BCL-2 is positive in up to half the cases and has been correlated with poorer prognosis⁽¹³⁾. Epstein-Barr virus is relatively common in cHL, but its frequency varies greatly among different types.

HODGKIN LYMPHOMA: STAGING AND THERAPY

The University of Texas MD Anderson Cancer Center (MDACC) diagnostic and treatment algorithms for HL are shown in Fig. 10-8.

Diagnosis

- FNA alone is insufficient
- Hematopathology review of all slides with at least one tumor paraffin block. Rebiopsy if consult material is non-diagnostic.
- Core needle biopsy may be adequate if diagnostic, but an excisional/nodal biopsy is recommended.
- Recommend staining for CD15, CD30, T and B panels, CD20, PAX5
- Adequate immunophenotype to confirm diagnosis
 - Paraffin panel for Hodgkin lymphoma (HL) including nodular lymphocyte predominant HL:
 - CD20, PAX-5, CD30, CD3, CD15, and CD45 (LCA)
 - EBER
- EBV proteins (ie, LMP1) recommended for N.S. grade 2 or anaplastic variants
- Of use in certain circumstances**
- Immunohistochemical studies:
 - LMP1
 - BOB1, OCT2, and CD79a (diff. dx with B-cell lymphoma, unclassifiable with features intermediate between classical HL and DLBCL and primary mediastinal large B-cell Lymphoma).
 - CD21, CD23, or CD35 (follicular dendritic cell markers), CD57, BCL6 and IgD in cases of nodular lymphocyte predominant HL (may help with T-cell/histiocyte-rich large B-cell lymphoma)
 - CD2, CD43, ALK and EMA (diff. dx with anaplastic large-cell lymphoma)
- Strongly recommend:**
- Core biopsy for tissue banking by protocol

Workup

- History and physical including:
 - B symptoms (fever, sweats, weight loss)
 - ETOH intolerance
 - Pruritus
 - Fatigue
 - Performance status
 - Exam of nodes
 - Spleen, liver
- CBC, differential, platelets
- LDH, Liver Function Tests including: alkaline phosphatase, AST, ALT, and albumin, BUN, creatinine
- ESR
- Screening for HIV 1, HIV 2, hepatitis B and C (HBcAb, HBsAg, HCVAb)
- Chest X-ray
- CT Neck, chest, abdomen and pelvis
- PET/CT
- Bilateral bone marrow biopsies
- MUGA or echocardiogram
- Counseling: Fertility, psychosocial if clinically indicated
- Useful in selected cases:**
- Pregnancy test: women of childbearing potential
- Discuss fertility issues and sperm banking for patients of child bearing potential
- Semen cryopreservation, if chemotherapy or pelvic radiotherapy contemplated

Patient Presentation Salvage Therapy

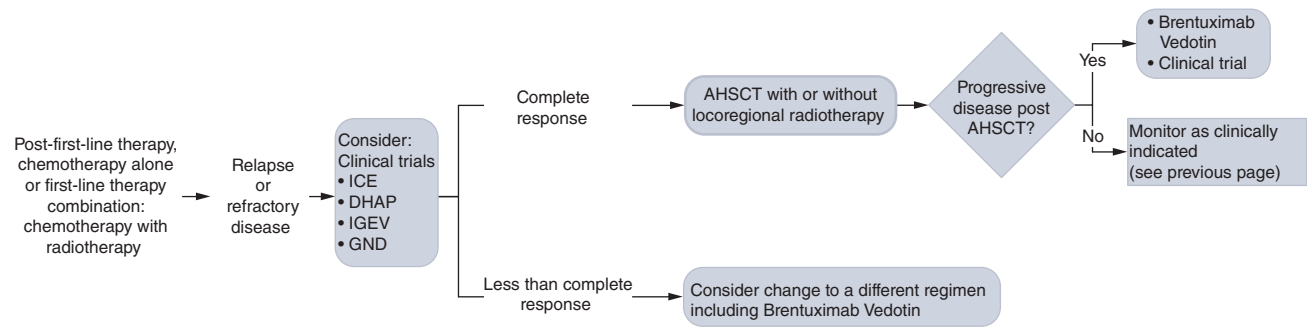

FIGURE 10-8 (Continued)

Staging of the Patients

The Ann Arbor system for staging patients with HL at the time of initial presentation forms the basis for the treatment of disease and has allowed comparison of results achieved by different investigators for more than two decades. Important modifications of the Ann Arbor system were developed at the Cotswold

Conference in 1989 (Table 10-3) (14). Since then, the staging evaluation has been changing. A recent recommendation for the staging procedure in lymphoma described the importance of positron emission tomography (PET)–computed tomography (CT) scan for fluoro-deoxyglucose (FDG)-avid lymphomas, of which HL is one example (15). For HL and other FDG-avid lymphomas, PET-CT improves the accuracy of staging

Table 10-3 Ann Arbor Staging System With Cotswold Modifications for Hodgkin Lymphoma

Stage I	Involvement of a single lymph node region or lymphoid structure (eg, spleen, thymus, Waldeyer ring) or a single extralymphatic site.
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of only one extralymphatic organ or site and lymph node region on the same side of the diaphragm (IIIE). The number of anatomic regions involved should be indicated by a subscript (eg, II ₃).
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by spleen involvement (IIIS) or by localized contiguous involvement of only one extralymphatic organ or site (IIIE) or both (IIISE).
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement.
Modifying Features	
A	No symptoms
B	Fever (>38°C), drenching night sweats, unexplained weight loss of >10% body weight within the preceding 6 months
X	Bulky disease: greater than one-third widening of the mediastinum, >10 cm maximum diameter of a nodal mass
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site
CS	Clinical stage
PS	Pathologic stage (as determined by laparotomy)

compared to CT scans for nodal and extranodal sites⁽¹⁶⁾. Positron emission tomography–CT leads to change in stage in 10% to 30% of patients, more often upstaging, although alteration in treatment occurs in fewer patients with no demonstrated impact on overall outcome. However, PET-CT is critical as a baseline measurement before therapy to increase the accuracy of subsequent response assessment⁽¹⁷⁾. In addition, contrast-enhanced CT scan should be included for a more accurate measurement of nodal size if required for clinical trials.

Patient Evaluation

The initial evaluation of patients with HL has both prognostic and therapeutic significance (see Fig. 10-8). Routine studies that should be performed include a complete blood cell count with differential, electrolytes, blood urea nitrogen (BUN), creatinine, liver function tests, lactate dehydrogenase (LDH), albumin, pregnancy test in women of childbearing age, erythrocyte sedimentation rate (ESR), pulmonary function test (PFT) with carbon monoxide diffusing capacity (DLCO), evaluation of cardiac ejection fraction, chest x-ray, CT of neck, chest, abdomen, and pelvis, and PET-CT (Table 10-4).

Bone marrow biopsy has been standard in lymphoma staging. However, the high sensitivity of PET-CT for bone marrow involvement has recently led to questioning the use of bone marrow biopsy as a staging procedure in several common histologies, including HL⁽¹⁵⁾. In one study in HL, 18% of patients had focal skeletal lesion on PET-CT, but only 6% had positive bone marrow biopsy, all with advanced-stage disease on PET-CT⁽¹⁸⁾. Patients with early-stage disease rarely have marrow involvement in the absence of a suggestive PET finding, and those with advanced-stage disease rarely have marrow involvement in the absence of disease-related symptoms. Although the issue is controversial and some institutions still perform bone marrow biopsy for the initial staging evaluation, almost all patients would not have been allocated to another treatment based on bone marrow biopsy results. Thus, the recommendation states that bone marrow biopsy is no longer indicated for the routine staging of HL.

Magnetic resonance imaging (MRI) has not superseded CT scanning of the chest and abdomen in the evaluation of HL. It is largely restricted to the assessment of specific situations such as bony involvement and spinal cord compression as well as in lieu of CT scans in pregnant patients.

Prognostic Factors

In HL patients at a low clinical stage (CS)—that is, CS I or CS II—several prognostic factors, based largely on

Table 10-4 Recommended Procedures for Staging of Hodgkin Lymphoma

History and examination	Identification of B symptoms
Radiologic and other assessments	Chest radiograph
	Computed tomographic (CT) scans including neck, chest, abdomen, and pelvis whole-body positron emission tomography (PET) scan
	Echocardiogram or multigated acquisition (MUGA) scan
	Pulmonary function tests
	Human immunodeficiency virus serology
	Pregnancy test in women of childbearing age
Hematologic procedures	Complete blood count with differential
	Erythrocyte sedimentation rate (ESR)
	Bilateral bone marrow aspiration and biopsy
Biochemical procedures	Liver function tests
	Serum albumin
	Lactate dehydrogenase
Procedures for use under special circumstances	Ultrasound scanning
	Magnetic resonance imaging

patients treated only with radiotherapy, have been identified through retrospective studies. Adverse factors are: (1) advanced age, which correlates with the presence of occult abdominal disease and with poor results of salvage therapy; (2) male sex; (3) MC histologic type, which is associated with the presence of occult abdominal disease; (4) B symptoms, also associated with the presence of occult abdominal disease; (5) large mediastinal mass, defined as a mass measuring greater than one-third the chest diameter on a standard chest radiograph; (6) a larger number of involved nodal regions; (7) an elevated ESR; (8) anemia; and (9) a low serum albumin level^(19, 20).

International organizations have defined various systems that calculate the risk of recurrence of disease or, in some cases, death, after treatment for HL. The European Organization for the Research and Treatment of Cancer (EORTC) has defined CS I and CS II patients as having an unfavorable risk of development

Table 10-5 Prognostic Classification of the EORTC and GHSG Groups for Clinical Stage I/II Hodgkin Lymphoma**EORTC**Unfavorable (presence of *any* of the following):

Age ≤50 years

ESR >50 mm/h without B symptoms, ESR >30 mm/h with B symptoms

≤4 nodal sites of involvement

Bulky mediastinal mass

GHSGUnfavorable (presence of *any* of the following):

ESR >50 mm/h without B symptoms, ESR >30 mm/h with B symptoms

≤3 nodal sites of involvement

Bulky mediastinal mass

Extranodal involvement

EORTC, European Organization for the Research and Treatment of Cancer; ESR, erythrocyte sedimentation rate; GHSG, German Hodgkin Lymphoma Study Group.

of recurrence if any of the following factors apply: (1) age >50 years, (2) no symptoms present with ESR >50 mm/h or B symptoms with ESR >30 mm/h, (3) large mediastinal mass, (4) stage II, or (5) at least four nodal regions involved⁽²¹⁾. The GHSG has assigned CS I and CS II patients to the category of unfavorable disease with any of the following adverse factors: (1) large mediastinal mass, (2) at least three nodal regions involved, (3) no symptoms present with ESR >50 mm/h or B symptoms with ESR >30 mm/h, or (4) localized extranodal infiltration (so-called E lesions) (Table 10-5)⁽²²⁾. In advanced disease, the International Prognostic Score (IPS) was developed on the basis of an analysis of 5,141 patients most of whom were initially treated with an anthracycline-containing chemotherapy regimen. Seven factors were identified, as shown in Table 10-6⁽²³⁾.

Table 10-6 International Prognostic Score (IPS) for Hodgkin Lymphoma

Hemoglobin <10.5 g/dL

Age ≤45 years

Male sex

Lymphocyte count <600/μL or <8% of white blood cell count

Serum albumin <4 g/dL

White blood cell count ≤15,000/μL

Stage IV disease (Ann Arbor system)

Data from Moccia AA, Donaldson J, Chhanabhai M, et al: International Prognostic Score in advanced-stage Hodgkin's lymphoma: altered utility in the modern era, *J Clin Oncol*. 2012 Sep 20;30(27):3383-3388.

Response Assessment

Prior to 1999, the criteria used to assess response to therapy were not routinely standardized. The International Working Group (IWG) formulated guidelines for the assessment of response to therapy in 1999⁽²⁴⁾. The criteria were based on CT scan and have been used internationally. With the introduction of the PET scan, the guideline has been updated twice, in 2007 and in 2014^(15, 25). Based on the high negative predictive value (95%-100%) and positive predictive value (>90%) of PET scan in the response evaluation for HL⁽²⁶⁾, current recommendations for response evaluation clearly state that PET-CT is more accurate than CT for end-of-treatment assessment. Previous guidelines for reviewing PET scan were based on imprecise visual interpretation, whether the scan is positive or negative, and whether it is intended for end-of-treatment evaluation using mediastinal blood pool as the comparator⁽²⁷⁾. More recent guidelines recommend using a 5-point scale assessment (Deauville criteria, Table 10-7) for clinical trials including interim analysis and end-of-treatment assessment. A score of 1 or 2 is considered to represent complete metabolic response. A score of 4 or 5 is considered to be treatment failure at the end-of-treatment evaluation. There are difficulties in the interpretation of a score of 3, in which the uptake is higher than mediastinum but less than or equivalent to liver. Recent data suggest that most patients with a score of 3 have good prognosis at the end of treatment⁽²⁸⁾. However, in response-adapted trials exploring treatment de-escalation, a more cautious approach may be preferred.

Treatment of Hodgkin Lymphoma**Nodular Lymphocyte-Predominant Hodgkin Lymphoma**

Because of the rarity of this disease, it is difficult to derive the information by randomized prospective clinical trials. Recently, several well-designed single-arm phase II trials and large retrospective analyses have been reported.

Table 10-7 Five-Point Deauville Criteria

Score 1: no uptake

Score 2: uptake ≤ mediastinum

Score 3: uptake > mediastinum but ≤ liver

Score 4: moderately increased uptake > liver

Score 5: markedly increased uptake > liver and/or new lesions related to lymphoma

Score X: New areas of uptake unlikely to be related to lymphoma

Early-Stage Disease

Although radiation as a single modality for treatment would be considered inferior treatment for patients with early-stage cHL, multiple studies have observed excellent outcomes using radiation therapy (RT) alone for early-stage NLPHL.

In the retrospective review by the GHSG on the HD-4 and HD-7 trials, the 2-year freedom from treatment failure (FFTF) and overall survival (OS) rates were 92% and 100% respectively, with involved-field RT (IFRT), compared with 100% and 94% respectively, for extended-field RT (EFRT)⁽²⁹⁾. Also, our center (MDACC) reported excellent outcomes with RT alone for stage IA and IIA patients⁽³⁰⁾. With a median follow-up of 8.8 years, only 1 of 20 patients who received limited-field RT experienced relapse. The best outcome was noted in stage IA patients, who had a 5-year relapse-free survival rate of 95%. The Harvard study group reported a retrospective analysis of long-term outcomes of 113 patients with early-stage NLPHL⁽³¹⁾. Ten-year progression-free survival (PFS) and OS rates were 64% and 100%, respectively, with limited-field RT, and 81% and 95%, respectively, with EFRT. Of note, 86% of patients who received chemotherapy alone had relapse of disease.

These observations indicate that: (1) chemotherapy alone is not indicated for NLPHL, (2) RT alone would be accepted as the standard of management for early-stage NLPHL without bulky disease or B symptoms, and (3) limited-field RT is appropriate to reduce the toxicity and mortality. With these retrospective studies, no improvement was seen with combined-modality treatment (chemotherapy and RT) compared with RT alone. However, the data from the British Columbia Cancer Agency (BCCA) have suggested a potential improvement in the outcomes for adding a brief course of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) before RT in patients with early-stage NLPHL⁽³²⁾. Ten-year PFS and OS rates were 65% and 84%, respectively, for RT alone, and 91% and 93%, respectively, for combined-modality treatment. As with retrospective studies, cautious interpretation is needed because of possible selection bias, variable staging procedures, availability of supportive care, and differences in duration of follow-up for the different treatments.

Because of high CD20 expression in NLPHL, rituximab monotherapy was evaluated for the treatment of early-stage NLPHL. Two prospective studies have been reported by the GHSG and the Stanford group^(33, 34). Overall response rates (ORRs) were high (100% in both studies). However, the responses were not durable. Currently, the National Comprehensive Cancer Network (NCCN) guidelines recommend IFRT alone for early-stage NLPHL without B symptom. B symptom and bulky disease are uncommon presentations

for NLPHL and would be treated with combined-modality treatment as for cHL.

Advanced-Stage Disease

Because at least 70% to 80% of patients with NLPHL are diagnosed with early-stage disease, defining the optimal treatment regimen for advanced-stage disease is challenging. Chemotherapy is the mainstay of treatment for advanced-stage disease.

The GHSG compared the outcome of patients with NLPHL and cHL enrolled in prospective trials⁽⁷⁾. There were no significant differences in FFTF between NLPHL and cHL, with 50-month FFTF rates of 77% and 75%, respectively. Of note, the chemotherapy regimens used in the GHSG trials were COPP (cyclophosphamide, vincristine, procarbazine, and prednisone), COPP/ABVD, and BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), which contain higher dose of alkylating agents than ABVD. The BCCA reported a matched-control analysis of patients with NLPHL and cHL treated with ABVD or ABVD-like chemotherapy⁽³⁵⁾. Although not statistically significant, there was a trend toward an inferior PFS for patients with NLPHL versus cHL (44% vs 77% at 15 years; $P = 0.096$). These studies have suggested that alkylating agents may provide some therapeutic advantage. We have reported the results of R-CHOP (rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone) in patients with advanced-stage NLPHL⁽³⁶⁾. The ORR with R-CHOP was 100%, with a complete response (CR) rate of 90%, and no relapses or transformations have been observed at a median follow-up of 42 months.

Currently, NCCN guidelines list therapeutic options such as CVP (cyclophosphamide, vincristine, and prednisone), CHOP, and ABVD with or without rituximab. The standard approach to patients with advanced-stage NLPHL at MDACC is R-CHOP based on our data.

Relapsed and Transformed Disease

Patients with NLPHL may have late relapse or transform to B-cell lymphoma, for which standard treatment is not well defined. Rituximab has been evaluated for treatment of relapsed NLPHL. In a study by the GHSG that enrolled 14 patients, rituximab therapy resulted in an ORR of 100%, a CR rate of 57%, and a median time to progression of 33 months⁽³⁷⁾. The Stanford group examined the benefit of limited versus extended rituximab therapy in the frontline and relapsed settings⁽³³⁾. Eighteen patients with relapsed NLPHL were enrolled in the study. The ORR with rituximab monotherapy was 100%, and the 5-year PFS was 71.4% with rituximab maintenance therapy of 4 weekly infusions every 6 months for 2 years. These

results indicate that rituximab monotherapy is effective in relapsed NLPHL.

Transformation at time of relapse can also occur. In a retrospective study by the BCCA, 95 patients were identified as diagnosed with NLPHL over a 40-year time period⁽³⁸⁾. Median time of follow-up was 6.5 years, and 14% of patients experienced transformation. Median time to transformation was 8.1 years, with 4:1 ratio of DLBCL to TCRBCL. In the 10 patients with transformed lymphoma, the 10-year PFS and OS rates were 52% and 62%, respectively.

The rarity of the disease makes it difficult to prospectively evaluate the role of autologous stem cell transplantation (ASCT) for patients with relapsed or refractory NLPHL. However, patients who relapse with transformation should be managed according to algorithms for DLBCL. An MDACC retrospective study reviewed the outcomes for 26 patients who underwent ASCT. At time of transplantation, many had transformation to TCRBCL. At time of ASCT, 85% were in remission, with 35% in CR. At a median follow-up of 50 months, the event-free survival (EFS) rate was 69%⁽³⁹⁾.

MD Anderson Approach

We treat stage IA and IIA LPHL patients with IFRT. It is rare for a stage I or II patient to present with B symptoms, but if a patient does, we treat the patient with (particularly for stage IIB) combined-modality therapy with an anthracycline-containing chemotherapy regimen followed by IFRT. Our preferred regimen is R-CHOP. For advanced-stage patients, we treat with R-CHOP for six cycles. Patients who relapse can be considered for extended rituximab therapy. For patients with evidence of transformation to DLBCL or TCRBCL, if anthracycline-containing chemotherapy had already been given, we use salvage chemotherapy with regimens such as rituximab plus ICE (ifosfamide, carboplatin, and etoposide) followed by ASCT.

Classical Hodgkin Lymphoma

The common practice for treatment and participation in clinical trials is to divide cHL patients into three treatment groups: early stage favorable, early stage unfavorable, and advanced stage.

Early-Stage Favorable Hodgkin Lymphoma

Treatment of early-stage favorable HL is evolving. Historically, wide-field RT or EFRT without chemotherapy was the standard of care⁽⁴⁰⁾. Extended-field RT produced superior disease-free survival (DFS) compared with IFRT⁽⁴¹⁾. More than 90% of patients achieved CR with this approach; however, the relapse rate was unacceptably high ($\geq 30\%$). In addition, EFRT had considerable long-term side effects. In a large prospective

analysis of over 15,000 HL patients, the actuarial risk of developing a solid tumor was 21.9% at 25 years after HL diagnosis, with the absolute risk being nearly 50%. Common secondary solid tumors were female breast and lung cancers⁽⁴²⁾. The key studies comparing RT alone with combined-modality strategies were conducted by the GHSG and EORTC. In the GHSG HD-7 trial, patients were randomly assigned to receive either 30 Gy of EFRT alone or two cycles of ABVD followed by the same RT⁽⁴³⁾. Although, response rates did not differ between the two treatment arms, the 7-year FFTF rate was significantly better in the combined-modality arm (88% vs 67%). The results of the randomized EORTC H8F trial were similar. Treatment arms consisted of three cycles of MOPP (mechlorethamine, vincristine, procarbazine, prednisone)/ABV (doxorubicin, bleomycin, vinblastine) followed by IFRT or subtotal nodal irradiation (STNI) alone⁽⁴⁴⁾. Patients receiving combined-modality treatment had a significantly superior 5-year EFS (98% vs 74%) and better 10-year OS estimates (97% vs 92%). As a result of these two large randomized controlled trials and the recognition of notable long-term side effects and high relapse rates, EFRT monotherapy has now been abandoned in favor of combined-modality therapy, which is now the standard treatment for early-stage HL.

Combined-modality therapy has evolved based on the premise that this approach results in high freedom from recurrence in early-stage HL and that efficacy can be maintained using less toxic chemotherapy and RT regimens. At MDACC, investigators performed a retrospective analysis of 286 patients with early-stage HL treated with chemotherapy followed by IFRT or EFRT with a median dose of 40 Gy⁽⁴⁵⁾. Five-year relapse-free survival (RFS) and OS rates were 88% and 93%, respectively. The type and number of chemotherapy cycles used did not significantly affect RFS and OS. However, the 5-, 10-, and 15-year cumulative risks of developing solid tumors in patients treated with chemotherapy and IFRT were 0%, 6.9%, and 11.4%, respectively. These results were strikingly more favorable than those of chemotherapy plus EFRT (2.7%, 11.1%, and 28.7%, respectively).

There are many completed and ongoing trials addressing issues of the best modality, best RT field, optimal dose of RT, optimal combination of drugs, number of cycles, and optimal timing of chemotherapy, with the goals being to maintain efficacy and minimize toxicities^(22, 46-50) (Table 10-8).

The key study in combined-modality therapy for the current standard treatment is the HD-10 trial by the GHSG⁽²²⁾. The GHSG HD-10 trial had four arms testing two versus four cycles of ABVD followed by 20 versus 30 Gy of IFRT in patients with favorable early-stage HL. This trial addressed both the optimal dose of RT and the optimal number of cycles of chemotherapy.

Table 10-8 Key Trials for Patients With Favorable Early-Stage Hodgkin Lymphoma

Trial	Trial Design
Milan 1990 to 1997	ABVD × 4 → STLI
	ABVD × 4 → IFRT
Stanford	Stanford V × 8 weeks → IFRT
EORTC/GELA H9F	EBVP × 6 → IFRT 20 Gy
	EBVP × 6 → IFRT 30 Gy
	EBVP × 6 alone
GHSG HD-10	ABVD × 2 → IFRT 2 Gy
	ABVD × 4 → IFRT 20 Gy
	ABVD × 2 → IFRT 30 Gy
	ABVD × 4 → IFRT 30 Gy
GHSG HD-13	ABVD × 2 → IFRT 30 Gy
	ABV × 2 → IFRT 30 Gy
	AVD × 2 → IFRT 30 Gy
	AV × 2 → IFRT 30 Gy
EORTC/LYSA/FIL H10F	ABVD × 3 → INRT 30 Gy (+ 6 Gy)
	ABVD × 2 → then PET scan
	• If PET negative → ABVD × 2
	• If PET positive → BEACOPP escalated × 2 → INRT 30 Gy (+ 6 Gy)
GHSG HD-16	ABVD × 2 → IFRT 20 Gy
	ABVD × 2 → then PET scan
	• If PET negative → stop treatment
	• If PET positive → IFRT 20 Gy

ABV, doxorubicin, bleomycin, vinblastine; ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; AV, doxorubicin, vinblastine; AVD, doxorubicin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; EBVP, epirubicin, bleomycin, vinblastine, prednisone; EORTC, European Organization for Research and Treatment of Cancer; FIL, Fondazione Italiana Linfomi; GELA, Groupe d'Etude des Lymphomes de l'Adulte; GHSG, German Hodgkin Lymphoma Study Group; IFRT, involved-field radiotherapy; INRT, involved-node radiotherapy; LYSA, Lymphoma Study Association; PET, positron emission tomography; Stanford V, mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone; STLI, subtotal lymphoid irradiation.

The ABVD two- and four-cycle arms both had CR rates of 97%. The 20- and 30-Gy IFRT groups had CR rates of 97% and 98%, respectively. With a median follow-up of 7.5 years, there were no differences among the four groups in PFS, FFTE, and OS. The four-cycle ABVD and 30-Gy IFRT treatment groups had more toxicity than the less intensive treatment groups. Based on these data, the least toxic regimen, two cycles of ABVD and 20 Gy of IFRT, is the current standard approach for favorable early-stage HL.

In the next trial by the GHSG, the HD-13 trial, the aim was to determine whether bleomycin or dacarbazine can be omitted from chemotherapy (⁴⁷). This

four-arm trial investigated ABVD, AVD (doxorubicin, vinblastine, dacarbazine), ABV, and AV (doxorubicin, vinblastine) plus 30 Gy of IFRT. In this trial, the ABV and AV plus IFRT arms were closed because of concern for higher relapses. Five-year FFTF rates were 93%, 81%, 89%, and 77% with ABVD, ABV, AVD, and AV, respectively. Based on this trial, both dacarbazine and bleomycin cannot be omitted from ABVD without a substantial loss of efficacy. The standard treatment for patients with early-stage favorable HL should remain ABVD followed by IFRT.

Recently, several studies have evaluated the use of interim PET scan for treatment stratification. The EORTC/Lymphoma Study Association (LYSA)/Fondazione Italiana Linfomi (FIL) H10 trial was conducted to assess whether involved-node radiotherapy (INRT) could be omitted without compromising PFS in patients attaining a negative early PET scan after two cycles of ABVD as compared with standard combined-modality treatment (⁴⁶). The patients were randomized to a standard treatment giving RT irrespective of PET status after two cycles of ABVD or to an experimental arm that omitted RT if the PET was negative after two cycles of ABVD. Patients with a positive interim PET continued treatment with two cycles of escalated BEACOPP. The chemotherapy-only arm (four cycles of ABVD) was closed due to an increased number of events, and all patients with a negative PET received additional RT. Although the median follow-up time was very short (1.1 years), 1-year PFS was significantly lower in the experimental arm than the standard arm (94.9% vs 100.0%). In contrast, the UK RAPID trial showed noninferior outcome for patients who omitted RT after negative PET scan (⁵¹). In this trial, patients were randomized to IFRT or to the no further treatment arm if they had a negative PET scan after three cycles of ABVD. The 3-year PFS rates were 93.8% versus 90.7%, and the 3-year OS rates in an intent-to-treat analysis were 97.0% and 99.5% in patients who received IFRT and no further treatment, respectively. Thus, there was a trend toward improved PFS for patients who received IFRT. Another trial is ongoing by the GHSG. The randomized GHSG HD-16 trial resembles the H10 trial. Patients are randomized to a standard treatment arm or an experimental arm that omits RT if the PET scan is negative after two cycles of ABVD. The question of whether treatment can be further reduced based on the results of the PET scan is the subject of ongoing clinical trials.

The MD Anderson Approach

The treatment for favorable early-stage HL is still evolving. Patients are typically screened for clinical protocol options if available. As standard therapy, we use two cycles of ABVD plus 20 Gy of IFRT for this group of patients.

Early-Stage Unfavorable Hodgkin Lymphoma

Combined-modality approaches consisting of four cycles of chemotherapy followed by IFRT represent the standard of care for patients with early-stage unfavorable HL. Multiple trials have shown that reduction of radiation field does not lead to inferior clinical outcomes. In a retrospective analysis conducted at MDACC, 286 patients (1980-1995) with early-stage HL were treated with chemotherapy followed by IFRT or EFRT. The type and number of chemotherapy regimens used did not significantly affect RFS and OS. There was a trend toward higher risks of secondary tumors in the EFRT group⁽⁴⁵⁾. In the EORTC H8U trial, three different regimens were randomly compared⁽⁴⁴⁾. Patients were assigned to receive either six cycles of MOPP/ABV plus IFRT, four cycles of MOPP/ABV plus IFRT, or four cycles of MOPP/ABV plus subtotal nodal plus spleen irradiation. The MOPP/ABV regimen followed by IFRT resulted in 88% EFS at 5 years and 85% OS at 10 years with no difference noted compared to the other treatment arms. Thus, four cycles of chemotherapy is the standard for patients with early-stage unfavorable HL. Similar to early-stage favorable HL, ABVD alone was more effective than MOPP and equally as effective as, but less toxic than, the alternating regimen MOPP/ABVD⁽⁵²⁾. Given the relapse rates with ABVD, there is interest in evaluating alternative more intensive regimens^(46,53-56) (Table 10-9).

To address whether ABVD or the Stanford V regimen (mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone) would be the best approach for patients with early-stage bulky unfavorable HL, the intergroup Southwest Oncology Group (SWOG)/Eastern Cooperative Oncology Group (ECOG) 2496 trial was conducted⁽⁵³⁾. In this trial, patients with early-stage bulky unfavorable disease (they also included advanced-stage disease in the trial) were randomized to six cycles of ABVD followed by IFRT at 36 Gy to bulk greater than 5 cm versus 12 weeks of Stanford V followed by the same IFRT plan of care. In this patients group, there were no difference in ORR and FFS between ABVD and Stanford V.

To improve the tumor control in this patient group, the BEACOPP regimen was compared to ABVD in trials by both the GHSG and the EORTC. In the EORTC H9U trial, patients were randomized to receive either six cycles of ABVD followed by IFRT, four cycles of ABVD followed by IFRT, or four cycles of BEACOPP baseline followed by IFRT. All patients received 30 Gy of IFRT. At a median follow-up of 4 years, EFS and OS remain statistically equivalent in all arms, with EFS ranging from 87% to 91% and OS ranging from 93% to 95%⁽⁵⁶⁾. Although the final results of this trial are pending, BEACOPP could not show a benefit over ABVD at the time of analysis. The GHSG HD-11 trial randomized patients to four arms of therapy and

Table 10-9 Key Trials for Patients With Unfavorable Early-Stage Hodgkin Lymphoma

Trial	Trial Design
SWOG/ECOG 2496	ABVD × 6 → IFRT 36 Gy to >5 cm disease
	Stanford V × 12 weeks → IFRT 36 Gy to >5 cm disease
EORTC/GELA H9U	ABVD × 6 → IFRT (36–40 Gy)
	ABVD × 4 → IFRT (36–40 Gy)
	BEACOPP × 4 → IFRT (36–40 Gy)
GHSG HD11	ABVD × 4 → IFRT 30 Gy
	ABVD × 4 → IFRT 20 Gy
	BEACOPP baseline × 4 → IFRT 30 Gy
	BEACOPP baseline × 4 → IFRT 20 Gy
GHSG HD-14	ABVD × 4 → IFRT 30 Gy
	BEACOPP escalated + ABVD × 2 → IFRT 30 Gy
	BEACOPP escalated + ABVD × 2 → then PET scan
EORTC/LYSA/FIL H10U	ABVD × 4 → INRT 30Gy (+ 6 Gy)
	ABVD × 2 → then PET scan
	• If PET negative → ABVD × 4
GHSG HD-17	• If PET positive → BEACOPP escalated × 2 → INRT 30 Gy (+ 6 Gy)
	BEACOPP escalated + ABVD × 2 → IFRT 30 Gy
	BEACOPP escalated + ABVD × 2 → then PET scan
	• If PET negative → stop treatment
	• If PET positive → INRT 30 Gy

ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; ECOG, Eastern Cooperative Oncology Group; EORTC, European Organization for Research and Treatment of Cancer; FIL, Fondazione Italiana Linfomi; GELA, Groupe d'Etude des Lymphomes de l'Adulte; GHSG, German Hodgkin Lymphoma Study Group; IFRT, involved-field radiotherapy; INRT, involved-node radiotherapy; LYSA, Lymphoma Study Association; PET, positron emission tomography; Stanford V, mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone; SWOG, Southwest Oncology Group.

evaluated four cycles of ABVD followed by 30 versus 20 Gy of IFRT and compared outcomes to four cycles of BEACOPP baseline followed by 30 versus 20 Gy of IFRT. The FFTR with BEACOPP was superior in patients who received 20 Gy of IFRT, whereas there were no differences between BEACOPP and ABVD in patients who received 30 Gy of IFRT. Overall survival did not differ significantly between the four treatment arms. Thus, BEACOPP was not adopted as a standard chemotherapy regimen for patients with early-stage unfavorable HL due to increased toxicity observed in comparison with ABVD⁽⁵⁵⁾.

The GHSG HD-14 trial introduced escalated BEACOPP to evaluate a more intensive regimen⁽⁵⁴⁾. Patients received four cycles of ABVD followed by 30 Gy of IFRT or two cycles of BEACOPP escalated followed by two cycles of ABVD (2 + 2) and then 30 Gy of IFRT. At a median follow-up of 43 months, there was better tumor control (5-year FFTF estimate of 94.8%) with the 2 + 2 protocol, compared with the ABVD arm (5-year FFTF of 87.7%). There was no significant difference in OS between the two arms. Based on these trials, ABVD remains the standard chemotherapy for patients with early-stage unfavorable HL.

Similar to early-stage favorable HL, current trials for patients with early-stage unfavorable HL, such as the EORTC/Groupe d'Etude des Lymphomes de l'Adulte H10U and GHSG HD-17, are evaluating the treatment stratification according to the result of an interim PET scan. The standard arm in the EORTC/LYSA/FIL H10U trial consisted of four cycles of ABVD followed by 30 Gy of INRT irrespective of the result of an interim PET scan performed after the second cycle of ABVD. In the experimental arm, patients with a negative PET received a total of six cycles of ABVD without consolidation RT, whereas patients with a positive PET continued treatment with two cycles of escalated BEACOPP before receiving INRT. However, as for patients with early-stage favorable HL, the chemotherapy-only arm (six cycles of ABVD) was closed due to an increased number of events, so that all patients with a negative PET received additional RT. There was no difference in the 1-year PFS between the standard and experimental arms (97.3% vs 94.7%). In the GHSG HD-17 trial, all patients received chemotherapy according to the 2 + 2 regimen before a PET scan was performed. In the standard arm, patients received an additional 30 Gy of IFRT irrespective of the results of the PET scan. In the experimental arm, patients with a negative PET scan stopped treatment, whereas patients with a positive PET scan received 30 Gy of INRT. This ongoing trial plans to evaluate whether it is possible to spare RT in patients with a negative PET scan after intensive escalated BEACOPP.

A trial conducted by the National Cancer Institute of Canada (NCIC) and the ECOG indicated that chemotherapy-only approaches appear possible in patients with early unfavorable HL, at least in patients with nonbulky disease⁽⁵⁷⁾. The trial randomized patients with early-stage unfavorable clinical features to receive either four to six cycles of ABVD or two cycles of ABVD followed by STNI. At a median follow-up of 11.3 years, freedom from disease progression was better in patients who receiving combined-modality treatment; however, OS was better for patients treated with chemotherapy alone. This was mainly caused by the increased number of deaths from secondary neoplasia among patients who had received combined-modality treatment. Nevertheless, we should keep in mind that

STNI is outdated and no longer used. Chemotherapy alone might be a treatment option in patients with nonbulky early-stage unfavorable HL, but combined-modality therapy should remain standard until further data support that the chemotherapy-only approach is feasible.

The MD Anderson Approach

In summary, treatment with four cycles of ABVD plus 30 Gy of IFRT is presently a standard-of-care option for early-stage unfavorable HL. We screen patients for any available clinical protocols. If a patient has a bulky mediastinal mass of 10 cm or greater, we typically treat with six cycles of ABVD followed by IFRT.

Advanced-Stage Hodgkin Lymphoma

Treatment of advanced-stage HL usually consists of six to eight cycles of chemotherapy. The ABVD regimen was shown to be effective and less toxic than MOPP and MOPP/ABVD in a randomized clinical trial by the Cancer and Leukemia Group B (CALGB)⁽⁵²⁾. With ABVD, MOPP, and MOPP/ABVD, 5-year failure-free survival rates were 61%, 50%, and 65%, and 5-year OS rates were 73%, 66%, and 75%, respectively. Based on the trial, the chemotherapy regimen most often used in the United States is ABVD. However, the GHSG has established escalated BEACOPP as a standard treatment for advanced-stage HL. Many trials are addressing whether one regimen may be more suitable for the treatment of advanced HL than another, and the issue has been the subject of ongoing debate for more than decade. Various chemotherapy regimens have been developed in an attempt to improve outcomes^(26, 52, 58-61) (Table 10-10).

The GHSG HD-9 trial, a three-arm randomized trial, evaluated four cycles of COPP/ABVD versus eight cycles of BEACOPP baseline versus eight cycles of BEACOPP escalated^(61, 62). The BEACOPP escalated regimen showed significantly better survival than the other two arms. With BEACOPP escalated, COPP/ABVD, and BEACOPP baseline, 5-year FFTF rates were 87%, 69%, and 76%, respectively. The 5-year OS rates were 91%, 83%, and 88%, respectively.

The GHSG HD-12 trial investigated whether the number of cycles of BEACOPP escalated could be de-escalated by evaluating eight cycles of BEACOPP escalated versus four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline (4 + 4) and what the potential added benefit of consolidation RT would be in treating sites of initial bulk or residual disease⁽⁶⁰⁾. Severe toxicity and therapy-related death rates were similar in both arms, and the survival outcome was slightly inferior in the 4 + 4 regimen. Thus, the trial could not address how to decrease the toxicity while maintaining the efficacy of eight cycles of BEACOPP escalated.

Table 10-10 Key Trials for Advanced-Stage Hodgkin Lymphoma

Trials	Design
CALGB	ABVD × 6 to 8
	ABVD/MOPP × 12
	MOPP × 6 to 8
GHSG HD-9	COPP/ABVD × 8
	BEACOPP baseline × 8
	BEACOPP escalated × 8
GHSG HD-12	BEACOPP escalated × 8 → IFRT to bulk/residual mass
	BEACOPP escalated × 8
	BEACOPP escalated × 4 + BEACOPP baseline × 4 → IFRT to bulk/residual mass
	BEACOPP escalated × 4 + BEACOPP baseline × 4
GHSG HD-15	BEACOPP escalated × 8 → IFRT to PET-positive residual masses ≤2.5 cm
	BEACOPP escalated × 6 → IFRT to PET-positive residual masses ≤2.5 cm
	BEACOPP-14 × 8 → IFRT to PET-positive residual masses ≤2.5 cm
LYSA H34	ABVD × 8
	BEACOPP escalated × 4 + BEACOPP baseline × 4
GITIL	ABVD × 6 to 8 depends on the response after four cycles
	BEACOPP escalated × 4 + BEACOPP baseline × 4
	• High-dose chemotherapy is planned by protocol at the time of progression or relapse
GHSG HD-18	BEACOPP escalated × 2 → then PET scan
	• If PET negative
	• Additional BEACOPP escalated × 4
	• Additional BEACOPP escalated × 2
	• If PET positive
	• Additional BEACOPP escalated × 4
	• Additional BEACOPP escalated × 4 + rituximab

ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; CALGB, Cancer and Leukemia Group B; COPP, cyclophosphamide, vincristine, procarbazine, prednisone; GHSG, German Hodgkin Lymphoma Study Group; GITIL, Gruppo Italiano Terapie Innovative nei Linfomie; IFRT, involved-field radiotherapy; LYSA, Lymphoma Study Association; MOPP, mechlorethamine, vincristine, procarbazine, prednisone; PET, positron emission tomography.

The next GHSG trial also aimed to reduce treatment toxicity without compromising efficacy⁽²⁶⁾. The trial evaluated the role of response evaluation based on PET scan in assessing the need for IFRT. Chemotherapy consisted of eight cycles of BEACOPP escalated, six cycles of BEACOPP escalated, or eight cycles of BEACOPP-14, a time-dense variant of the BEACOPP baseline protocol. Additional localized RT was only applied to patients who had PET-positive residual lymphoma larger than 2.5 cm at the end of chemotherapy. With eight cycles of BEACOPP escalated, six cycles of BEACOPP escalated, and eight cycles of BEACOPP-14, the 5-year FFTF rates were 85%, 89%, and 85%, respectively, and the 5-year OS rates were 92%, 95%, and 95%, respectively. The negative predictive value for the postchemotherapy PET scan so that IFRT to PET-negative lesions would be omitted was very high (94.1% at 12 months). This superiority for six

cycles of BEACOPP escalated was mainly attributed to the lower rate of treatment-related adverse events and fewer deaths due to secondary neoplasia. Based on this trial, treatment with six cycles of BEACOPP escalated was adopted as a standard chemotherapy for advanced-stage HL by the GHSG.

The interim analysis of the most recent trial by the GHSG, HD-18, was presented⁽⁶³⁾. In this trial, patients initially receive two cycles of BEACOPP escalated. Then, interim PET scan is performed, and patients are randomized. The standard arm consists of a total of six cycles of BEACOPP escalated irrespective of the result of the interim PET. In the experimental treatment arm, patients with a CR by interim PET scan are randomized to receive either four or two cycles of BEACOPP escalated. Patients with PET-positive residual disease after two cycles of chemotherapy are randomized to receive either a total of four additional

cycles of BEACOPP escalated or rituximab plus BEACOPP escalated. There were no significant differences in the survival between the rituximab plus BEACOPP escalated and the BEACOPP escalated arms. The PFS in PET-positive patients receiving standard treatment with BEACOPP escalated was higher than expected, with a 3-year PFS of over 90%. In this trial, PET result after cycle 2 of therapy was not able to determine a high-risk patient group.

In the SWOG S0816 trial, patients with stage III or IV disease underwent a baseline PET scan⁽⁶⁴⁾. They then received two cycles of ABVD, and the PET scan (PET-2) was repeated. If the PET-2 scan was negative, four further cycles of ABVD were given. If the PET-2 scan was positive, treatment was changed and intensified to BEACOPP escalated for six cycles for patients who were human immunodeficiency virus (HIV) negative and to BEACOPP standard for six cycles for patients who were HIV positive. This trial was also the first American study to use centralized real-time intergroup review (SWOG, ECOG, CALGB) of the PET scan results for treatment decisions. Response-adapted therapy with centralized interim PET review was highly feasible, even in an intergroup setting. However, the 2-year PFS of PET-2–positive patients was still lower than that of PET-2–negative patients of (61% vs 79%), even though they received six more cycles of BEACOPP escalated after PET-2.

The Gruppo Italiano Terapie Innovative nei Linfomie (GITIL) conducted a similar trial⁽⁶⁵⁾. In GITIL HD0607, patients started with two cycles of ABVD chemotherapy, and then the PET-2 scan was performed. If the patients were PET negative, they received another four cycles of ABVD with or without RT. If the patients were PET positive, they received four cycles of BEACOPP escalated and two cycles of BEACOPP baseline. The 1-year PFS rates of patients with PET-2–positive and PET-2–negative scans were 81% and 95%, respectively.

At this point, response-adapted therapy based on interim PET scan should be performed in well-designed clinical trials, and longer follow-up data of the completed trials are essential.

Even with the results of the GHSG HD-9 trial, first-line chemotherapy for advanced-stage HL is still a matter of debate. The standard arm used in the HD-9 trial was COPP/ABVD, not ABVD alone. Three randomized trials have been conducted to address this issue. One Italian group conducted the HD2000 trial and LYSA conducted the H34 trial to compare the outcome between BEACOPP and ABVD^(58, 66). In the HD2000 trial, patients were randomly assigned to receive six cycles of ABVD, four cycles of BEACOPP escalated plus two cycles of BEACOPP baseline, or six courses of CEC (cyclophosphamide, lomustine, vindesine, melphalan, prednisone, epidoxorubicin, vincristine,

procarbazine, vinblastine, and bleomycin). Patients who received BEACOPP had higher PFS and OS rates than patients who received ABVD (5-year PFS, 81% vs 68%; 5-year OS, 92% vs 84%). In the H34 trial, patients were randomly assigned to receive eight cycles of ABVD or four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline. Both PFS and OS were higher in the BEACOPP arm than the ABVD arm (5-year PFS, 93% vs 75%; 5-year OS, 99% vs 92%). These two trials showed a higher efficacy with BEACOPP than ABVD.

However, GITIL reported that ABVD has a similar efficacy to BEACOPP if high-dose chemotherapy (HDCT) is planned at the time of relapse of refractory disease⁽⁵⁹⁾. In the GITIL trial, patients were randomly assigned to either four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline or to six to eight cycles of ABVD, each followed by local RT when indicated. Patients with residual or progressive disease after the initial therapy were to be treated with high-dose salvage therapy with ASCT. The 7-year FFTR was significantly better with BEACOPP than ABVD (85% vs 73%); however, there was no significant difference in the 7-year OS between arms after completion of the overall planned treatment (89% vs 84%). Although two out of three randomized trials showed some benefit in survival with BEACOPP, longer follow-up is essential to confirm the conclusion because the toxicities such as secondary malignancy would be an issue for the long-term survival in young patients. Most of the institutes in the United States are still using ABVD as first-line chemotherapy, mostly because of its high efficacy, high tolerability, and lower toxicities compared with BEACOPP escalated^(66a).

The MD Anderson Approach

We screen patients for available protocols for initial treatment of advanced-stage disease. As a standard approach off clinical protocol, we treat these patients with six to eight cycles of ABVD. Although the data supporting IFRT for advanced-stage disease is controversial, we sometimes consider IFRT for patients who have presented with an initial bulky mass and who continue to have a residual mass at the end of therapy with PET-negative status.

The Value of Positron Emission Tomography Scan in Hodgkin Lymphoma

A PET scan is useful not only for staging but also for response evaluation and evaluation of expected outcome in patients with HL. An interim PET scan obtained after two cycles of therapy (PET-2) was a stronger prediction of outcome than the IPS, with 2-year PFS for patients with a positive PET-2 of 13% compared with 95% for those with a negative PET-2⁽⁶⁷⁾. The PET-2

also strongly predicts treatment failure⁽⁶⁸⁾. In a meta-analysis, a positive PET-2 in low-intermediate-risk advanced HL patients was a reliable predictor of poor response⁽⁶⁹⁾. The value of the interim PET scan is now being evaluated in prospective clinical trials. The SWOG S0816 phase II intergroup trial is evaluating interim PET in stage III or IV cHL patients treated with two cycles of ABVD. Patients who have a negative PET receive four additional cycles of ABVD; PET-positive patients receive BEACOPP baseline if HIV positive and BEACOPP escalated if HIV negative.

The HD-15 trial showed a negative predictive value of 94% for PET after BEACOPP-based therapy in advanced-stage HL⁽⁷⁰⁾. The PFS at 12 months was 96% for PET-negative patients and 86% for PET-positive patients. At the time of posttreatment examination, PET has higher diagnostic and prognostic value than conventional CT⁽⁷¹⁻⁷³⁾. The role of PET prior to transplantation was also evaluated: a negative PET prior to ASCT is significantly associated with higher EFS. In a study by the Memorial Sloan-Kettering Cancer Center, the 5-year EFS was 80% in patients with PET-negative status and 40% in patients with PET-positive status before transplantation⁽⁷⁴⁾.

Refractory or Relapsed Hodgkin Lymphoma

Although many patients with HL are cured with frontline therapy, 10% to 15% of patients with early-stage disease with unfavorable risk factors and 40% of patients with advanced-stage disease with high-risk factors can develop relapse or refractory disease.

Relapsed HL can be divided into three subgroups: early relapse within 12 months of CR after first-line chemotherapy; late relapse after CR >12 months after first-line chemotherapy; and primary refractory HL (ie, patients who never achieve a CR). Moskowitz et al identified the following three prognostic factors associated with EFS in patients receiving ICE, followed by HDCT and ASCT: CR less than 1 year, extranodal disease, and presence of B symptoms. The 5-year EFS was 83% in patients with zero to one factor compared with 10% if all three factors were present⁽⁷⁵⁾.

For patients with relapsed or refractory disease after standard frontline management, additional salvage chemotherapy followed by HDCT plus ASCT is the standard approach. One of the key goals of salvage chemotherapy is to achieve CR prior to ASCT. The response rates of multiple salvage regimens are listed in Table 10-11. It is difficult to directly compare these regimens because they have not been evaluated in randomized clinical trials.

Although we screen all patients for available protocols at relapse, the most common salvage chemotherapies outside clinical trials are the platinum-containing regimens such as ICE or DHAP (cisplatin, cytarabine, dexamethasone). With ICE, the ORR was 84% and

Table 10-11 Salvage Chemotherapy Regimens for Hodgkin Lymphoma

Regimen	ORR (%)	CR (%)
DHAP	88	21
ASHAP	70	34
ESHAP	73	41
MINE	73	34
ICE	85	26
IGEV	81	54
GND	70	19
GDP	62	10

ASHAP, doxorubicin, methylprednisolone, cytarabine, cisplatin; CR, complete response; DHAP, dexamethasone, cytarabine, cisplatin; ESHAP, etoposide, methylprednisolone, cytarabine, cisplatin; GDP, gemcitabine, dexamethasone, cisplatin; GND, gemcitabine, vinorelbine, pegylated liposomal doxorubicin; ICE, ifosfamide, carboplatin, etoposide; IGEV, ifosfamide, gemcitabine, vinorelbine; MINE, mitoguanzone, ifosfamide, vinorelbine, etoposide; ORR, overall response rate.

the CR rate was 26%. The DHAP regimen showed similar results, with ORR of 89% and CR rate of 21%. Gemcitabine-containing regimens are also effective. With GND (gemcitabine, vinorelbine, pegylated liposomal doxorubicin), the ORR was 70%, with a CR rate of 19%. With GDP (gemcitabine, dexamethasone, platinum), the ORR was 62%, with a CR rate of 10%.

High-Dose Chemotherapy With Autologous Stem Cell Transplantation for Relapsed Hodgkin Lymphoma

For patients with chemotherapy-sensitive disease, the treatment of choice after relapse is HDCT followed by ASCT. This recommendation is based on reports from two randomized clinical trials^(76, 77). In the BNLI study, patients with relapsed or refractory HL received BEAM (carmustine, etoposide, cytarabine, and melphalan) at high doses followed by an ASCT or at lower doses (mini-BEAM) without an ASCT. The 3-year freedom from second treatment failure was significantly better for patients who received HDCT (53% vs 10%). The GHSG/European Group for Blood and Marrow Transplantation (EBMT) randomized trial compared four cycles of DEXA-BEAM (dexamethasone plus BEAM) versus two cycles of DEXA-BEAM followed by ASCT. At 3 years, the FFTR in the high-dose therapy group was 55% versus 34% with four cycles of chemotherapy.

Multiple investigators have shown that response to salvage chemotherapy is a strong predictor of long-term outcome after ASCT. The 5-year OS for patients who were in CR at the time of ASCT was 79% compared with 59% for those in PR and 17% for those with resistant disease at the time of ASCT⁽⁷⁸⁾. Studies have shown the impact of pre-ASCT PET scan results

on EFS. Patients with negative pre-ASCT PET scans have significantly higher EFS and failure-free survival rates compared to patients with positive pre-ASCT PET scans ^(79, 80). A European intergroup evaluated a dose-intensified regimen before ASCT ⁽⁸¹⁾. Patients were randomly assigned after two cycles of DHAP to ASCT or sequential cyclophosphamide, methotrexate, and etoposide before ASCT. There were no significant differences between the two treatment arms in terms of mortality, FFTE, and OS. Thus, the less toxic approach consisting of two cycles of DHAP (or other salvage regimen such as ICE) followed by HDCT and ASCT remains the standard of care for patients with relapsed HL.

Treatment of Relapse After Autologous Stem Cell Transplantation

Patients with disease progression after ASCT uniformly have a poor outcome. In a study of HL patients who failed ASCT, the median time to progression after the next therapy was only 3.8 months, and the median survival after ASCT failure was 26 months ⁽⁸²⁾. An international multicenter retrospective study showed that the survival of patients who relapsed after an ASCT did not improve from 1981 to 2007 ⁽⁸³⁾. However, there has been a major advance in the treatment of relapsed or refractory HL in the last 5 years.

Brentuximab Vedotin

CD30 was considered an ideal target for monoclonal antibody therapy for HL, because its expression is highly restricted to the HRS cells. Brentuximab vedotin (BV), or SGN-35, is an intravenously administered antibody-drug conjugate that consists of the CD30-specific monoclonal antibody conjugated with monomethyl auristatin E (MMAE) by linker peptide. Binding of the antibody-drug conjugate to CD30 on the cell surface causes internalization of the drug by endocytosis, and the drug subsequently travels to the lysosome, where proteases cleave the linker and release MMAE to the cytosol ⁽⁸⁴⁾. Released MMAE binds to tubulin and disrupts the microtubule polymerization, resulting in cell cycle arrest and apoptotic death of CD30-expressing cells. After efficacy was shown in a phase I trial including 45 patients with relapsed or refractory CD30-positive hematologic malignancies, a pivotal phase II study with 102 patients with HL who had relapsed after HDCT and ASCT was conducted ^(85, 86). Patients received BV 1.8 mg/kg every 3 weeks up to a maximum of 16 cycles. The ORR was 75%, with a CR rate of 34%. These data led to the first drug approval by the US Food and Drug Administration (FDA) for the treatment of HL in more than 30 years. Durable remission was reported with longer follow-up ⁽⁸⁷⁾, and the median OS and PFS were 40.5 months and 9.3 months,

respectively. The 3-year PFS rate of patients who achieved CR with BV was 58%. This survival outcome is notable considering that the patients enrolled in this trial had disease progression after ASCT.

Achieving CR before ASCT is the key to better outcomes in patients with relapsed or refractory HL. Therefore, BV is often used as a third-line therapy in patients who have not achieved CR after second-line salvage chemotherapy such as ICE. The Seattle group retrospectively evaluated the efficacy of BV in patients who were refractory to platinum-based salvage chemotherapy ⁽⁸⁸⁾. Fifteen patients who had PET-positive disease after platinum-based salvage therapy were treated with a median of four cycles of BV. Normalization of PET scan occurred in 8 (53%) of 15 patients but was only observed in patients who had achieved partial remission or stable disease after salvage therapy. This suggests that BV can achieve PET-CR in a considerable subset of patients with platinum-refractory HL prior to ASCT.

BV is also effective in patients who relapse after allogeneic stem cell transplantation (allo-SCT). Twenty-five patients who relapsed after allo-SCT received BV. The ORR and CR rates were 50% and 38%, respectively. The median PFS was 7.8 months, and the median OS was not reached.

Many clinical trials are ongoing to evaluate BV in various settings; these include as salvage combinations with chemotherapy prior to ASCT, as initial therapy in combinations with chemotherapy and as maintenance therapy after ASCT for high-risk patients.

A phase II study evaluating single-agent BV and augmented ICE salvage therapy prior to ASCT was conducted. Patients received BV for two cycles, followed by PET. Patients who achieved PET-CR proceeded to ASCT. Patients who failed to achieve PET-CR received two cycles of augmented ICE prior to consideration for ASCT. Preliminary results showed that among 28 patients who underwent ASCT, 9 patients (32%) achieved PET-CR with two cycles of BV ⁽⁸⁹⁾. Maintenance therapy with BV after ASCT was evaluated in a placebo-controlled randomized phase III study (AETHERA) ⁽⁹⁰⁾. Patients were enrolled in this study if they were (1) refractory to frontline therapy, (2) had relapse <12 months after frontline therapy, or (3) had relapse ≥12 months after frontline therapy with extranodal disease. The median PFS was 43 months with BV and 24 months with placebo. This represents a significant 43% reduction in the risk of disease progression with BV. Once finalized, these results will potentially change the standard treatment of high-risk patients who relapse after first-line chemotherapy.

A phase III trial comparing BV plus AVD (ABVD without bleomycin) versus standard ABVD in patients with newly diagnosed advanced-stage HL is ongoing (NCT01712490). A phase I study comparing BV in

combination with ABVD or AVD treatment showed a high CR rate of 96%. However, BV combined with bleomycin resulted in a high rate of pulmonary toxicity (44%)⁽⁹¹⁾. Based on this phase I trial, BV is combined with AVD. This BV+AVD combination, if superior to ABVD, may change the standard of care in patients with newly diagnosed advanced-stage HL.

Gemcitabine

Gemcitabine-containing regimens are effective. A phase II study of single-agent gemcitabine, 200 mg/m² given on days 1, 8, and 15 of a 28-day schedule, showed an ORR of 43% with a CR rate of 14%⁽⁹²⁾. The GVD regimen (gemcitabine, vinorelbine, and pegylated liposomal doxorubicin) was evaluated by the CALGB in 91 patients with relapsed or refractory HL. The ORR was 70%, with a CR rate of 19%⁽⁹³⁾. The 4-year PFS and OS rates in transplant-naïve patients treated with GVD followed by ASCT were 52% and 70%, respectively. In patients in whom prior transplant failed, the 4-year DFS and OS rates were 10% and 34%, respectively. The GDP regimen produced similar results, with an ORR of 62% and a CR rate of 10%. A combination regimen named IGEV (ifosfamide, gemcitabine, vinorelbine) was evaluated in 91 patients and produced an ORR of 81% with a high CR rate of 54%; 60% of primary refractory patients responded to IGEV⁽⁹⁴⁾.

Bendamustine

Bendamustine is a bifunctional alkylating agent derived from 2-chloroethylamine that had been a standard chemotherapy for indolent lymphoma (follicular lymphoma and mantle cell lymphoma)^(95, 96). The Memorial Sloan-Kettering Cancer Center conducted a phase II trial of bendamustine in patients with HL who relapsed after ASCT or who were not eligible for ASCT⁽⁹⁷⁾. Patients received bendamustine of 120 mg/m² on days 1 and 2 of a 28-day cycle, for six planned cycles. The ORR was 53%, including a 33% CR rate; the median PFS was 5.2 months. Preliminary data of a phase I/II study for the combination of bendamustine and BV for relapsed/refractory transplant-naïve patients showed an ORR of 94% with CR rate of 82%⁽⁹⁸⁾. At the time of report, 20 of 34 patients who had a response to this combination had undergone ASCT.

Allogeneic Stem Cell Transplantation

The main advantage of an allo-SCT is its graft-versus-HL effect. Retrospective studies have shown this benefit by documenting lower relapse rates in allo-SCT patients who have chronic graft-versus-host disease (GVHD) and by showing that donor lymphocyte infusion (DLI) can induce relatively long-lasting remissions⁽⁹⁹⁾. Initial studies of allo-SCT in HL patients described high rates of nonrelapse mortality

(NRM), up to 61%. More recent studies evaluated reduced-intensity conditioning (RIC) and have shown decreases in treatment-related mortality (TRM). Overall, RIC allo-SCT induces modest long-term remissions with a PFS rate of 30%^(100, 101).

The EBMT reviewed 168 patients who had undergone allo-SCT⁽¹⁰¹⁾. Seventy-nine patients received myeloablative conditioning, and 89 patients received RIC. Fifty-two percent of patients had undergone a prior ASCT and 45% had chemosensitive disease. The NRM was significantly lower and OS was significantly better with RIC versus myeloablative conditioning. One-year NRM was 23%, and 5-year PFS and OS were 18% and 28%, respectively, in patients who received RIC.

At MDACC, we reviewed the outcomes of 58 patients who received RIC with fludarabine-melphalan in preparation for allo-SCT⁽¹⁰²⁾. Overall, 83% of patients had undergone a prior ASCT and 52% had chemotherapy-sensitive disease at the time of allo-SCT. The TRM at 2 years was 15%, with nearly half of the TRM occurring within the first 100 days after allo-SCT. The incidence of chronic GVHD was 73%. The 2-year PFS and OS rates were 32% and 64%, respectively. There was a trend toward improvement in PFS for those with chemotherapy-sensitive disease but not for OS. Allogeneic stem cell transplantation is still an important option for eligible patients who relapse after ASCT.

Novel Agents

Advances in our understanding of HL pathology and biology have led to the development of promising targeted agents.

Programmed Death-1 Inhibitors

Nivolumab is a programmed death (PD)-1 immune checkpoint inhibitor antibody that selectively blocks the interaction between PD-1 and its ligands PD-L1 and PD-L2. This PD-1 pathway has a mechanism that normally leads to downregulation of cellular immune response. By inhibiting this interaction, nivolumab can enhance T-cell function, which may result in antitumor activity. Nivolumab has been evaluated in a phase II trial for patients with relapsed or refractory HL⁽¹⁰³⁾. Twenty-three patients were treated; 78% had received ASCT and 78% had received BV before nivolumab. Nivolumab was given at a dose of 3 mg/kg every 2 weeks. The ORR was 87%, with a CR rate of 17%. The 6-month PFS rate was 86%. Nivolumab thus showed substantial therapeutic activity and an acceptable safety profile in patients with previously heavily treated relapsed or refractory HL. Nivolumab has been granted "Breakthrough Therapy Designation" by the FDA, and a pivotal trial is ongoing (NCT02181738).

Another PD-1 inhibitor, pembrolizumab, was evaluated in a phase IB trial in patients who had

disease progression or relapse with BV⁽¹⁰⁴⁾. Similar to nivolumab, a promising level of efficacy was seen, with an ORR of 53% and a CR rate of 20% at 12 weeks in 15 patients who were evaluable for response at the time of the preliminary report.

Histone Deacetylase Inhibitor

Histone deacetylases (HDACs) act on lysine amino acid groups on multiple proteins including many transcription factors. The HDACs are grouped into four classes, with classes I, II, and IV being zinc dependent. Several HDAC inhibitors are being investigated as therapies for relapsed or refractory HL. Panobinostat is an HDAC class I and II or pan-HDAC inhibitor and has been evaluated in a phase II trial in patients with relapsed or refractory HL after ASCT⁽¹⁰⁵⁾. Patients received panobinostat 40 mg orally three times a week for 21-day cycles. For the 129 patients enrolled in the trial, the ORR was 21%, with a CR rate of 4%. Treatment was well tolerated; the most common grade 3 to 4 adverse event was thrombocytopenia. The median PFS was 6.1 months, and 1-year OS was 78%.

We have conducted a phase I/II randomized trial of ICE with or without panobinostat in patients with relapsed or refractory HL (NCT01169636). Preliminary results of the trial showed an ORR of 86% with a CR rate of 71%. All patients who achieved response were able to proceed to ASCT.

Mocetinostat, another HDAC inhibitor, was evaluated in a phase II trial in patients with relapsed or refractory HL. The initial dose of 110 mg orally three times a week for 28-day cycles was reduced to 85 mg because 70% of patients required dose reduction for toxicity. Among 51 patients treated, 60% had a reduction in tumor measurements, with 24% achieving partial response. Toxicities included thrombocytopenia, fatigue, pneumonia, anemia, and pericardial effusion.

Mammalian Target of Rapamycin Inhibitors

Everolimus is an oral agent that targets the mammalian target of rapamycin (mTOR) complex 1 (mTORC1). Hodgkin lymphoma cells have an activated PI3K pathway (upstream of mTOR) and may be susceptible to inhibition of this pathway. Everolimus was evaluated in a phase II trial in patients with relapsed HL⁽¹⁰⁶⁾. Nineteen patients were enrolled, and 87% had received ASCT before everolimus. The ORR was 47%, with eight partial responses and one CR. The median time to progression was 7.2 months, with four responders remaining progression free at 12 months. Synergistic activity between everolimus and panobinostat was suggested by *in vitro* studies. We conducted a phase I trial of everolimus plus panobinostat in patients with relapsed or refractory lymphoma⁽¹⁰⁷⁾. Among the 30 patients treated, 14 patients had HL. The ORR was

43%, with a CR rate of 15%. However, grade 3 to 4 thrombocytopenia was reported in 64% of patients, limiting the future development of this combination.

Several clinical trials evaluating the combination of mTOR inhibitors and other drugs are ongoing. Sirolimus was evaluated in combination with an HDAC inhibitor, vorinostat, in a phase I trial at MDACC⁽¹⁰⁸⁾. The ORR was 57%, with a CR rate of 32% in heavily pretreated patients. Brentuximab vedotin will be evaluated in combination with mTOR inhibitors such as sirolimus, temsirolimus, and everolimus (NCT01902160, NCT02254239).

The MD Anderson Approach

Patients with relapsed or refractory HL are planned for second-line or salvage chemotherapy followed by an ASCT. We screen patients who have relapsed or refractory HL for current clinical trial options including our current randomized phase II clinical trial of panobinostat plus ICE (P-ICE) versus ICE. Patients who respond to salvage chemotherapy are planned to undergo ASCT. The role of BV for maintenance in patients with high risk of relapse after ASCT is an evolving topic. Based on the positive data recently presented for the AETHERA trial, this could become a standard of care. We screen patients with relapsed HL after an ASCT for novel agent clinical trial options. The preference is to treat with either BV if not previously given before ASCT or with a BV combination treatment on protocol including our planned BV plus dual mTORC1 inhibitor MLN0128 phase I trial. For patients who have early disease relapse or refractory disease after BV treatment, we consider novel agent protocols such as the PD-1 inhibitor trials. For patients not eligible or who do not wish to enroll in clinical trials, we consider chemotherapy regimens such as GND, bendamustine, or others. Given the benefits versus risks of allo-SCT, a subset of patients can be potentially considered for this approach, particularly otherwise healthy patients who achieve complete remission with addition therapies.

CONCLUSION

Although standard frontline chemotherapy with or without radiation therapy offers a high cure rate for cHL, approximately 20% of patients will develop refractory or relapsed disease. Thus, the challenge that remains is how to best develop strategies of therapy that increase the cure rates for the refractory/relapsed group of patients, while decreasing both short- and long-term toxicities, including secondary malignancies, for patients who are cured of their disease with current standard approaches. Huge recent achievements have

occurred on both fronts, including a decrease of both the number of cycles of chemotherapy and the doses of RT for patients with early-stage disease, and introduction of novel therapeutics such as BV into frontline regimens paired with chemotherapy. Despite the fact that BV is a clear therapeutic advance, there remains a continued need to develop new therapies. Recently completed trials have shown significant promise for several new molecularly targeted therapeutic agents, with the PD-1 inhibitors demonstrating the ability to have significant efficacy even in patients with BV-resistant disease. Future directions are anticipated to increase the focus on evaluating the efficacy of combinations of targeted agents, with likely future trials exploring the potential activity of chemotherapy-free targeted treatment combinations in the frontline setting. Better understanding of the molecular biology of both cHL and NLP HL will also lead to more rationally designed novel agent trials and allow us to best select treatment strategies. The future of HL treatment has evolved significantly over the past decade, and these successes will only be significantly multiplied over the next decade to follow.

INTRODUCTION

Plasma cell dyscrasias are heterogeneous disorders arising from the proliferation of a monoclonal population of plasma cells. Some of these disorders can present serendipitously as benign processes that can be observed; others are highly aggressive and require immediate intervention. The most common plasma cell dyscrasia is monoclonal gammopathy of undetermined significance (MGUS), a benign condition that can be observed. Related disorders include smoldering multiple myeloma (SMM), multiple myeloma (MM), solitary plasmacytoma of the bone, extramedullary plasmacytoma, Waldenström macroglobulinemia (WM), primary amyloid light-chain (AL) amyloidosis, heavy-chain disease, POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome, and the recently recognized TEMPI (telangiectasias, elevated erythropoietin and erythrocytosis, monoclonal gammopathy, perinephric fluid collection, and intrapulmonary shunting) syndrome. The spectrum of MGUS, SMM, and MM represents a natural progression of the same disease. This chapter focuses on the etiology, genetics, biology, diagnosis, clinical features, and current therapy of MM and other plasma cell disorders.

Major recent discoveries have changed the way we understand, diagnose, and treat plasma cell dyscrasias. The initial sequencing of the myeloma genome and single-cell genetic analysis paved the way for the concept of intraclonal heterogeneity and Darwinian selection of clones. Increasingly sensitive diagnostic and monitoring techniques allow for more accurate

diagnosis, minimal residual disease monitoring, and detection of early relapse. New diagnostic criteria for MM have been implemented, and the introduction of novel classes of agents such as immunomodulatory drugs and proteasome inhibitors has led to improved overall survival. Additionally, immunotherapy using monoclonal antibodies against different myeloma targets has shown promising activity in clinical trials. Major advances have also occurred in WM as a highly recurrent single point mutation of the *MYD88* gene has been identified, and new treatments that abrogate this highly active pathway are already in use. Finally, a new paraneoplastic syndrome, the TEMPI syndrome, has been identified and described.

MULTIPLE MYELOMA

Multiple myeloma is a malignant proliferation of plasma cells. In virtually all cases, myeloma cells (as well as their precursors MGUS and SMM) secrete immunoglobulins. Usually, myeloma cells secrete immunoglobulin (Ig) G (60%); other types are less common (IgA 20%, IgD 2%, IgE <0.1%, biclonal <1%). Light chain-only secretion is noted in 18%; <5% of patients do not secrete a heavy- or light-chain immunoglobulin (nonsecretory MM).

Epidemiology and Risk Factors

In 2014, approximately 24,000 people were diagnosed with MM in the United States, and 11,090 died from the disease. The median age at diagnosis is 69 years.

The incidence is highest in the age range of 65 to 74 years (27.7%), followed by the 75- to 84 year-old range (24.7%). The annual age-adjusted incidence of the disease per 100,000 population is 7.2 among white men and 4.3 among white women. Among African Americans, the frequency doubles to 14.8 in men and 10.5 in women. There is also a difference in mortality by racial group. The annual age-adjusted mortality rate per 100,000 is 4.0 and 2.5 in white men and women, respectively, and 7.7 and 5.3 in African American men and women, respectively. The incidence and mortality rates are lowest among Asians and Pacific Islanders.

Risk factors that predispose to MGUS and MM point toward common shared etiologic environmental and genetic factors. Age is a risk factor for MGUS, because its prevalence is four times higher among individuals ≥80 years old than among those 50 to 59 years old. Increased risk of MGUS has also been reported in first-degree family members of patients with MGUS and MM (risk ratio between 2 and 3). In a study of black and white women of similar socioeconomic status, obesity, black race, and increasing age conferred an increased risk of MGUS. Personal and family history of autoimmune or inflammatory disorders as well as infections have been linked to an increased risk of MGUS and MM. Exposure to infections has been hypothesized to be involved in the malignant transformation of MM, or it could represent impaired immunity associated with MGUS and SMM, which often precedes a diagnosis of MM. Radiation exposure, pesticides, and cleaners are also associated with an increased risk of MGUS and MM.

Although MM is not an inherited disease, more than a hundred familial cases have been reported in the literature. The largest series described 39 unique families with 79 MM cases. Both dominant and recessive inherited traits may play a role in familial MM. Large genomic studies have identified low penetrant genetic variants that confer a modest increase in the risk of developing MM ^(1, 2). Based on epidemiologic and familial aggregation studies, most of the inherited risk of developing MM may result from different genetic polymorphisms, each of which has only a small effect on the predisposition to develop disease ⁽³⁾.

Pathophysiology and Genetics/Molecular Classification

Multiple myeloma arises from terminally differentiated B cells or even early committed B cells (germinal center B cells) that manifest clinically as more differentiated plasma cells. The major role of normal differentiated plasma cells is to produce immunoglobulins (antibodies) to fight infections. To become an effective part of the adaptive immune system, B cells must undergo immunoglobulin gene rearrangement and

affinity maturation in response to antigens presented by antigen-presenting cells within the lymph node germinal center. For this to occur, hypervariable regions in the immunoglobulin heavy chain locus (IGH in chromosome 14q32) undergo programmed mutations (somatic hypermutation) through which, among others, double DNA strand breaks and chromosomal translocations are generated. The primary etiology of MM has been linked to IGH translocations and increased copies of odd-numbered chromosomes (hyperdiploidy), which result in cyclin D dysregulation. These events can be observed early in the course of monoclonal gammopathies (such as in MGUS or SMM) as well as in MM, suggesting that they are primary genetic events. Initial whole-genome and exome sequencing in 38 MM patients confirmed the complexity of genetic alterations seen in MM and uncovered secondary mechanisms of transformation to MM ⁽⁴⁾. Secondary events included mutations in the oncogene MYC (most commonly observed in plasma cell leukemia or aggressive forms of MM), mutations in the nuclear factor-κβ (NF-κβ) pathway, including BRAF and RAS, and chromosome copy number abnormalities such as deletions, amplifications, or additions. Changes in DNA methylation patterns are also important secondary events leading to increased tumor diversity and more aggressive forms of plasma cell dyscrasias (Table 11-1).

Different tests for gene expression profiling (GEP) are available for molecular classification of MM. Currently, molecular profiling of MM is mostly used for research purposes (eg, identification of high-risk MM for inclusion in clinical trials). These tests may become increasingly important as we develop more personalized treatment for MM.

Serial genomic analysis during the disease course of myeloma patients has identified different MM subclones within the same tumor. This has been termed

Table 11-1 Genetic Alterations Found in Monoclonal Gammopathies, From Monoclonal Gammopathy of Undetermined Significance to Plasma Cell Leukemia

Primary genetic events
IGH translocations [t(4;14), t(6;14), t(14;20), t(14;16), t(11;14)]
Hyperdiploidy (trisomies of chromosomes 3, 5, 7, 9, 11, 15, 21)
Secondary genetic events
Additions (1q, 17q, 12p)
Deletions (1p, 13, 11q, 14q, 17p, 6q, 8p)
Translocations [t(8;14)]
Methylation changes (global hypomethylation and gene-specific hypermethylation)
Mutations in NF-κβ pathway (TRAF3, I-κβ)
Proliferation (NRAS, KRAS, BRAF, MYC, MAPK, PI3K, MET)

intraclonal heterogeneity. In this model, different myeloma subclones compete for selection as they are exposed to the microenvironment and therapeutic pressures⁽⁵⁾. Single-cell genetic analysis at diagnosis confirmed that MM is highly heterogeneous and characterized by the accumulation of a diverse range of mutations at the subclonal level⁽⁶⁾. In this scenario, the acquisition of new mutations leads to new subclones with different clinical phenotypes and sensitivities to therapy. Intraclonal heterogeneity in myeloma has many potential implications for therapy, suggesting that subclonal targeting in combination therapies may be needed to eradicate the multiple subclones. Increasing genetic complexity is seen with progression from MGUS to MM and plasma cell leukemia, which may suggest that earlier treatment may result in improved clinical outcomes.

The bone marrow microenvironment also plays a role in the etiology of MM and its related disorders. Plasma cells communicate effectively with the microenvironment in a process called cell trafficking. Upregulation of cytokines that increase vascular permeability, proliferation, or cell homing (interleukin [IL]-6, vascular endothelial growth factor, and insulin-like growth factor) have been involved in the progression to MM. Gene expression profiling has revealed that modulation of certain genes can lead to a permissive microenvironment that promotes growth of myeloma subclones leading to active disease⁽⁷⁾. Thus, targeting the microenvironment is an area of extensive research that, combined with therapeutic targeting of myeloma subclones, may lead to improved outcomes. New and effective antimyeloma combination therapies and well-designed clinical trials are needed to test these hypotheses.

Clinical Presentation

The clinical presentation of MM and its precursors is variable. Patients with MGUS or SMM usually do not present with specific myeloma-related symptoms. Their diagnosis is often incidental based on workup for a low albumin-to-globulin ratio, high serum protein, or other conditions such as autoimmune diseases, peripheral neuropathy, skin rashes, or hemolytic anemias.

In contrast, patients initially presenting with MM usually have at least one of the CRAB criteria (hyperCalcemia, Renal disease, Anemia, and Bone disease) classically used to define symptomatic MM. Anemia is the most common finding, occurring in 73% of patients, and is typically a normocytic, normochromic anemia. Anemia can be due to a variety of factors, including marrow replacement or cytokine production by plasma cells, which lead to decreased erythropoiesis, or decreased erythropoietin levels due to renal disease⁽⁸⁾.

FIGURE 11-1 Radiographic image of the skull showing “punched out” osteolytic lesions characteristic of multiple myeloma.

Bone pain is common, occurring in 60% of patients, and related to increased resorption of bone, leading to lytic bone lesions. Painful vertebral compression fractures can occur and may represent a medical emergency when associated with symptoms of cord compression. Increased bone resorption has been attributed to factors such as RANK ligand (RANKL), osteoprotegerin (OPG), macrophage inflammatory protein (MIP)-1 α , IL-6, and IL-3, which stimulate osteoclast activity in areas infiltrated by plasma cells as a result of interactions between plasma cells and the microenvironment (Fig. 11-1).

An elevated creatinine is a presenting sign in 50% of patients. Renal disease is often attributed to light-chain cast nephropathy resulting from precipitation of light chains that bind to Tamm-Horsfall mucoproteins secreted by cells in the ascending loop of Henle. These precipitated complexes obstruct the distal convoluted tubules and collecting ducts, leading to tubular atrophy and interstitial fibrosis. Other causes of renal failure include hypercalcemia, leading to nephrocalcinosis, as well as amyloidosis, heavy-chain disease, and light-chain disease.

Hypercalcemia >11 mg/dL is present in 10% of patients and represents a medical emergency requiring hydration with isotonic saline and bisphosphonate therapy with zoledronic acid or pamidronate in moderate or severe cases. Calcitonin can also be used to rapidly reduce serum calcium levels.

Other common presenting symptoms include fatigue (32%) and weight loss (20%). Due to immune dysfunction, patients are at risk for infections. About 7% to 18% of patients may present with extramedullary plasmacytomas. Less common symptoms include fever, splenomegaly, hepatomegaly, and lymphadenopathy.

Diagnostic Workup

Once a plasma cell dyscrasia is suspected, a comprehensive diagnostic workup should be initiated to demonstrate the presence or absence of a clonal plasma cell

disorder, to determine if end-organ damage is present, and to evaluate laboratory markers related to prognosis. These should include the following components.

Laboratory Studies

- Complete blood count (CBC)
- Serum chemistries including creatinine, calcium, albumin, lactate dehydrogenase (LDH), β_2 -microglobulin, and immunoglobulin levels (IgG, IgA, IgM)
- Serum protein electrophoresis with immunofixation to quantify monoclonal protein (M-protein) and determine immunoglobulin isotype
- Serum free light-chain assay to evaluate the ratio of serum kappa to lambda light chains
- Urinalysis with 24-hour urine collection with protein electrophoresis and immunofixation (Fig. 11-2)

Imaging Studies

- Skeletal survey with plain films of the axial and appendicular skeleton is the minimum standard of care to evaluate lytic bone lesions.
- Advanced imaging with either whole-body low-dose computed tomography (CT), positron emission tomography–computed tomography (PET-CT), or magnetic resonance imaging (MRI) can detect up to 80% more lesions compared with plain film x-rays.
 - An advanced imaging modality is particularly recommended in the diagnosis of SMM to detect subtle bone lesions that would warrant the initiation of treatment. It is also helpful in assessing baseline disease burden as an adjunct to serum and urine markers prior to initiation of treatment in MM.
 - A CT scan can be helpful in the characterization of soft tissue masses in the case of extramedullary plasmacytomas and can direct to an area to be biopsied.
 - An MRI scan is useful for evaluating the axial skeleton in the presence of symptoms and assessing for spinal cord compression. It can also identify

abnormal marrow uptake as T1-weighted images will show a diffuse decrease in marrow signal intensity but will enhance with the administration of contrast.

- Positron emission tomography–computed tomography can be prone to false-positive findings but has more specificity due to increased metabolic uptake at the site of lytic lesions and is the preferred initial baseline advanced imaging modality at the University of Texas MD Anderson Cancer Center (MDACC) in combination with skeletal surveys.
- There is no role for nuclear bone imaging because bone scan isotopes are not taken up by lytic lesions.

Bone Marrow Aspiration and Biopsy

- Morphologic review and immunohistochemistry (Fig. 11-3)
- Flow cytometry for immunophenotyping of plasma cells:
 - Plasma cells are positive for CD38 and CD138.
 - Normal plasma cells have higher expression of CD19 and CD45; malignant plasma cells typically lack these surface antigens.
 - Malignant plasma cells have increased expression of CD56 and CD117; normal plasma cells have weak expression of these markers.
- Conventional cytogenetic karyotyping
- Fluorescent in situ hybridization (FISH) for recurrent chromosomal deletions, amplifications, and translocations that have prognostic significance; these include:
 - Deletion 13q14, deletion 17p13 (*TP53*), and deletion of 1p32
 - Amplification of 1q21

FIGURE 11-2 Serum protein electrophoresis demonstrates an M-protein peak (left). Immunofixation confirms it to be monoclonal IgG lambda type.

FIGURE 11-3 Multiple myeloma bone marrow aspirate. Some plasma cells have cytoplasmic immunoglobulin inclusions (Wright-Giemsa, 500 \times).

- Translocations involving the immunoglobulin heavy-chain locus on chromosome 14q32 and its common partners, including 11q13 (*CCND1*), 4p16 (*FGFR3* and *MMSET*), 16q23 (*c-MAF*), 6p21 (*CCND3*), and 20q12 (*MAFB*)
- Gene expression profiling of the CD138⁺ bone marrow aspirate plasma cells to identify high-risk MM and to facilitate inclusion in clinical trials

Other Tests

- Abdominal wall fat pad biopsy (warranted if there are signs and symptoms suggestive of amyloidosis; see separate discussion), which should be stained with Congo red stain. Amyloid fibrils show green birefringence under polarized light.
- Serum viscosity (if there are concerns for hyperviscosity usually due to elevated IgM levels in WM; see separate discussion). Hyperviscosity should be a clinical diagnosis, and therapeutic plasma exchange should not be delayed while waiting for the results of serum viscosity level.

Myeloma Diagnostic Criteria

Based on the above workup, a diagnosis of a plasma cell dyscrasia may be made, which can span the spectrum of the premalignant MGUS stage to SMM to full malignant transformation to MM. Definitions of these clinical stages according to the International Myeloma Working Group (IMWG) criteria are summarized in Table 11-2^(*). Historically, SMM and MM have been distinguished by the presence of end-organ damage as defined by CRAB criteria. The 2014 updated IMWG criteria were revised to reclassify some SMM patients as having MM (even in the absence of symptoms) if certain biomarkers were present that might indicate impending development of CRAB features. These include clonal bone marrow plasmacytosis $\geq 60\%$, an involved-to-uninvolved serum free light chain ratio ≥ 100 , or more than one focal lesion on MRI studies of at least 5 mm in size. Patients with SMM and at least one of these biomarkers have a 70% to 80% chance of progression to MM at 2 years compared to 20% (10% per year) in the absence of these high-risk features. Initiating therapy in these patients may delay the onset of

Table 11-2 Definitions of MGUS, SMM, and MM by 2014 IMWG Criteria

		Definition	Progression Rate
Premalignant	Monoclonal gammopathy of undetermined significance (MGUS)	<ul style="list-style-type: none"> • Monoclonal protein < 3 g/dL • Clonal bone marrow plasma cells $< 10\%$ • Absence of CRAB^a criteria related to plasma cell clonal disorder • In light-chain MGUS^b, urinary monoclonal protein must be < 500 mg/24 h 	<ul style="list-style-type: none"> • 1% per year for MGUS • 0.3% per year for light-chain MGUS
	Smoldering multiple myeloma (SMM)	<ul style="list-style-type: none"> • Serum monoclonal protein ≥ 3 g/dL or urinary monoclonal protein ≥ 500 mg/24 h and/or bone marrow plasmacytosis 10%-60% • Absence of CRAB criteria^a or amyloidosis 	10% per year (see Table 11-9 for risk stratification in SMM)
	Multiple myeloma (MM)	<ul style="list-style-type: none"> • Clonal bone marrow plasma cells $\geq 10\%$ or biopsy-proven bony or extramedullary plasmacytoma AND • Evidence of end-organ damage attributed to a plasma cell disorder as defined by CRAB^a criteria OR ≥ 1 biomarker of malignancy, which includes bone marrow clonal plasmacytosis $\geq 60\%$, involved-to-uninvolved serum free light chains ≥ 100, or > 1 focal lesion on magnetic resonance imaging studies that is at least 5 mm in size 	Not applicable

^aCRAB criteria:

1. HyperCalcemia: Serum calcium > 1 mg/dL above the upper limit of normal or > 11 mg/dL.

2. Renal insufficiency: creatinine clearance < 40 mL/min or serum creatinine > 2 mg/dL.

3. Anemia: hemoglobin < 2 g/dL below the lower limit of normal or < 10 g/dL.

4. Bone lesions: one or more osteolytic lesions on skeletal survey, computed tomography (CT) scan, or positron emission tomography–CT.

^bDefined as abnormal free light-chain ratio (< 0.26 or > 1.65) in the absence of immunoglobulin heavy-chain expression on immunofixation.

MM-defining end-organ damage events and associated morbidity and adverse effects on quality of life.

Staging and Risk Stratification

The course of MM is heterogeneous. Risk stratification using staging and prognostic tools may yield insights into the underlying disease biology and expected course. Prognostic studies can help stratify patients in clinical trials and may help guide therapy [eg, bortezomib in t(4;14) and del 13q].

International Staging System

The International Staging System (ISS) was established in 2005 by the IMWG after a retrospective analysis of the outcomes of >10,000 patients across 17 different centers. In this study, β_2 -microglobulin and albumin were powerful correlates of median survival, and patients could be categorized into three stages based on serum levels at diagnosis (Table 11-3). Because β_2 -microglobulin is renally excreted, high levels may be found in the presence of renal failure, which makes the interpretation of the ISS in this setting challenging. The ISS is the current preferred staging method and has supplanted the previously used Durie-Salmon staging system, which was confounded by observer-dependent variables, such as degree of lytic bone lesions, that added subjectivity in its assessment. It is important to note that the ISS has only been validated at the time of diagnosis in patients with MM and should not be extrapolated to patients with MGUS or SMM.

Risk Stratification

In addition to the ISS, patients can be stratified into standard-, intermediate-, and high-risk categories based on cytogenetic findings by both conventional karyotyping and FISH. Other high-risk features include elevated serum LDH, extramedullary disease, circulating plasma cells, and a high-risk GEP pattern as defined by a 70-gene panel. Risk stratification based on these criteria is summarized in Table 11-4.

Table 11-3 International Staging System

• Stage I Parameters: Albumin >3.5 g/dL and β_2 -microglobulin <3.5 mg/L Median Overall Survival: 62 months
• Stage II Parameters: Neither stage I nor stage III Median Overall Survival: 44 months
• Stage III Parameters: β_2 -microglobulin >5.5 mg/L Median Overall Survival: 29 months

Table 11-4 Risk Stratification of Newly Diagnosed Multiple Myeloma

Standard Risk	Intermediate Risk	High Risk
t(11;14) t(6;14) Hyperdiploid karyotype	t(4;14) Del 13q Hypodiploid karyotype	Del 17p13 Amplification of 1q21 t(14;20) t(14;16) Lactate dehydrogenase $\geq 2\times$ institutional upper limit of normal Plasma cell leukemia High-risk gene expression profiling signature

Response Criteria

International Myeloma Working Group Uniform Response Criteria

The IMWG proposed new guidelines in 2006 to standardize response criteria in MM and to define disease progression to facilitate comparisons of outcomes between treatment centers and for reporting results in clinical trials. These International Uniform Response Criteria guidelines are summarized in Table 11-5. Assessment of response with M-protein measurements using serum protein electrophoresis, urine protein electrophoresis, and serum free light-chain assay is recommended prior to each cycle of therapy. Bone marrow biopsy is necessary to monitor disease in the absence of a measurable M-protein in the serum or urine or to document a complete or stringent complete response. Serial imaging assessments may be required if soft tissue plasmacytomas are present at baseline.

Minimal Residual Disease

In recent years, the fraction of patients achieving deep responses, including complete remission, after initial MM therapy has increased significantly. This correlates with improved progression-free survival (PFS) and overall survival (OS) in several studies ⁽¹⁰⁾. With a deepened level of remission, more sensitive methods to assess and monitor minimal residual disease (MRD) have been investigated. These include flow cytometry, allele-specific polymerase chain reaction (ASO-PCR), and next-generation sequencing (NGS)-based assays ⁽¹¹⁾. MRD may soon be used as a valid surrogate end point to compare treatment strategies and advise on consolidation and maintenance therapies. At present, MRD assessment by multiparameter flow cytometry is the most reproducible method in MM. It has a sensitivity of 10^{-5} if at least 2×10^6 cells from bone marrow aspirates are analyzed. An international effort to adopt standardized or harmonized MRD detection

Table 11-5 IMWG International Uniform Response Criteria

Response Category	Criteria
sCR	Meets criteria for CR PLUS Normal FLC ratio AND No clonal cells in bone marrow by immunohistochemistry or immunofluorescence
CR	Negative serum and urine immunofixation AND Disappearance of any soft tissue plasmacytomas AND ≤5% plasma cells in bone marrow
VGPR	Serum and urine M-protein detectable by immunofixation but negative M-protein OR ≥90% reduction in serum M-protein plus urine M-protein level <100 mg per 24 h
PR	≥50% reduction of serum M-protein and reduction in 24-h urinary M-protein by ≥90% or to <200 mg per 24 h If unmeasurable serum and urine M-protein, ≥50% decrease in the difference between involved and uninvolved FLC levels If unmeasurable serum and urine M-protein serum FLC assay, ≥50% reduction in plasma cells is required in place of M-protein, as long as baseline bone marrow plasma cell percentage was ≥30% In addition to above criteria, a ≥50% reduction in the size of any baseline soft tissue plasmacytoma is required
SD	Not meeting criteria for CR, VGPR, PR, or progressive disease
PD	Increase of ≥25% from baseline in at least one of the following: Serum M-component (the absolute increase must be ≥0.5 g/dL) Urine M-component (the absolute increase must be ≥200 mg/24 h) Difference between involved and uninvolved FLC levels if serum and urine M-protein are unmeasurable (the absolute increase must be >10 mg/dL) Bone marrow plasma cell percentage (the absolute % must be ≥10%) Development of new bone lesions or soft tissue plasmacytomas or definite increase in size of existing bone lesions or soft tissue plasmacytomas Development of hypercalcemia >11.5 mg/dL related to plasma cell dyscrasia

CR, complete response; FLC, free light chain; IMWG, International Myeloma Working Group; M-protein, monoclonal protein; PD, progressive disease; PR, partial response; sCR, stringent complete response; SD, stable disease; VGPR, very good partial response.

assay and analysis by multiparameter flow cytometry in clinical practice and in clinical trials is ongoing.

Treatment of Newly Diagnosed Multiple Myeloma

After the diagnostic workup and risk stratification are complete, patients who meet the criteria for MM as defined by IMWG criteria should initiate therapy. The most important initial assessment is whether a patient is a candidate for high-dose chemotherapy and autologous stem cell transplantation (SCT), largely based on existing comorbidities and age. In the transplant-eligible population, current MM standard of care involves frontline chemotherapy, followed by consolidative high-dose melphalan and autologous SCT, followed by maintenance therapy. Some chemotherapy agents (eg, melphalan) may adversely affect stem cell collection and should be avoided in the initial therapy of transplant-eligible patients. Melphalan may be included in the frontline therapy of transplant-ineligible patients.

Frontline Therapy for Transplant-Eligible Patients

A number of different regimens can be used in the frontline setting for transplant-eligible patients. These usually consist of two- or three-drug combinations, and the choice of therapy is individualized based on factors such as patient comorbidities (neuropathy, diabetes), preferred route of administration (oral, intravenous, or subcutaneous), and underlying disease biology [eg, bortezomib in t(4;14) and del 13q]. Patients are usually given two to four cycles of therapy prior to stem cell collection to reduce disease burden before proceeding to high-dose chemotherapy and autologous stem cell rescue. Given the evidence that the depth and duration of response may translate into improved long-term outcomes, we generally prefer the three-drug regimens over the two-drug regimens as initial therapy in newly diagnosed patients.

Lenalidomide and Dexamethasone

The efficacy of the second-generation immunomodulatory drug (IMiD) lenalidomide combined with dexamethasone (Len/Dex) was initially demonstrated in

the relapsed and refractory setting. Subsequently, a randomized phase III study in newly diagnosed MM compared lenalidomide plus high-dose dexamethasone versus placebo plus high-dose dexamethasone (¹²). Overall response rates (ORR), defined as a partial response or greater, and very good partial response (VGPR) rates were significantly higher in the Len/Dex arm (78% and 63%, respectively) versus the placebo/Dex arm (48% and 16%, respectively). The 1-year PFS rate was also higher in the Len/Dex arm (78% vs 52%), although there was no significant difference in OS between the two groups (94% vs 88%). Grade 3 or 4 neutropenia was higher with Len/Dex (21% vs 5%), as was the rate of venous thromboembolism (VTEs) (23.5% vs 5%) despite aspirin prophylaxis.

To possibly decrease the dexamethasone dose while retaining efficacy, a randomized study was conducted with lenalidomide in combination with high-dose dexamethasone (40 mg on days 1-4, 8-11, and 17-20 every 4 weeks) versus low-dose dexamethasone (40 mg on days 1, 8, 15, and 22 every 4 weeks) (¹³). Patients receiving high-dose dexamethasone achieved a higher ORR (79% vs 68%) after four cycles of therapy. However, a second interim analysis at 1 year demonstrated a statistically significant superior OS in the low-dose dexamethasone arm compared to the high-dose arm (96% vs 87%). This was attributed to increased toxicities of high-dose dexamethasone therapy including VTEs and infections. Based on this study, lenalidomide is recommended to be given in combination with low-dose dexamethasone.

Bortezomib and Dexamethasone

The proteasome inhibitor bortezomib in combination with dexamethasone was studied as frontline therapy in a large phase III trial comparing bortezomib and dexamethasone versus vincristine, doxorubicin, and dexamethasone (VAD) therapy prior to autologous SCT (¹⁴). Postinduction ORR (78.5% vs 62.8%), ≥VGPR rates (37.7% vs 15.1%), and complete response (CR) or near complete response (nCR) rates (14.8% vs 6.4%) all favored the bortezomib and dexamethasone arm over the VAD arm. There was also a trend toward improved median PFS in the bortezomib and dexamethasone arm (36.0 vs 29.7 months) but no difference in OS. In a separate analysis, initial treatment with bortezomib and dexamethasone prior to autologous SCT was shown to overcome the adverse prognostic features of t(4;14) in relation to event-free survival (EFS) and OS compared to VAD, although del 17p remained a poor prognostic factor regardless of the treatment regimen. Herpes simplex prophylaxis with acyclovir or valacyclovir should be given with bortezomib-containing regimens. Subcutaneous administration of bortezomib is preferred because it has similar efficacy as the intravenous route with decreased peripheral neuropathy (¹⁵).

Cyclophosphamide, Bortezomib, and Dexamethasone

The addition of oral cyclophosphamide to bortezomib and dexamethasone (CyBorD) was studied in phase II trials. In the EVOLUTION phase II trial, patients were randomized to receive bortezomib, lenalidomide, and dexamethasone (VRD); bortezomib, lenalidomide, cyclophosphamide, and dexamethasone (VDCR); or CyBorD, all followed by maintenance bortezomib for four 6-week cycles (¹⁶). The study was later amended to add an additional day 15 dose of cyclophosphamide, in addition to days 1 and 8, in patients receiving CyBorD. Patients receiving the modified CyBorD regimen achieved an ORR of 82%, with a VGPR or better rate of 53% and a CR rate of 47%. The 1-year PFS rate was 100%.

In another phase II study, standard twice-weekly (days 1, 4, 8, and 11) bortezomib was compared to weekly bortezomib (days 1, 8, 15, and 22) in combination with weekly cyclophosphamide and dexamethasone (¹⁷). ORR (88% vs 93%) and VGPR rates (60% vs 61%) were similar in both the twice-weekly and weekly bortezomib groups. In addition to demonstrating the efficacy of the three-drug combination of CyBorD, this study also suggested that weekly (instead of twice-weekly) bortezomib could be used to reduce treatment-related toxicity because it resulted in fewer grade 3 and 4 adverse events compared to the twice-weekly schedule (37% and 3% vs 48% and 12%, respectively).

Bortezomib, Lenalidomide, and Dexamethasone

The efficacy of VRD has also been demonstrated in several phase II trials. A phase I/II study evaluating the safety and efficacy of VRD resulted in an impressive 100% ORR in the phase II part, with 74% of patients achieving VGPR or better (¹⁸). As mentioned, VRD was also included as one of the arms in the phase II EVOLUTION trial, which resulted in an 85% ORR, with a VGPR or better rate of 51% and a CR rate of 24% (¹⁶). Phase III studies are ongoing comparing VRD with bortezomib and dexamethasone (NCT00522392) or lenalidomide and dexamethasone (NCT00644228) in the frontline setting. In addition, the role and timing of autologous SCT are being reexamined in the era of novel agents in a large international phase III trial of frontline VRD followed by lenalidomide maintenance therapy (with the option of SCT at the time of relapse) versus VRD followed by autologous SCT as per the current standard of care (NCT01208662). Phase II studies are also evaluating the efficacy of the second-generation proteasome inhibitor carfilzomib in combination with lenalidomide and dexamethasone (CRD) in the frontline setting with delayed autologous SCT; early results show rapid and deep responses with less peripheral neuropathy (^{19,20}). These studies will clarify the role of novel triplet combinations in the frontline setting and provide insight as to whether deeper

responses, including molecular responses, with the multiple novel agents in combination, ultimately translate into improved long-term outcomes (Table 11-6).

Frontline Therapy for Transplant-Ineligible Patients

Initial treatment regimens for transplant-eligible patients can also be used in transplant-ineligible patients. Without the need to collect autologous stem cells, the alkylating agent melphalan can be incorporated into frontline therapy in nontransplant candidates. For 40 years, melphalan and prednisone (MP) represented the standard of care for transplant-ineligible patients. However, the addition of novel agents to the MP backbone and non-melphalan-containing combinations now form the new standard of preferred regimens.

Thalidomide/Lenalidomide, Melphalan, and Prednisone

The Gruppo Italiano Malattie Ematologiche dell'Adulto (GIMEMA) compared melphalan, prednisone, and thalidomide (MPT) with MP (²¹). The ORR (76% vs 47.6%) and nCR/CR rates (27.9% vs 7.2%) favored the MPT arm. The median PFS was better in the MPT arm (21.8 vs 14.5 months), although the median OS was similar (45.0 vs 47.6 months). Subsequent phase III studies also demonstrated improved ORR and PFS with MPT compared to MP, with both the Intergroupe Francophone du Myélome (IFM) 99-06 and IFM 01-01 studies also showing a higher OS rate with MPT compared to MP.

Melphalan, prednisone, and lenalidomide (MPL) was also compared with MP alone in a phase III trial comparing MPL with lenalidomide maintenance (MPL-L) versus MPL versus MP (²²). The ORR was significantly higher in patients receiving MPL-L or MPL (77% and 68%, respectively) compared to those receiving MP (50%). Although MPT and MPL are superior to MP alone in terms of ORR and PFS, increased toxicity with the addition of a third drug must be carefully balanced with enhanced efficacy, because grade 3 and 4 adverse events were more pronounced in the MPT and MPL arms compared to MP. Although not compared head-to-head, nonhematologic grade 3 and 4 adverse events were less frequent with MPL compared to MPT (^{22, 23}).

Bortezomib, Melphalan, and Prednisone

Bortezomib plus MP (VMP) was also compared with MP alone in a large randomized phase III trial. The ORR and CR rates were 71% and 30%, respectively, in patients receiving VMP versus 35% and 4%, respectively, in the MP arm. Median PFS was better with VMP (24.0 vs 16.6 months). An OS benefit for VMP versus MP (median, 56.4 vs 43.1 months) was also reported in the final analysis (²⁴). Again, the benefits of efficacy must be weighed carefully against toxicity, as grade 3 and 4 adverse events, particularly peripheral neuropathy, were greater in the VMP arm (13%).

Non-Melphalan-Based Regimens

The role of melphalan-containing regimens in transplant-ineligible patients has been challenged. Lenalidomide and low-dose dexamethasone (Rd) in four-week cycles until disease progression versus the same

regimen for a fixed duration of 72 weeks versus MPT in 6-week cycles for 72 weeks were compared in a randomized phase III study in over 1,500 transplant-ineligible patients ⁽²⁵⁾. Although the ORRs were similar between the three arms, median PFS favored continuous Rd (25.5 months) versus 18 cycles of Rd (20.7 months) and MPT (21.2 months). There was a trend toward improved 3-year OS with continuous Rd (59%) versus fixed-duration Rd (56%) and MPT (51%). There was also a trend toward fewer grade 3 and 4 adverse events in the continuous Rd arm (70%) compared to the MPT arm (78%), in particular grade 3 and 4 neutropenia and neuropathy. However, there was a higher incidence of grade 3 and 4 infections with continuous Rd (29%), likely related to the longer duration of glucocorticoid use.

A community-based phase IIIB trial compared bortezomib and dexamethasone (BD) versus bortezomib, thalidomide, and dexamethasone (BTD) versus melphalan, prednisone, and bortezomib (MPB) followed by maintenance bortezomib ⁽²⁶⁾. The ORR, PFS, and OS were similar across all three arms. Discontinuation due to adverse events was highest in the BTD arm (35%) compared to BD (24%) and MPB (30%). This demonstrates the safety and efficacy of the use

of BD in the elderly population. In general, the incorporation of novel agents to combination therapy has improved ORR and long-term outcomes in elderly, transplant-ineligible patients. However, treatment must be individualized based on comorbidities and disease characteristics as well as the patient's own goals of care (Table 11-7).

Stem Cell Transplantation

Autologous Stem Cell Transplantation

High-dose melphalan without autologous SCT was first reported in 1983 by McElwain and colleagues from the Royal Marsden Hospital. Compared with chemotherapy alone, intensified chemotherapy followed by autologous SCT appears to prolong OS in previously untreated patients with MM. One comparative study and two randomized trials showed that autologous SCT provided survival benefits of approximately 12 months.

In the French IFM 90 trial, high-dose chemotherapy supported by autologous SCT was compared with conventional chemotherapy in 200 previously untreated patients with MM <65 years of age ⁽²⁷⁾. The results showed a higher CR rate (22% vs 5%) and higher rates

^aStatistically significant.

of 5-year EFS (28% vs 10%) and OS (52% vs 12%) in the autologous SCT group. The median OS in patients assigned to the SCT arm was 13 months longer (57 vs 44 months).

The Medical Research Council Myeloma VII trial compared conventional-dose chemotherapy with high-dose therapy and autologous SCT in 401 previously untreated patients with MM <65 years old (²⁸). The rates of CR were significantly higher in the autologous SCT group (44% vs 8%). Intent-to-treat analysis showed a significant higher rate of OS and PFS with SCT. Compared with standard therapy, autologous SCT increased median OS by almost 12 months (54.1 vs 42.3 months). There was a trend toward a greater survival benefit in patients with poor prognosis (defined by β_2 -microglobulin level >8 mg/L).

In three other randomized studies, however, there has been no survival benefit with autologous SCT (²⁹⁻³¹). Comparison among these trials is difficult due to the variability in patient eligibility including age, induction chemotherapy, conditioning regimen for SCT, and definitions of response. Subsequent trials have confirmed that autologous SCT deepens the response obtained with primary therapy. Thus, autologous SCT has become standard of care for eligible patients based on performance status and organ function. Most recently, a retrospective analysis of 1,038 patients with MM treated at the Mayo Clinic (2001-2010) reported a superior OS after autologous SCT. The median OS was 4.9 years without autologous SCT and not reached with autologous SCT (³²).

Many different preparative regimens have been assessed over the last 20 years, but only one prospective randomized trial by the IFM has directly compared two different preparative regimens (³³). In 282 newly diagnosed patients <65 years old, high-dose melphalan at 200 mg/m² was shown to be superior to a combination of melphalan 140 mg/m² plus 8 Gy of total-body irradiation (TBI), mainly due to reduced toxicity including mucositis and transplant-related mortality. Melphalan remains the standard of care, but the addition of novel agents to conditioning is being investigated.

Transplantation can be performed either early after induction therapy or later at disease progression. Fermand et al compared early and late autologous SCT and reported a similar OS (³¹). However, the average time without symptoms, treatment, and treatment toxicity were significantly better with early autologous SCT. A retrospective study of 167 patients who received induction therapy containing at least one of three novel agents (lenalidomide, thalidomide, or bortezomib) followed by autologous SCT either within 12 months of diagnosis or later found a higher CR rate in the early autologous SCT arm but no difference in PFS or OS. The potential benefit of early versus late autologous SCT was assessed in a trial randomizing

patients between 55 and 65 years of age to either conventional chemotherapy alone or chemotherapy followed by autologous SCT. With a median follow-up of 120 months, a trend toward better EFS, but no OS benefit, was observed in patients undergoing early transplantation (³¹). Finally, the US Intergroup Trial S9321 found no PFS or OS benefit with early SCT (²⁹). A recent cost analysis study by Pandya et al suggests that early autologous SCT is cost-effective compared to delayed autologous SCT (³⁴).

At MDACC, we offer autologous SCT to all eligible patients after induction therapy regardless of age. We use a preparative regimen of melphalan 200 mg/m² (unless the patient is treated on a clinical trial with a novel preparative regimen). In selected patients (>70 years old or dialysis dependent), we lower the melphalan dose to 140 mg/m². We offer tandem autologous SCT only in the setting of a clinical trial or if there is significant residual disease after first autologous SCT. A second salvage transplant is an option for patients with relapsed disease; we offer this mainly to patients whose benefit from transplant was >1 year and whose disease burden can be significantly reduced by salvage chemotherapy. We offer maintenance therapy after transplantation (discussed later).

Allogeneic Stem Cell Transplantation

The curative potential of allogeneic SCT results from a graft-versus-tumor effect and dose-intensive therapy rescued with a tumor-free graft. The existence of a graft-versus-myeloma effect was first documented by Tricot and colleagues and later confirmed in large single- and multi-institutional series of donor lymphocyte infusions. High-dose therapy is toxic but potentially curative. To overcome toxicity from high-dose regimens and to extend applicability to older patients with significant comorbidities, allogeneic SCT with reduced-intensity conditioning regimens has been attempted.

Two prospective trials investigated a tandem autologous plus reduced-intensity allogeneic SCT approach as part of the initial therapy for MM, with conflicting results. The IFM group reported on the outcomes of patients with high-risk disease (defined at the time as high levels of β_2 -microglobulin and deletion of chromosome 13 by FISH) who received initial autologous SCT with melphalan 200 mg/m² (³⁵). Sixty-five patients had an human leukocyte antigen (HLA)-identical sibling donor, of whom 46 received a reduced-intensity conditioning regimen consisting of fludarabine, busulfan, and antithymocyte globulin (ATG). Patients without an HLA sibling donor received a second autologous SCT prepared with melphalan 220 mg/m². On an intent-to-treat basis, the OS and the EFS did not differ significantly between the two groups (median OS and EFS, 35 and 25 months with allogeneic SCT vs 41 and

30 months with autologous SCT, respectively). There was a trend toward better OS with tandem autologous SCT (median, 47.2 vs 35 months) for patients who actually received a reduced-intensity allogeneic SCT.

The Italian Cooperative Group performed a similar study⁽³⁶⁾. After a median follow-up of 3 years, non-relapse mortality was 11% for the autologous-plus-allogeneic group versus 4% for the tandem autologous group ($P = 0.09$). The CR rates were significantly higher in the autologous-plus-allogeneic group than the tandem autologous group (46% vs 16%), as was OS (84% vs 62%) and EFS (75% vs 41%). A follow-up analysis at 7 years further suggests a long-term survival and disease-free survival advantage with allogeneic SCT over standard autologous SCT (median OS, not reached vs 5.3 years; median EFS, 39 vs 33 months)⁽³⁷⁾. The Bone Marrow Transplant Clinical Trials Network (BMT CTN) enrolled 710 patients, of whom 625 had standard-risk disease; 156 patients received autologous SCT followed by allogeneic SCT, whereas 366 patients underwent tandem autologous SCT. The 3-year PFS was 43% with autologous-allogeneic SCT and 46% with autologous-autologous SCT. No OS difference was seen⁽³⁸⁾. A long-term follow-up analysis of the NMAM2000 study by the European Society for Blood and Marrow Transplantation demonstrated that PFS and OS with autologous SCT followed by reduced-intensity allogeneic SCT were improved at 96 months compared to autologous SCT alone (PFS and OS: 22% and 49% vs 12% and 36%, respectively)⁽³⁹⁾. Specifically, autologous SCT followed by reduced-intensity conditioning allogeneic SCT seemed to overcome the poor prognostic impact of del 13q.

At MDACC, we only perform reduced-intensity allogeneic SCT. We use the tandem autologous plus allogeneic SCT approach only in the setting of a clinical trial. Allogeneic SCTs are offered to patients with relapsed, chemotherapy-sensitive disease who are <70 years old, have an HLA-identical sibling or unrelated donor, and are in good general physical condition. Our preparative regimen is a combination of fludarabine and melphalan (100 or 140 mg/m²), with ATG added for unrelated donor SCT.

To improve outcomes of autologous transplantation by adding a graft-versus-myeloma component, current laboratory research and clinical trials at MDACC are focused on eradicating MRD after autologous SCT using cellular therapy and vaccines.

Maintenance Therapy

The curability of MM has long been a matter of discussion. A small proportion of patient may achieve long-term survival and possibly a cure, but most patients relapse even after initial complete remission is

achieved⁽⁴⁰⁾. To delay the time to disease recurrence, maintenance therapy following autologous SCT has been explored to limit growth of residual malignant plasma cells. Initial maintenance strategies included interferon- α , although treatment-related toxicities such as flu-like symptoms and malaise made it challenging to administer. The approval of thalidomide in the late 1990s renewed interest in maintenance therapy. Multiple trials showed improvements in PFS and sometimes OS with thalidomide maintenance after autologous SCT. Toxicities related to long-term therapy, notably peripheral neuropathy, made it difficult to tolerate.

Given its more favorable side effect profile, lenalidomide maintenance therapy after autologous SCT was next explored. The Cancer and Leukemia Group B (CALGB) study randomized patients to lenalidomide or placebo maintenance starting 100 days following autologous SCT⁽⁴¹⁾. PFS was significantly greater in the lenalidomide arm (46 vs 27 months); OS was also significantly better. The IFM reported a similar trial in which patients received two 4-week cycles of consolidation with lenalidomide 25 mg after autologous SCT before being randomized to lenalidomide maintenance versus placebo⁽⁴²⁾. PFS also favored lenalidomide maintenance (median PFS, 41 vs 23 months), but there was no difference in OS. Both studies reported an increase in second primary malignancies with lenalidomide maintenance (8% in the CALGB and IFM studies) versus placebo (3% in CALGB and 4% in IFM). However, when all competing factors for death are considered (including death from relapsed MM), patients have a much higher risk of mortality from other causes rather than secondary malignancies^(43, 44). Potential risks and benefits of lenalidomide maintenance should be discussed with patients to make informed decisions. Lenalidomide maintenance can also be considered in nontransplant patients after initial therapy based on the phase III MPL-L versus MPL versus MP study described earlier⁽²²⁾.

Bortezomib maintenance therapy was investigated in the phase III Hemato-Oncologie voor Volwassenen Nederland (HOVON)-65/German Multicenter Myeloma Group (GMMG)-HD4 trial, where patients were randomized to receive either VAD or bortezomib, doxorubicin, and dexamethasone (PAD) induction, followed by high-dose melphalan and autologous SCT⁽⁴⁵⁾. Patients were then randomized again to receive either thalidomide or bortezomib maintenance therapy for 2 years. The CR rates, PFS, and OS all favored bortezomib-containing induction and maintenance regimens, and benefit was also noted in high-risk patients with del 17p. In general, we offer patients lenalidomide maintenance therapy following autologous SCT at MDACC. In the setting of high-risk

cytogenetic features, bortezomib consolidation/maintenance should be considered based on the HOVON data.

Treatment of Relapsed/Refractory Multiple Myeloma

We recommend enrollment in clinical trials when possible for all patients with relapsed/refractory MM. Alternatively, there are a number of therapeutic options that have gained regulatory approval that may be considered in this setting.

Immunomodulatory Drugs

Many patients may already be on maintenance lenalidomide at the time of disease recurrence. Increasing to standard-dose lenalidomide (25 mg daily for 21 out of 28 days) with or without dexamethasone is an option. Two large phase III trials demonstrated the efficacy of lenalidomide and dexamethasone compared to dexamethasone alone, with ORR, PFS, and OS favoring the combination. Although high-dose dexamethasone was used in these trials, low-dose dexamethasone is typically given in combination with lenalidomide in this setting, extrapolating from data comparing these approaches in frontline therapy.

Pomalidomide is a third-generation IMiD with greater in vivo potency than thalidomide and lenalidomide. In a phase III study in relapsed/refractory MM, patients were randomized to receive either pomalidomide plus low-dose dexamethasone (Pd) versus only high-dose dexamethasone (⁴⁶). Around 75% patients were double refractory to both lenalidomide and bortezomib. The ORR was 35% with Pd versus 10% with high-dose dexamethasone. The median PFS was 4.0 months with Pd versus 1.9 months with high-dose dexamethasone. Based on these results, pomalidomide gained US Food and Drug Administration (FDA) approval in 2013 for MM refractory to last therapy and prior bortezomib and lenalidomide exposure.

Proteasome Inhibitors

Bortezomib has shown efficacy in relapsed MM in two large randomized phase III trials. The APEX phase III trial compared intravenous bortezomib to high-dose dexamethasone; ORR, PFS, and OS were all superior in the bortezomib arm. As mentioned, subcutaneous bortezomib is favored over the intravenous route due to similar efficacy and less peripheral neuropathy (¹⁵).

Bortezomib has also been studied in combination with other agents. The addition of pegylated liposomal doxorubicin in combination with bortezomib gained

regulatory approval after demonstrating superior PFS compared to bortezomib monotherapy in relapsed/refractory bortezomib-naïve MM patients, although the ORRs were not statistically different between the two groups (⁴⁷). Phase II data of VRD in relapsed/refractory MM resulted in an ORR of 64%. Median PFS was 8.5 months, and median OS was 30 months (⁴⁸). The CyBorD regimen may also be considered in relapsed MM based on phase II data.

The second-generation proteasome inhibitor carfilzomib recently gained regulatory approval for patients exposed to bortezomib and an IMiD and whose disease was refractory to last therapy. Like bortezomib, carfilzomib inhibits the chymotrypsin-like activity of the 20S proteasome, but its unique structural properties allow for greater specificity and irreversible binding to its target. The efficacy of carfilzomib in relapsed/refractory MM was established in a single-arm phase II trial of 266 patients, all of whom received prior IMiD therapy, and all but one patient received prior bortezomib (⁴⁹). The ORR was 24%. Among 169 patients refractory to both bortezomib and lenalidomide, the ORR was 15%. Only 12% of patients reported any grade of treatment-emergent peripheral neuropathy.

The role of carfilzomib in relapsed and/or refractory MM continues to evolve, as it is being tested in combination with other novel agents. Interim results of a phase III study comparing carfilzomib, lenalidomide, and dexamethasone (CRd) with lenalidomide and dexamethasone (Rd) were recently reported (⁵⁰). In this study, 66% of patients received prior bortezomib and 20% received prior lenalidomide. The median PFS was significantly longer with CRd compared with Rd (26.3 vs 17.6 months). The combination of carfilzomib, pomalidomide, and dexamethasone has also shown promising results (⁵¹). However, the impact of carfilzomib on OS is uncertain. An interim analysis of a phase III study that randomized relapsed/refractory patients to carfilzomib versus glucocorticoid therapy did not meet its primary end point of OS benefit (⁵²). Finally, although earlier studies established the maximum-tolerated dose of carfilzomib at 20 mg/m² for cycle 1 and 27 mg/m² for subsequent cycles, phase I and II data have emerged demonstrating the safety and efficacy of higher doses of carfilzomib up to 56 mg/m² administered over 30 minutes compared to a 2- to 10-minute intravenous bolus given in earlier studies (⁵³). An ongoing Southwest Oncology Group randomized phase II study is comparing high-dose versus low-dose carfilzomib (with dexamethasone in both arms).

Investigational Agents

Although IMiDs and proteasome inhibitors now form the backbone of most MM regimens, both in the upfront

and relapsed settings, several promising new classes of investigational agents have shown both safety and promising efficacy in phase I and II clinical trials. These include novel immunotherapeutic approaches with the anti-CD38 antibody daratumumab⁽⁵⁴⁾ and the anti-SLAMF7 antibody elotuzumab in combination with lenalidomide and low-dose dexamethasone⁽⁵⁵⁾, both of which have garnered “breakthrough therapy” designations from the FDA based on early efficacy data. Phase III studies are comparing lenalidomide and low-dose dexamethasone with or without elotuzumab in both relapsed/refractory (NCT01239797) and newly diagnosed MM (NCT01891643). These same combinations with lenalidomide and low-dose dexamethasone are also being tested in phase III trials with daratumumab in both relapsed/refractory (NCT02076009) and frontline MM (NCT02252172).

Histone deacetylase (HDAC) inhibitors have also shown promising activity. Although they only have modest activity as single agents, the potential of HDAC inhibitors has been most pronounced in combination with other anti-MM drugs, namely bortezomib. Disruption of aggresome formation by HDAC inhibition may provide potent synergy with proteasome inhibition by interfering with protein turnover and inducing the unfolded protein response. Based on this rationale, the pan-deacetylase inhibitor panobinostat was studied in combination with bortezomib and dexamethasone and compared to placebo, bortezomib, and dexamethasone in a large phase III trial⁽⁵⁶⁾. At interim analysis, PFS was significantly higher with

panobinostat compared to placebo (11.99 vs 8.08 months); OS was similar. The ORR did not differ between the arms, although the depth of response (CR or nCR) was significantly higher in the panobinostat arm. Concerns have been raised about drug efficacy (measured only by PFS) in the setting of significant toxicities, particularly grade 3 and 4 thrombocytopenia, diarrhea, and fatigue. In the future, more selective HDAC inhibitors with fewer off-target effects may need to be developed and tested for the full potential of this therapeutic approach to be realized.

ARRY-520, a novel antimitotic, inhibits the kinesin-spindle protein (KSP). In a phase II study, ARRY-520 was given with or without low-dose dexamethasone in relapsed/refractory MM⁽⁵⁷⁾. Patients in the cohort with low-dose dexamethasone were all refractory to lenalidomide and bortezomib; the ORR was 22%. A phase II trial with ARRY-520 in combination with carfilzomib or bortezomib is ongoing (Table 11-8).

Monoclonal Gammopathy of Undetermined Significance

The 2014 IMWG guidelines define MGUS as a serum M-protein <3 g/dL, <10% clonal marrow plasma cells, and absence of end-organ damage (CRAB criteria and myeloma-defining events; see Table 11-2) attributed to an underlying plasma cell proliferative disorder. The 2014 standard of care for MGUS is surveillance every 6 to 12 months with a physical exam and typical MM

serum and urine studies. Patients with MGUS can also be risk stratified for progression to MM according to established models (Table 11-9).

Smoldering Multiple Myeloma

Smoldering MM is defined as having a serum M-protein of ≥3.0 g/dL and/or ≥10% more marrow plasma cells without evidence of end-organ damage as defined by CRAB criteria and MM-defining events (see Table 11-2). Compared with MGUS, this premalignant clonal plasma cell proliferation carries a higher risk of progression to overt MM. In a large retrospective study of 276 patients with SMM followed over 26 years, the risk of progression to MM was 10% per year for the first 5 years, 3% per year for the next 5 years, and 1% per year for the last 10 years.

There is great heterogeneity in the SMM disease course. Some patients may remain asymptomatic for the rest of their lives, whereas others may rapidly develop

disease that meets MM criteria. Efforts have been made to risk stratify SMM to help predict the clinical course, guide surveillance strategies, and design trials for early intervention. One prognostic model found that patients with both clonal bone marrow plasmacytosis ≥10% and serum M-protein ≥3 g/dL had an 87% chance of MM progression at 15 years compared to 70% with only ≥10% marrow plasma cells (but monoclonal protein of <3 g/dL) and 39% with only monoclonal protein ≥3 g/dL (but <10% bone marrow plasma cells) ⁽⁵⁸⁾. Later, a serum free light-chain ratio of <0.125 or >8 was suggested as an independent prognostic factor for disease progression and incorporated into the prognostic score for SMM. A number of other factors have been shown to increase the risk of progression such as high-risk cytogenetics [del 17p, t(4;14), amplification of 1q], ≥95% aberrant marrow plasma cells by flow cytometry, IgA M-protein, immunoparesis of uninvolved immunoglobulins, circulating plasma cells by slide-based immunofluorescence, and proteinuria ⁽⁵⁹⁾.

Through these studies, a very-high-risk group was identified, with a 2-year progression risk of 70% to 80%, when there is at least one of the following risk factors: $\geq 60\%$ bone marrow plasmacytosis, an involved-to-uninvolved serum free light-chain ratio ≥ 100 , or more than one focal lesion on MRI that is at least 5 mm in size. This prompted revisiting the classical definition of SMM and led the IMWG in 2014 to recategorize asymptomatic patients with SMM who meet these criteria as having active MM requiring therapy (⁹).

The benefits of preemptive treatment of high-risk SMM are still unclear. Until this is further clarified, treatment of high-risk SMM should be undertaken preferentially through clinical trials. A phase III trial comparing lenalidomide and dexamethasone versus observation in high-risk patients found an improvement in median PFS in the treatment arm (median PFS, not reached vs 26 months) and a significant 3-year OS benefit (94% vs 80%, $P = 0.03$) (⁶⁰). However, results have not yet been replicated in other studies, and an excessive mortality rate in the observation arm for SMM patients has raised concerns about the interpretation of these results.

At MDACC, we recommend that patients with high-risk SMM be enrolled in a clinical trial. In the absence of clear data, we would otherwise recommend observation and close surveillance in these patients, although this practice may change soon as we gather data from relevant trials focused on high-risk SMM.

Solitary Plasmacytoma of Bone

A solitary plasmacytoma of bone is defined by the presence of a plasmacytoma without bone marrow evidence of monoclonal plasma cells, lytic bony lesions, or other clinically significant sequelae of MM. About 24% to 72% of patients with a solitary plasmacytoma have a monoclonal protein in the serum or urine. Initial workup should include all of the aforementioned serum and urine laboratory studies used in evaluation of MM, as well as advanced imaging with PET-CT or MRI to rule out multifocal disease that would upstage the disease to MM. Biopsy of the solitary plasmacytoma to demonstrate clonal plasma cells and a unilateral bone marrow biopsy to rule out systemic disease are necessary. Treatment should include radiation therapy of at least 40 Gy, although one may consider a dose of up to 50 Gy for lesions greater than 5 cm. After radiation therapy, surveillance should be performed with serial measurements of serum and urine M-protein levels and imaging studies, initially every 3 months and then less frequently. Patients who progress to overt MM during surveillance should follow the treatment guidelines for MM.

Patients with solitary plasmacytoma of bone often progress to MM within 2 to 4 years, with a median

OS of 7.5 to 12 years. In one study, persistence of a serum M-protein 1 year after radiation therapy was an adverse prognostic factor predicting a 10-year myeloma-free survival of 29% compared to 91% with undetectable M-protein. Another study found that an abnormal free light-chain ratio and a serum M-protein >0.5 g/dL were significant adverse factors for disease progression at 5 years.

OTHER PLASMA CELL DYSCRASIAS

Waldenström Macroglobulinemia

Background

Waldenström macroglobulinemia is an uncommon, low-grade malignancy characterized by the presence of lymphoplasmacytic cells together with the presence of a monoclonal IgM paraprotein. The median age at diagnosis is between 63 and 68 years. Men are more commonly affected, and the disease is more common among whites than other populations. Recent data show that 67% to 100% of WM cases are associated with a mutation of the myeloid differentiation primary response 88 (*MYD88*) gene located on chromosome 3p22 (⁶¹).

Clinical Presentation and Diagnostic Workup

Many patients are asymptomatic at diagnosis. When symptoms develop, they are caused by tumor infiltration (cytopenias, hepatomegaly, splenomegaly), circulating IgM (hyperviscosity, cryoglobulinemia, and/or cold agglutinin anemia), and/or tissue deposition of IgM (neuropathy, glomerular disease, and/or amyloidosis). Symptomatic hyperviscosity syndrome may be associated with visual disturbances, dizziness, cardiopulmonary symptoms, decreased consciousness, and a bleeding diathesis. Polyneuropathies are common. Some are associated with antigenic targets of the monoclonal serum IgM, including myelin-associated glycoprotein (MAG) and sulphatide. Others are caused by direct tumor infiltration, tissue deposition of IgM, the amount and properties of the circulating monoclonal IgM, or binding of unidentified antigens. Patients may also present with cold or warm autoimmune hemolytic anemia, iron deficiency anemia, or dilutional anemia.

Initial evaluation (Table 11-10) in suspected WM should include a CBC, serum chemistries, liver function tests, viral hepatitis serologies, serum protein electrophoresis (SPEP) and immunofixation, quantitative immunoglobulin levels, and a β_2 -microglobulin. In patients suspected of having a cryoglobulinemia, a cryocrit should be drawn and, together with SPEP and quantitative immunoglobulin specimens, should

Table 11-10 Initial Workup for Waldenström Macroglobulinemia

Essential Testing	Useful Under Certain Circumstances
History and physical	MYD88 L265P AS-PCR
CBC with differential, BUN, creatinine, electrolytes, liver function tests	testing of bone marrow biopsy
Quantitative immunoglobulins	Funduscopy examination ^c
Serum protein electrophoresis (SPEP) and immunofixation	Coombs test
Urine protein electrophoresis (UPEP) and immunofixation	Anti-myelin associated glycoprotein (anti-MAG) antibody/anti-GM1 antibody
Serum viscosity ^a	electromyogram
Hepatitis B and C serology	Congo red staining of abdominal fat pad biopsy and/or bone marrow biopsy
Cryocrit ^b	
Cold agglutinin titer	
Unilateral bone marrow aspirate and biopsy	

AS-PCR, allele-specific polymerase chain reaction; BUN, blood urea nitrogen; CBC, complete blood count.

^aMost patients with serum viscosity of less than 4 cP will not have symptoms of hyperviscosity.

^bIf cryocrit positive, then initial and follow-up cryocrit and SPEP samples should be measured under warm conditions.

^cWhen hyperviscosity is suspected.

immediately be placed in a 37°C water bath to facilitate accurate assessment. A serum viscosity level and cold agglutinin titer/Coombs test should be drawn if hyperviscosity or a hemolytic anemia, respectively, is suspected. Iron studies should be considered for patients having a microcytic anemia. Bone marrow biopsy should be performed to demonstrate infiltration by lymphoplasmacytic cells and can help determine the cause of an existing anemia. Flow cytometry will typically show a pattern of sIgM⁺, CD19⁺, CD20⁺, CD22⁺, and CD79⁺. Testing for the MYD88 L265 gene mutation in the marrow or peripheral blood can help distinguish WM from marginal zone lymphoma and MM, where the incidence of this mutation is low (⁶¹). Patients should have baseline CT scans (chest, abdomen, and pelvis) to evaluate for extramedullary disease. An ophthalmologic examination should be performed to look for retinal changes (hemorrhages or “sausage vessels”) in patients with suspected hyperviscosity syndrome.

Asymptomatic patients can be followed every 3 months during the first year, with longer follow-up intervals thereafter, in the setting of disease stability (⁶²). In such patients, the risk of developing symptomatic disease is about 6% in the first year, 39% at 3 years, and 55% at 5 years, so lifelong follow-up is necessary (⁶²). Higher M-protein and marrow infiltration have been

Table 11-11 Treatment Indications for Waldenström Macroglobulinemia

• Symptomatic hyperviscosity (eye grounds, neurologic changes)
• Hemoglobin <10 g/dL
• Platelet count ≤100,000/μL
• Bulky adenopathy
• Symptomatic organomegaly
• Symptomatic cryoglobulinemia
• Amyloidosis
• Neuropathy

associated with increased risk of progression to symptomatic disease (⁶²).

At MDACC, therapy is initiated for symptomatic hyperviscosity, hemoglobin <10 g/dL, platelet count ≤100,000/μL, bulky adenopathy, symptomatic organomegaly, symptomatic cryoglobulinemia, or significant peripheral neuropathy (Table 11-11) (⁶³). Therapy for hyperviscosity consists of prompt initiation of plasma exchange followed by chemotherapy. Because of the risk of precipitating symptomatic hyperviscosity in patients with high levels of circulating IgM, packed red cell transfusions should be used conservatively and should preferably be administered after plasma exchange in high-risk patients.

Frontline Therapy

When autologous SCT may be considered at relapse, nucleoside analogs should be avoided prior to stem cell harvest, and primary therapy with a proteasome inhibitor or alkylator, together with rituximab with or without dexamethasone, should be considered (^{64, 65}). Combinations of bortezomib-rituximab with or without dexamethasone result in an ORR of 57% to 83%. Carfilzomib-rituximab-dexamethasone showed an ORR of 68% (^{65, 66}). Comparable ORRs (77%-96%) have been seen with alkylating agent-based regimens (rituximab plus rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]; rituximab-cyclophosphamide-vincristine-prednisone; rituximab-cyclophosphamide-dexamethasone; and rituximab-bendamustine) (⁶⁷). The use of single-agent rituximab should be reserved for patients unable to tolerate combination chemotherapy, because ORRs are low (20%-50%).

When future autologous SCT is not a consideration, nucleoside analog-based combinations may be considered. In a trial by the Waldenström Macroglobulinemia Clinical Trials Group, fludarabine-rituximab demonstrated an ORR of 96% and median PFS of

51.2 months (⁶⁸). In a phase II trial of 18 patients, two cycles of cladribine, cyclophosphamide, and rituximab yielded an ORR of 94%, and at a median follow-up of 8 years, median OS was not reached (⁶⁹).

Rituximab is integral to the treatment of WM but must be used with caution in patients with highly elevated IgM levels due to the potential for an associated IgM flare. In these cases, it is prudent to delay administration of rituximab until after the patient has received some cytoreductive therapy. Because this phenomenon can confound interpretation of results, disease response should be assessed after two cycles of induction therapy unless there is clear progression of extramedullary disease.

Treatment at Disease Relapse

At relapse, patients may be re-treated with a previously successful regimen if their initial remission lasted at least 1 year. When the initial disease-free-interval is shorter, use of one of the other frontline regimens (detailed above) should be considered.

Another effective option is the Bruton tyrosine kinase (BTK) inhibitor ibrutinib. In a phase II trial of 63 patients, ibrutinib showed an ORR of 57% and was well tolerated (⁷⁰). Immunomodulatory agents with or without rituximab have shown efficacy. Thalidomide-rituximab and lenalidomide-rituximab resulted in a major response rate of 64% and 25%, respectively. Pomalidomide monotherapy is associated with a \geq minor response rate of 33%.

For patients intolerant to rituximab, the fully humanized monoclonal anti-CD20 antibody ofatumumab may be useful. In patients who have previously received rituximab, two cycles of ofatumumab were associated with an ORR of 52% (⁷¹).

Alemtuzumab can also be considered because WM cells express CD52. In a phase II study of 28 previously treated patients with either lymphoplasmacytic lymphoma or WM, alemtuzumab-rituximab yielded an ORR of 76% (⁷²). However, this regimen is rarely used due to the associated high risk of CMV reactivation.

The role of SCT in WM is still being defined. In a retrospective review of 158 patients (32% had at least three prior lines of therapy), the 5-year PFS and OS rates with autologous SCT were 39.7% and 68.5%, respectively (⁷³). Several groups have also studied allogeneic SCT in WM. The 5-year PFS was between 49% and 56% but with notable treatment-related mortality (⁷⁴).

Future Directions

Next-generation proteasome inhibitors (eg, ixazomib, oprozomib), new anti-CD20 monoclonal antibodies (eg, GA-101), the HDAC inhibitor panobinostat, the toll-like receptor antagonist IMO-8400, and

second-generation BTK inhibitors are under study in WM. Emerging knowledge about the *MYD88* gene and *CXCR4* mutations may allow more rational disease-targeted therapies.

Systemic Light-Chain Amyloidosis

Background

Systemic light-chain (AL) amyloidosis is a rare plasma cell proliferative disorder. It results from organ deposition of amyloid fibrils that consist of the NH₂-terminal amino acid residues of the variable portion of the light-chain immunoglobulin molecule. The estimated age-adjusted incidence is 5.1 to 12.8 cases per million person-years. About 75% of cases are derived from lambda light chain. AL amyloidosis may result primarily from a small plasma cell clone in the bone marrow or may be associated with an underlying plasma cell dyscrasia or other B-cell malignancies. Coexisting AL amyloid deposits are identified in 10% to 15% of patients with MM.

The commonly affected organs include the heart, kidneys, liver, gastrointestinal tract, and peripheral nervous system. This leads to clinical symptomatology of nephrotic syndrome, cardiomyopathy, hepatomegaly, neuropathy, macroglossia, anemia, carpal tunnel syndrome, and periorbital purpura. The exact pathophysiology of organ or tissue damage in AL amyloidosis is not completely understood, but the reduction of serum free light-chain concentration after chemotherapy treatment results in improved cardiac function and suggests that free light chain plays an important role in organ dysfunction.

Clinical Presentation and Diagnostic Workup

The clinical presentation of AL amyloidosis depends on the spectrum and severity of organ involvement. The common clinical features at diagnosis include nephrotic syndrome with or without renal insufficiency, cardiomyopathy, autonomic neuropathy, and hepatosplenomegaly. Many patients have multisystem involvement at diagnosis (Table 11-12). The diagnosis requires histologic evidence of amyloid deposition in tissues either by aspiration of abdominal subcutaneous fat and/or biopsy of the organs involved, with the demonstration of clonal plasma cell disorder and abnormal free light chain in serum or urine. The pathognomic diagnostic feature of AL amyloidosis is a positive tissue stain with Congo red to demonstrate apple-green birefringence under polarized light. Mass spectrometry-based proteomic analysis of amyloid tissue should be pursued when available. This helps confirm the type of amyloid protein, because more than 10 forms of systemic amyloidosis are currently known, and

Table 11-12 Clinical Presentations of AL Amyloidosis

Organ Involvement	Clinical Presentation
Kidney	Nephrotic syndrome Renal failure
Heart	Abnormal electrocardiogram: low voltages in the standard leads Nondilated cardiomyopathy Arrhythmia
Peripheral and autonomic nervous system	Numbness Muscle weakness Carpal tunnel syndrome Postural hypotension Erectile dysfunction Altered bowel habit Anhidrosis
Gastrointestinal tract	Macroglossia Early satiety Diarrhea Malabsorption Gastrointestinal bleeding Hepatomegaly
Coagulation system	Periorbital purpura (racoon eyes) Abnormal clotting tests Life-threatening bleeding

correct typing is imperative for appropriate treatment (Table 11-13).

Prognosis and Staging

Even though patients commonly have a low burden of clonal plasma cells, long-term survival outcome is dismal due to organ impairment from amyloid deposition. The presence of cardiac involvement is a detrimental factor for survival. The median survival time is 4 months in patients presenting with congestive heart failure versus 16 months in those without it⁽⁷⁵⁾. Cardiac dysfunction is best assessed by the elevation of cardiac biomarkers: brain natriuretic peptide (BNP), N-terminal pro-brain natriuretic peptide (NT-proBNP), and cardiac troponin T (cTnT) and troponin I (cTnI). Many studies have confirmed the prognostic significance of markers of cardiac injury and dysfunction in AL amyloidosis, and they been incorporated in the staging system for AL amyloidosis⁽⁷⁶⁾. According to the Revised Prognostic Scoring System from the Mayo Clinic group, patients are assigned a score of 1 for each of the following: difference between involved and uninvolved light chain ≥ 18 mg/dL, cTnT ≥ 0.025 ng/mL, and NT-proBNP $\geq 1,800$ pg/mL. The median OS times of patients with Mayo stage I, II, III, and IV (score of 0, 1, 2, and 3, respectively) are 94, 40, 14, and 5.8 months, respectively⁽⁷⁶⁾.

Table 11-13 Laboratory and Pathologic Evaluation of AL Amyloidosis

Laboratory evaluation
Complete blood count with differential
Serum creatinine
Liver enzyme and bilirubin
Coagulation tests: prothrombin time, partial thromboplastin time, factor X
Serum protein electrophoresis (SPEP) and immunofixation
Urine protein electrophoresis (UPEP) and immunofixation
Serum free light chains
24-Hour urine protein
Cardiac troponin, brain natriuretic peptide (BNP), or N-terminal pro-BNP
Cardiac testing: electrocardiogram, echocardiogram, cardiac magnetic resonance imaging, chest x-ray
Peripheral nervous system: electromyography, nerve conduction test
Pulmonary function test
Pathologic evaluation
Bone marrow aspiration and biopsy with immunohistochemistry staining for kappa and lambda light chain
Abdominal fat pad aspiration or organ biopsy with Congo red staining for amyloid
Mass spectrometry for amyloid protein identification

Treatment

Treatment for AL amyloidosis is similar to that for MM, comprising mainly of various chemotherapy combinations or high-dose therapy with autologous SCT (HDT-ASCT), aimed at eliminating clonal plasma cells. The choice of treatment should be based on risk stratification. Patients with good performance status and normal cardiac markers should be considered for HDT-ASCT.

High-Dose Therapy With Autologous Stem Cell Transplantation

High-dose therapy with autologous SCT has been used since the early 1990s, and it is the only effective treatment modality associated with hematologic and organ responses as well as long-term survival^(77, 78). It is associated with high treatment-related mortality, ranging from 13% to 43%, especially in patients with cardiac involvement. Careful patient selection based on comorbidity index and cardiac staging is the key to successful outcome of high-dose therapy in AL amyloidosis. A randomized trial comparing HDT-ASCT with standard-dose melphalan plus high-dose dexamethasone showed no differences in hematologic or organ response. Landmark analysis examining only patients surviving more than 6 months after transplantation also showed no survival benefit for HDT-ASCT⁽⁷⁹⁾.

However, almost 25% of the patients in this study received reduced-dose melphalan conditioning, which has been associated with poor transplantation outcomes. A meta-analysis of 12 studies of HDT-ASCT showed no superiority of HDT-ASCT over conventional chemotherapy ⁽⁸⁰⁾. However, in the MDACC experience, improved 10-year survival outcomes were reported in patients undergoing HDT-ASCT compared to conventional chemotherapy ⁽⁷⁸⁾. At centers with extensive experience in treating AL amyloidosis, HDT-ASCT provides promising outcomes with careful patient selection ^(79, 81). Involvement of two or fewer organs and AL amyloidosis with renal involvement show best overall outcome with HDT-ASCT ⁽⁷⁸⁾.

Induction Therapy Before High-Dose Therapy With Autologous Stem Cell Transplantation

With the inclusion of novel agents in induction therapy, improvement in performance status can lead to transplantation eligibility for newly diagnosed patients ⁽⁸²⁾. A randomized trial evaluating the role of induction therapy containing bortezomib and dexamethasone followed by HDT-ASCT versus HDT-ASCT in newly diagnosed AL amyloidosis showed better responses and survival outcomes with induction therapy ⁽⁸³⁾. In our experience, incorporation of novel-agent induction therapy prior to transplantation is associated with improved survival ⁽⁷⁸⁾. There are no data to support maintenance treatment in AL amyloidosis.

Conventional Chemotherapy

The combination of melphalan and high-dose dexamethasone remains the gold standard for first-line treatment of transplant-ineligible patients and is associated with a good hematologic response (67%) and low toxicity (4%) ⁽⁸⁴⁾. Today, several novel therapeutic combination choices are available for transplant-ineligible patients. Immunomodulatory drugs such as thalidomide and lenalidomide have been investigated in the upfront and relapsed settings with hematologic response rates of 40% to 74% and organ response rates of 20% to 40% ^(85, 86). However, they have also been associated with serious adverse events including bradycardia, fatigue, sedation, and cytopenia ^(85, 87). Bortezomib in combination with conventional chemotherapy such as cyclophosphamide and/or dexamethasone is also effective ^(82, 88-90). Bortezomib has successfully been used as consolidation in patients who did not achieve a CR after HDT-ASCT to improve the quality of response ⁽⁹¹⁾.

POEMS Syndrome

POEMS syndrome, also known as osteosclerotic myeloma, is a paraneoplastic syndrome related to

Table 11-14 Diagnostic Criteria for Poems Syndrome

Major criteria	Polyneuropathy Monoclonal plasma cell disorder Sclerotic bone lesion Castleman disease VEGF elevation
Minor Criteria	Organomegaly Extravascular volume overload Endocrinopathy Skin changes Papilledema Thrombocytosis/polycythemia
Other	Pulmonary hypertension Clubbing Weight loss Hyperhidrosis Thrombosis Low vitamin B ₁₂ level

Diagnosis of POEMS syndrome is made with three of the major criteria, two of which must include polyneuropathy and a clonal plasma cell neoplasm, and at least one of the minor criteria.
VEGF, vascular endothelial growth factor.

an underlying clonal plasma cell disorder. The major diagnostic criteria are polyneuropathy, monoclonal gammopathy, sclerotic bone lesions, elevated vascular endothelial growth factor (VEGF), and Castleman disease. Minor features include organomegaly, endocrinopathy, characteristic skin changes, papilledema, extravascular volume overload, and thrombocytosis. The diagnosis of POEMS syndrome is made with three of the major criteria, two of which must include polyneuropathy and a clonal plasma cell neoplasm, and at least one of the minor criteria (Table 11-14) ⁽⁹²⁾. Patients may have delays in diagnosis because it is rare and resembles other neurologic diseases, most commonly chronic inflammatory demyelinating polyradiculoneuropathy. The natural history of POEMS syndrome is defined by progressive polyneuropathy and sclerotic bone disease, which leads to significant morbidity, along with mortality if respiratory compromise occurs. POEMS syndrome should be distinguished from the Castleman disease variant of POEMS syndrome, which has no clonal plasma cell association and usually no peripheral neuropathy.

The pathogenesis of this syndrome is not known. Risk stratification is solely based on the clinical phenotype. The extent of plasma cell clonal disease correlates with prognosis in POEMS, but the number of clinical criteria does not. Treatment is aimed at eradicating the underlying plasma cell clone and control of symptoms. With one to three sclerotic plasmacytomas (usually <1 cm in diameter each) without marrow infiltration,

localized radiation therapy may suffice. For patients with a dominant sclerotic bone lesion, frontline radiation therapy may be appropriate. Patients with diffuse sclerotic lesions, disseminated marrow involvement, or relapsed disease within 6 months of completing radiation therapy should receive systemic therapy adapted largely from therapy for MM. Alkylators such as melphalan are the mainstay of treatment; lenalidomide has shown promise with manageable toxicity⁽⁹³⁾. Therapies based on CHOP also show responses. Thalidomide and bortezomib have activity but could exacerbate disease-related peripheral neuropathy. Benefit from anti-VEGF antibodies is unproven⁽⁹⁴⁾.

High-dose melphalan and autologous SCT can lead to prolonged remissions and significant improvement in clinical symptoms. Seven patients with POEMS syndrome underwent autologous SCT at MDACC⁽⁹⁵⁾; all had significant or complete resolution of clinical symptoms, and PFS and OS at 5 years were 86% and 100%, respectively. Prompt recognition and institution of supportive care measures and therapy directed against the plasma cell clone result in the best outcomes.

TEMPI Syndrome

In 2011, six patients from the literature were recognized as having common clinical features defining a new multisystem disease characterized by telangiectasias, erythrocytosis with elevated erythropoietin levels, monoclonal gammopathy, perinephric fluid collections, and intrapulmonary shunting. This was termed the TEMPI syndrome⁽⁹⁶⁾. Bortezomib therapy improved disease-related clinical features, suggesting a pathogenic role of the monoclonal gammopathy^(97,98). Bone marrow examination of three patients showed marked erythroid hyperplasia⁽⁹⁹⁾. Elevated erythropoietin level and a normal VEGF level distinguish TEMPI from POEMS. Due to the disease rarity, patients suspected of having TEMPI syndrome should be referred to academic centers for management.

Immunoglobulin Heavy-Chain Disease

Heavy-chain diseases are plasma cell dyscrasias characterized by the production of heavy-chain immunoglobulin molecules (gamma, alpha, mu) that lack light chains. Alpha-chain disease is the most common variant and can be thought of as an extranodal marginal zone lymphoma of mucosa-associated lymph node tissue. The disease results from lymphocyte and plasma cell infiltration of the mesenteric nodes and small bowel and has features of malabsorption, such as diarrhea, weight loss, abdominal pain, edema, and clubbing. The heavy-chain molecule may be detected in serum, jejunal secretions, and urine⁽¹⁰⁰⁾. These patients may be treated with antibiotics or occasionally with

surgery. If symptoms persist or if a lymphoma is suspected, chemotherapy may be used.

Gamma heavy-chain disease is similar to lymphoplasmacytoid non-Hodgkin lymphoma⁽¹⁰¹⁾. Patients may present with fever, weakness, lymphadenopathy, hepatosplenomegaly, and Waldeyer ring involvement. Eosinophilia, leukopenia, and thrombocytopenia are common. Treatment with regimens similar to those used for non-Hodgkin lymphoma may be effective⁽¹⁰⁰⁾.

Mu heavy-chain disease is extremely rare and often seen in patients with chronic lymphocytic leukemia, although it has been described with underlying WM or MM⁽¹⁰²⁾. Vacuolated plasma cells are common in the marrow, and many patients have lambda light chains in urine. Therapy choice should follow existing recommendations for the underlying primary disease.

FUTURE DIRECTIONS

The last decade has seen unprecedented advances in the treatment of plasma cell dyscrasias. The advent of novel agents, notably proteasome inhibitors and IMiDs, has resulted in a doubling of the life expectancy in MM. These treatments have been incorporated in standard regimens for primary AL amyloidosis with improved outcomes. Proteasome inhibitors, anti-CD20 monoclonal antibodies, and drugs targeting the B-cell receptor pathway (eg, ibrutinib) have also represented important advances in WM therapy.

Many challenges remain. For example, MM is still considered mostly an incurable disease, and a subgroup of patients with high-risk MM have not benefited substantially from recent therapeutic advances. Promising investigational agents including immunotherapeutic approaches with monoclonal antibodies and rational combinations to overcome resistance are being tested.

Future work involves identifying predictive biomarkers to help individualize therapy in MM and related plasma cell dyscrasias to help maximize efficacy while balancing treatment toxicity. In high-risk SMM, the role of early preemptive therapy needs to be clarified. Improving our understanding of the molecular pathogenesis of MM and its genetic drivers through molecular profiling and refining current risk stratification models remain key priorities. Another important question is the role and timing of autologous SCT in the era of novel agents. Finally, as new drug combinations induce deeper responses in the frontline setting, significance of achieving molecular remissions is an area of intense research focus. Bridging these knowledge gaps will improve on the advances achieved over the last decade and offer greater individualized treatment approaches, leading to possible cure of MM and its related disorders.

Yago Nieto

BASIC CONCEPTS

High-dose chemotherapy (HDC) with autologous hematopoietic progenitor cell (HPC) transplant is an effective treatment modality for several hematologic malignancies and selected solid tumors. This chapter reviews its current role in the treatment of cancer and outlines promising future directions of progress.

High-dose radiation and chemotherapy are limited by toxicity to normal tissues, particularly the bone marrow. The doses of certain chemotherapeutic agents and radiation can be substantially escalated, with the goal of exploiting their dose-response effect, when followed by autologous or allogeneic transplantation of HPCs to restore hematopoiesis. Pluripotent HPC progenitors present in the graft proliferate and differentiate into the mature blood and immune cells. Autologous transplantation involves collection, cryopreservation, and infusion of the patient's own HPCs.

GENERAL PROCEDURES FOR AUTOLOGOUS TRANSPLANTATION

Preceding Conventional Dose Chemotherapy

Standard chemotherapy is usually given to reduce the tumor burden prior to proceeding with HPC transplantation (Fig. 12-1). In general, the best outcomes are noted in patients with chemosensitive disease, in complete remission (CR), or with minimal tumor burden at time of transplantation.

Stem Cell Collection

Bone marrow is collected via multiple aspirations from the posterior-superior iliac crest in a sterile environment (usually a surgical operating room) while the patient is under anesthesia. Ideally, HPCs should be collected while the patient's marrow is normocellular and uninvolved by the malignancy. Currently, bone marrow HPC collection is rarely, if ever, done for the purpose of autologous transplantation because HPCs can be collected from peripheral blood and engraft more rapidly when collected this way. Hematopoietic progenitor cells are normally infrequent in the blood but are mobilized into the blood during the recovery after chemotherapy and following treatment with granulocyte colony-stimulating factor (G-CSF). Peripheral blood progenitor cells (PBPCs) are collected using apheresis with continuous-flow cell separation. One to four daily apheresis sessions are usually required to achieve the minimal target CD34⁺ cell dose (at least $2 \times 10^6/\text{kg}$). The collected PBPCs are subsequently cryopreserved and stored.

Multiple factors have been shown to predict poor success in mobilization and collection, including advanced age; amount of preceding chemotherapy; presence of marrow-infiltrating disease; history of pelvic radiation; prior exposure to certain drugs (melphalan, carmustine, bendamustine); low premobilization platelet counts; short intervals from last chemotherapy cycle to mobilization; inadequate chemotherapy-mobilizing regimens or low-dose G-CSF⁽¹⁾; and previous treatment with four or more cycles of lenalidomide⁽²⁾. Peripheral blood CD34⁺ cells more than $10/\mu\text{L}$ are usually necessary for an adequate collection. Plerixafor has

The Autologous transplant process**1. Collection**

Stem cells are collected from the patient's bone marrow or blood.

**2. Processing**

Blood or bone marrow is processed in the laboratory to purify and concentrate the stem cells.

**3. Cryopreservation**

Blood or bone marrow is frozen to preserve it.

**5. Reinfusion**

The thawed stem cells are reinfused into the patient.

**4. Chemotherapy**

High dose chemotherapy and/or radiation therapy is given to the patient.

FIGURE 12-1 Autologous hematopoietic progenitor cell transplantation process.

become available as a second PBPC-mobilizing agent, effective for “poor mobilizers,” acting synergistically with G-CSF⁽³⁾.

High-Dose Therapy

Autologous transplants are most effective in diseases where up to a three- to fivefold dose escalation of myelosuppressive drugs or radiation leads to a markedly increased cytotoxic effect against the malignancy. The most commonly used drugs are alkylating agents.

The most common cause of failure after autologous HPC transplantation is relapse of the underlying malignancy. This usually occurs because of inadequate systemic cytoreduction, although it may also be caused by reinfusion of malignant cells contaminating the transplant infusion. The optimal HDC regimen is disease specific. Various approaches are being studied to improve the final outcomes, including novel chemotherapy agents^(4,5), monoclonal antibodies⁽⁶⁾, chemoradiotherapy^(7,8), and targeted radiation treatments. “Tandem” autologous HPC transplants have been studied in myeloma and germ-cell tumors⁽⁹⁾. In chemosensitive malignancies, increasing the total dose of therapy may markedly improve the tumor response, but this increases the severity of side effects. Thus, novel HDC regimens must be developed in carefully designed clinical trials to provide the optimal therapeutic index.

Reinfusion of Collected Stem Cells

Stem cells are infused intravenously after HDC is eliminated from the patient's bloodstream, usually 1 to 3 days after completion of the treatment. The cells circulate transiently and home to the bone marrow. Hematopoiesis is restored within a few weeks. Hematopoietic recovery is most rapid with infusion of high doses of CD34⁺ cells. Most centers require a minimum $2 \times 10^6/\text{kg}$ CD34⁺ cells per kilogram from peripheral blood⁽¹⁰⁾. Neutrophils recover typically in 7 to 10 days and platelets recover in 10 to 14 days after infusion.

Supportive Care

Patients usually receive G-CSF or other hematopoietic growth factors to accelerate neutrophil recovery. Patients are routinely prescribed prophylactic antibiotics and antiviral and antifungal therapy for prevention of infection during the initial phase of marrow engraftment and hematologic recovery.

CONTROVERSIES

Autologous Versus Allogeneic Hematopoietic Progenitor Cell Transplants

The relative role of allogeneic versus autologous transplants has been long debated for specific hematologic malignancies. Autologous HPC transplantation is a

process that carries less overall morbidity and mortality because the reinfused cells are not subject to immunologic rejection and do not produce graft-versus-host disease (GVHD). On the other hand, there is a risk of tumor contamination of the autologous HPCs. Some clinical studies have shown that autograft contamination is correlated with shortened disease-free survival (DFS) ⁽¹¹⁾ and that the presence of tumor cells or their inadequate purging in autologous samples may correlate with the extent of the disease. Gene-marking studies in neuroblastoma showed that persistent cancer cells in the autograft can contribute to systemic relapse. The risk of contamination of the graft is higher in patients with uncontrolled tumors and known marrow involvement. Perhaps more important, there is no evidence that immune-mediated graft-versus-tumor effect associated with allogeneic HPC transplantation occurs with autologous transplants.

COMPLICATIONS OF HIGH-DOSE CHEMOTHERAPY

High-dose chemotherapy produces profound pancytopenia that usually lasts from 7 to 10 days. Infectious complications can occur in the neutropenic period (ranging from febrile neutropenia to life-threatening septic episodes) and up to 6 months or more posttransplant in the case of *Pneumocystis jirovecii*, fungal infections, or zoster reactivation. Antibacterial prophylaxis with a fluoroquinolone, antiviral prophylaxis with acyclovir/valacyclovir, and antifungal prophylaxis with fluconazole are generally started at the time of stem cell infusion and continued until recovery from neutropenia. *Pneumocystis* prophylaxis (eg, trimethoprim/sulfamethoxazole) is usually started day 30 posttransplant for at least 6 months. Antiviral prophylaxis (acyclovir, valacyclovir) are given for 6 to 12 months ⁽¹²⁾.

High doses of chemotherapy may produce major toxicities in nonhematopoietic tissues. The oral mucosa and the gastrointestinal tract are generally the most sensitive tissues. The lungs, heart, liver, brain, and kidneys are less commonly affected and are generally affected in heavily pretreated patients or those with comorbid conditions. Overall, up to 4% of patients die from regimen-related toxicities or infections. This rate of treatment-related mortality makes autologous transplantation substantially safer than allogeneic transplantation.

Toxic interstitial pneumonitis occurs in up to 40% of patients undergoing high-dose therapy. It has been described with several different chemotherapy agents, such as carmustine ^(13, 14) and total-body irradiation (TBI) ⁽¹⁵⁾. It is particularly common in patients previously treated with mediastinal radiotherapy ^(16, 17).

Steroids constitute the mainstay of treatment of interstitial pneumonitis.

Cardiac toxicity is uncommon. It can be seen after high doses of cyclophosphamide or melphalan. Prior radiation therapy to the mediastinum or left chest wall and advanced age are also predictors of an increased risk of cardiac complications ⁽¹⁸⁾.

Central nervous system complications are rare, but dementia and leukoencephalopathy have been described as complications of HDC. Hypothyroidism frequently occurs 6 months to 2 years after therapy.

Hemorrhagic cystitis, after high-dose cyclophosphamide or ifosfamide, is uncommon and can be effectively prevented with MESNA (2-mercaptoethanesulfonate) ^(19, 20).

Sinusoidal obstruction syndrome (SOS) (formerly known as veno-occlusive disease or VOD) of the liver is one of the most feared complications associated with HDC. Its clinical syndrome is characterized by fluid retention, hyperbilirubinemia, and hepatomegaly, which can be painful ⁽²¹⁾. Its severity depends on the presence of multiorgan failure and the rapidity of bilirubin rise. Mild cases are often self-limited; severe cases are fatal in more than 80% of patients. Several factors predispose to the development of SOS, including prior liver impairment, older age, and iron overload. The use of oral busulfan and TBI have been most commonly associated with SOS, particularly if used along with cyclophosphamide ⁽²²⁾. Andersson et al pioneered the use of intravenous busulfan, which decreases the risk of SOS compared with the oral drug formulation ⁽²³⁾. Pharmacokinetic-guided dosing of busulfan has further decreased the incidence of SOS. Systemic anticoagulant and thrombolytic therapies to treat SOB are ineffective and are associated with major bleeding complications. Defibrotide has emerged as a promising therapy for severe cases of SOS but has not received approval by the Food and Drug Administration yet. Supportive care plays a crucial role, using diuretics and sodium restriction, avoidance of hepatotoxins, oxygen support, and renal replacement therapy if needed.

RESULTS OF AUTOLOGOUS TRANSPLANTATION

Non-Hodgkin Lymphoma

Autologous transplantation has been extensively studied in refractory-relapsed non-Hodgkin lymphoma (NHL).

Aggressive Lymphoma

High-dose chemotherapy and autologous stem cell transplant comprise a standard of care for patients

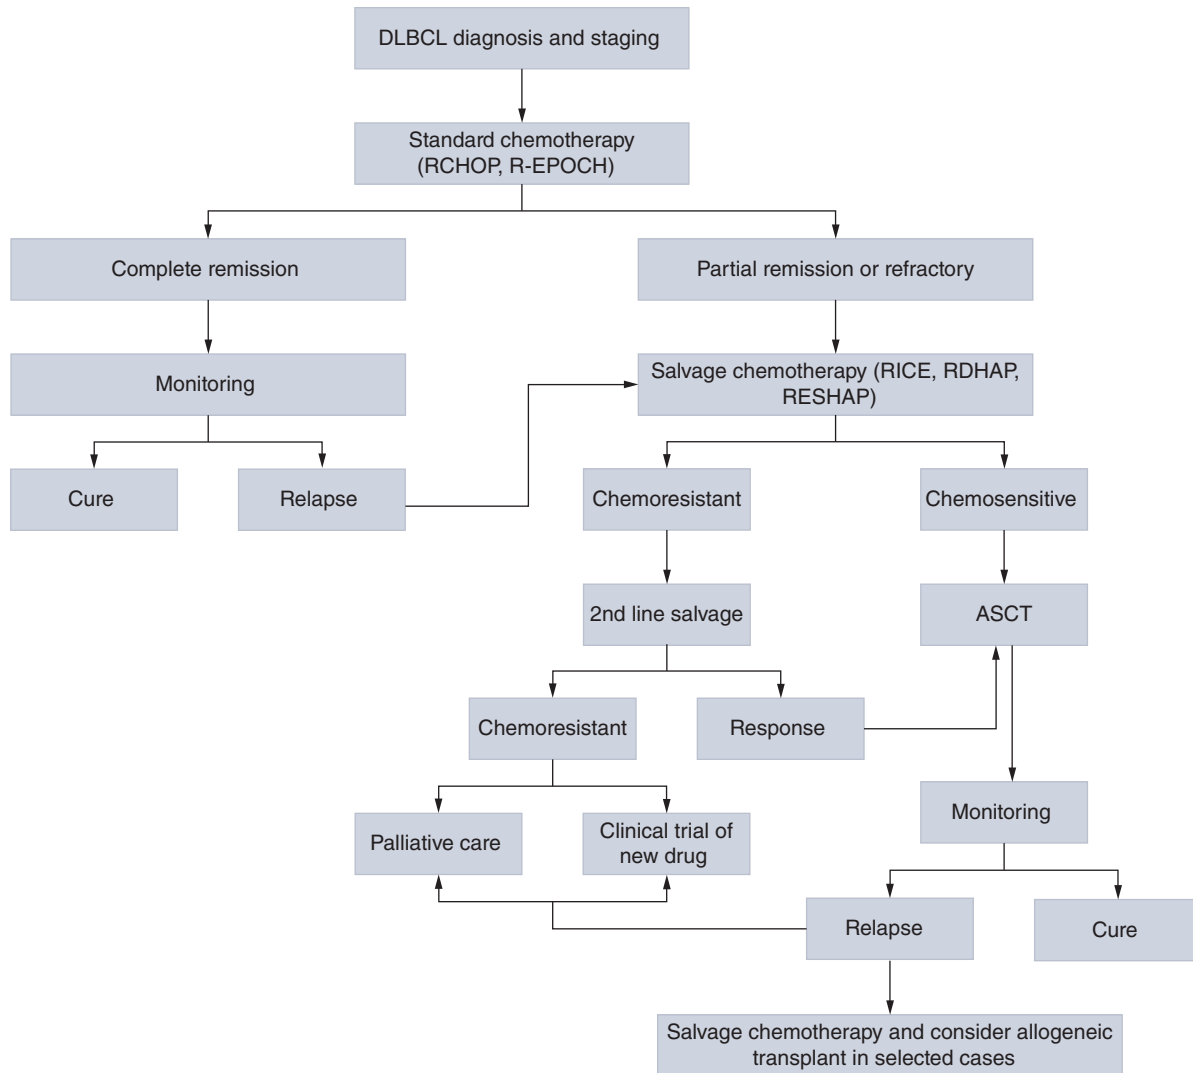

FIGURE 12-2 Algorithm for treatment of DLBCL: stepwise description of DLBCL treatment approach and the role of autologous and allogeneic progenitor cell transplantation after relapse. ASCT, allogeneic stem cell transplant.

with chemosensitive, relapsed, diffuse large B-cell lymphoma (DLBCL) ⁽²⁴⁾ (Fig. 12-2). Resistance to salvage chemotherapy, increased lactic dehydrogenase at the time of relapse or progression, prior complete remission (CR) of less than 12 months, and secondary International Prognostic Index (IPI) (ie, at the time of relapse or progression) greater than 1 have been described as adverse predictors of survival ⁽²⁵⁾. In the modern era of exposure to rituximab as part of first-line therapy (R-CHOP), the CORAL study has shown 3-year EFS rates of 25% in chemosensitive relapsed patients undergoing autologous stem cell transplantation ⁽²⁶⁾.

High-dose chemotherapy in the first CR has also been evaluated for patients with DLBCL and a high IPI ⁽²⁷⁻³⁰⁾. While some randomized studies have demonstrated an improvement in EFS, none has shown a benefit in overall survival (OS). Thus, autologous transplantation is not routinely used as consolidation in a first remission for DLCL.

Follicular Lymphoma

The role of autologous HPC transplantation remains unclear in the management of patients with chemosensitive, relapsed low-grade lymphoma (eg, follicular lymphoma, FL). The use of high-dose cyclophosphamide ⁽³¹⁾ and TBI ⁽³²⁾ has resulted in a 5-year EFS of 60% but has been largely abandoned due to the risk of secondary malignancies.

Historically, a major challenge has been the contamination of the autologous graft by malignant cells ⁽³³⁾. Recently, systemic treatment with rituximab has reduced the numbers of circulating lymphoma cells, thus yielding effective in vivo purging with high likelihood polymerase chain reaction–negative tumor-free PBPC grafts ^(34, 35).

Several randomized trials have shown improved outcomes after HDC for chemosensitive relapsed FL ^(36, 37). However, these studies were largely conducted in the

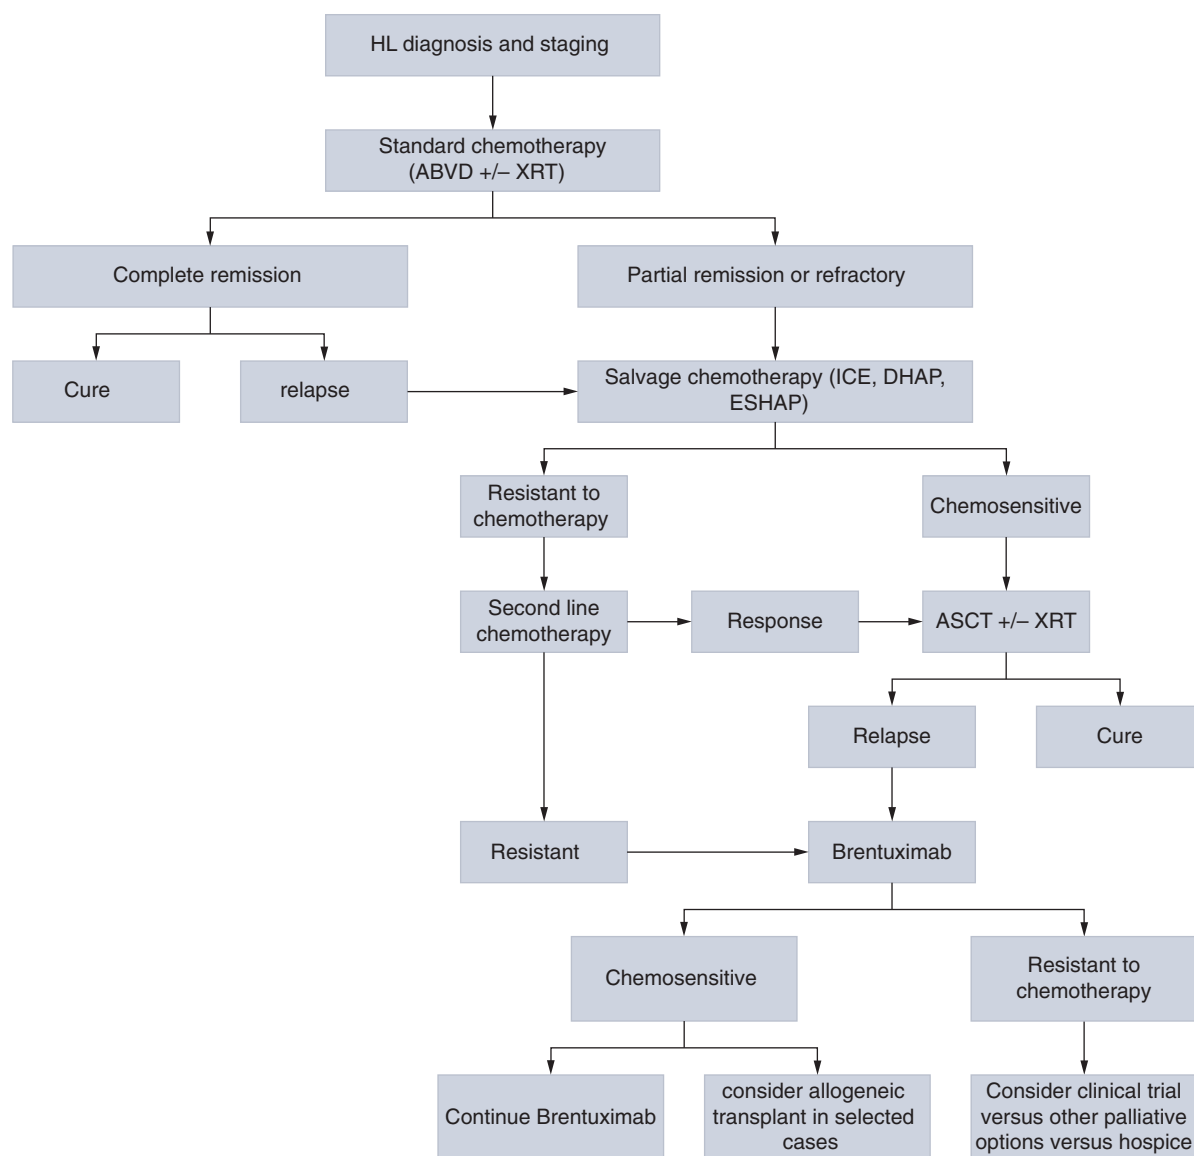

FIGURE 12-3 Algorithm for treatment of HL: stepwise description of HL treatment approach and the role of autologous and allogeneic progenitor cell transplantation after relapse.

prerituxumab era. The role of HDC in this setting in the current era remains unsettled.

Hodgkin Lymphoma

The majority of patients with Hodgkin lymphoma (HL) are curable with first-line therapy (Fig. 12-3). However, up to 20% of patients will not respond to first-line chemotherapy, and 30% will relapse after an initial response^(38,39). The use of HDC has been proven to be beneficial in the two settings, with expected long-term EFS of 30% to 40% for patients with primary refractory tumors sensitive to subsequent salvage therapy and of 30% to 65% for patients with chemosensitive relapsed HL^(40,41).

Unfavorable prognostic features for autologous transplant include a first CR shorter than 1 year, extra-nodal relapse, B symptoms at the time of relapse or progression, bulky (>5-cm) lesions at relapse, and relapse within a prior radiation field. Patients without unfavorable prognostic features have 4-year EFS rates of 70%, compared with less than 20% in patients with adverse features⁽⁴²⁾. Positron emission tomographic scan uptake at the time of HD has recently emerged as the main prognostic factor^(43,44).

Multiple Myeloma

High-dose therapy with autologous HPC transplantation is an established treatment for multiple myeloma,

where the use of high-dose melphalan provides OS benefit as consolidation of a response to first-line therapy⁽⁴⁵⁻⁴⁸⁾ (Fig. 12-4). To date, no other preparative regimen has been shown to be superior to single-agent melphalan (200 mg/m²)⁽⁴⁹⁾. The use of a second course of high-dose melphalan (“tandem” autologous transplants) has been shown to be superior to a single transplant in some⁽⁴⁹⁻⁵¹⁾, but not all, studies⁽⁵²⁾, particularly in patients who do not achieve at least a very good partial remission after the first procedure. The timing of transplant has been prospectively investigated in randomized studies. Early (after a brief course of first-line therapy) and late autotransplant (at a time of relapse after prolonged first-line therapy) trials⁽⁵³⁾

resulted in similar OS, with early autotransplantation offering improved quality of life, shorter duration of chemotherapy, and a longer median EFS. Induction therapy, including novel agents such as bortezomib or lenalidomide, appears to be the most effective induction treatment before HDC. Ongoing randomized trials in the United States and Europe are addressing the question of optimal timing of autologous transplant in the present era of novel agents.

Several retrospective analyses have demonstrated durable responses of a second salvage course of HDC with autologous SCT for patients with relapsed disease⁽⁵⁴⁾. In general, the outcomes appear more favorable for patients who relapse more than 12 months

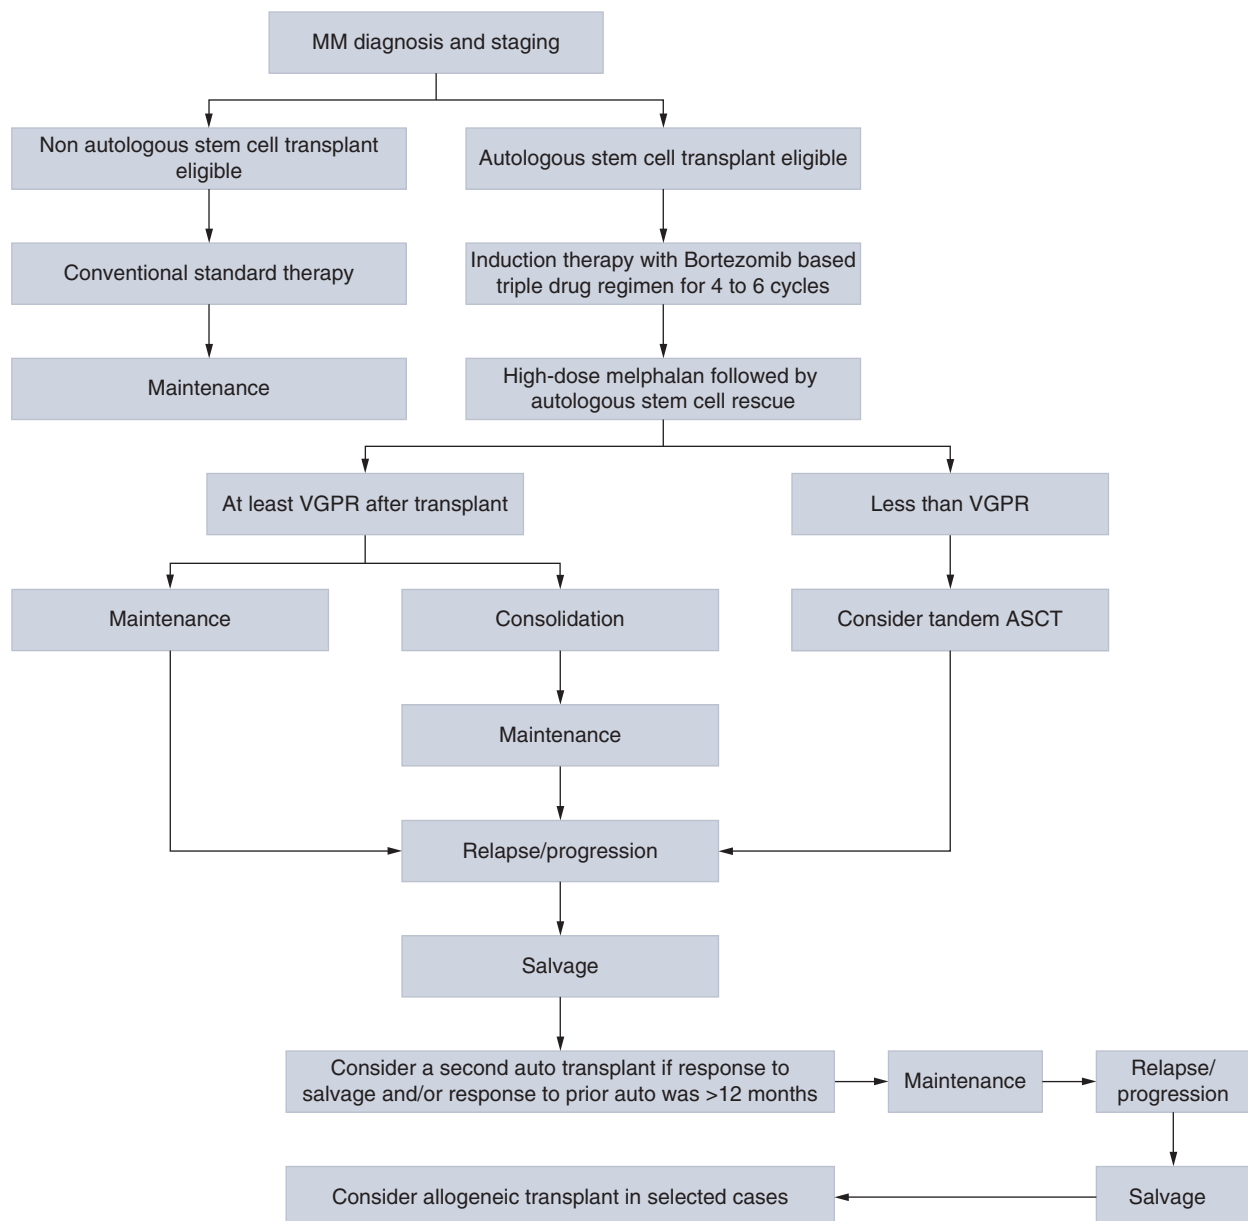

FIGURE 12-4 Algorithm for treatment of multiple myeloma (MM): stepwise description of multiple myeloma treatment approach and the role of autologous and allogeneic progenitor cell transplantation after relapse.

after a first autologous transplant and who respond to subsequent salvage treatment⁽⁵⁵⁾. More recently, the first randomized controlled trial has been completed comparing salvage HDC and autologous transplant to salvage conventional chemotherapy⁽⁵⁶⁾. In this study, there was a benefit for the transplant arm, with a significant improvement in time to progression.

Maintenance therapy posttransplant with lenalidomide prolongs EFS and perhaps OS, as shown in several randomized studies^(57, 58). There is uncertainty about the optimal duration of lenalidomide treatment. Its use after allogeneic stem cell transplantation has been associated with a small risk of secondary malignancies in the French, but not in the US, study.

Solid Tumors

The use of HDC for breast cancer or ovarian cancer has been abandoned. In contrast, tandem courses of carboplatin-containing HDC have been successful in curing patients with relapsed or refractory germ-cell tumors. Long-term EFS rates range from 10% for patients with cisplatin refractoriness and other poor-prognostic features to 70% for those with good-risk chemosensitive tumors in first relapse⁽⁵⁹⁾.

FUTURE DIRECTIONS

Patients with rapid recovery of lymphocyte counts have had the best progression-free survival after autologous stem cell transplantation⁽⁶⁰⁾. Following myeloablative therapy and autologous transplantation, there is homeostatic expansion of lymphocytes. This provides an opportunity for active vaccination or infusion of antigen-specific, tumor-reactive lymphocytes or to infuse genetically modified lymphocytes to enhance antitumor effects. One recent approach utilizes redirecting the specificity of T cells using a chimeric antigen receptor T cell (CAR-T) toward tumor-related antigens such as CD19 or CD20 in lymphomas⁽⁶¹⁾.

SUMMARY AND CONCLUSIONS

High-dose chemotherapy with autologous HPC transplantation is an effective modality to achieve major antitumor cytoreduction. Autologous transplants need to be integrated into the multimodality management of hematologic malignancies and GCTs. Many current studies focus on posttransplant strategies to prevent regrowth of minimal residual disease, including molecularly targeted approaches and angiogenesis inhibition. Further clinical trials are needed to optimize the use of autologous HPC transplantation in the overall treatment of cancer.

Allogeneic Transplantation

Jonathan E. Brammer
Borje S. Andersson
Chitra Hosing

INTRODUCTION

For patients with hematologic malignancies, allogeneic stem cell transplantation (alloSCT) provides potentially curative therapy over standard therapeutic approaches in patients whose disease is incurable with standard chemotherapy. With the development of novel techniques of transplantation, including reduced-intensity conditioning (RIC) and management of transplant-associated toxicities, increasing numbers of patients with advanced age or comorbidities can undergo this potentially lifesaving procedure. According to the most recent statistics from the Center for International Blood and Marrow Transplant Research (CIBMTR), a consortium that collects data from over 400 transplant centers worldwide, over 9,000 patients received alloSCT in 2011, up from 7,500 in 2001 (¹). Given the increasing frequency of stem cell transplants worldwide, practitioners need to be familiar with the key concepts regarding the indications, procedures, and management of this technique. This chapter reviews the current state of alloSCT, with particular attention to strategies utilized at the MD Anderson Cancer Center (MDACC). The specific indications for alloSCT are briefly discussed, but a more in-depth discussion of indications is found in chapters covering specific disease states.

Background and Rationale

Allogeneic stem cell transplantation was first explored in humans in the late 1950s and early 1960s based on observations in animal models that lethal

myelosuppression induced by total-body irradiation (TBI) could be overcome by the infusion of healthy, untreated bone marrow (²). The initial experience was limited to patients with terminal leukemia or severe marrow failure states resulting from radiation exposure or disease. Almost all of these early patients died from complications of graft failure, graft-versus-host disease (GVHD), infections, or primary disease (³). The first successful allogeneic bone marrow transplant was reported in 1968 in a patient with severe combined immunodeficiency (⁴). Since these initial experiences, alloSCT has been used to treat thousands of patients with historically incurable diseases.

In the early days of the field, it was thought that the curative effect of alloSCT was provided primarily by the high doses of chemotherapy and radiation administered, and that the donor bone marrow simply allowed for hematopoietic recovery in an adequate period of time. However, it was later determined that the stem cell graft, and associated donor immunity, was responsible for the curative potential of alloSCT. This graft-versus-tumor (GVT) effect was first demonstrated in a landmark study published in 1990 (⁵). This study showed decreased rates of relapse in patients who experienced GVHD, an auto-immune syndrome associated with human leukocyte antigen (HLA) mismatch between the donor and recipient. Patients who experienced GVHD had lower rates of relapse compared to patients who either did not experience GVHD or received T-cell-depleted/syngeneic grafts. Patients with GVHD had a strong GVT effect, suggesting that similar mechanisms underlie the immunologic biology of both processes. However, it does not appear that

FIGURE 13-1 Components of allogeneic hematopoietic transplantation.

GVHD is necessary for the GVT effect. Separating the adverse effects of GVHD from the therapeutic effect of the GVT effect remains the goal of current efforts to maximize the benefit of alloSCT.

The primary components of all allogeneic hematopoietic transplants are schematically represented in Fig. 13-1 and include recipient, donor, preparative regimen, stem cell source, prophylaxis against GVHD (including posttransplant immune suppression), and posttransplant supportive care. Successful allografting depends on careful consideration of all these components in an effort to minimize the risks of potentially fatal posttransplant complications.

COMPONENTS OF ALLOGENEIC STEM CELL TRANSPLANTATION

Recipient

Allogeneic stem cell transplantation is indicated for a variety of hematologic disorders, although the indication for alloSCT is dependent on the disease, remission status, stage, cytogenetics, and molecular markers in an individual patient. According to the CIBMTR database, the most common indications for alloSCT worldwide are, in decreasing order: acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), myelodysplasia/myeloproliferative disease, nonmalignant disease, non-Hodgkin lymphoma (NHL), other malignant disease, chronic lymphocytic leukemia (CLL), aplastic anemia, chronic myelogenous leukemia (CML), Hodgkin lymphoma (HL), and multiple myeloma (MM).

The most important recipient-related factors are disease status at transplant and comorbidity status. Over the past 5 years, two risk scores have been

developed that enable clinicians to determine who the best transplant recipient is and when transplant should occur. The first is the Armand Disease Risk Index (DRI) (⁶). This analysis identified four risk groups (low, intermediate, high, very high) based on disease type (AML, ALL, cytogenetic classification, etc.) and disease stage (remission status, complete remission [CR], partial remission, induction failure, etc.). Patients in the low, intermediate, high, and very high risk groups had 4-year overall survival (OS) rates of 64%, 46%, 26%, and 6%, respectively, with higher rates of relapse in the higher-risk groups. This scoring system was validated in multivariate analysis as an independent predictor of OS, progression-free survival (PFS), relapse, and nonrelapse mortality (NRM). Subsequent investigators have confirmed the outcomes associations with DRI as well (⁷). The second important tool utilized in selecting patients for alloSCT is the comorbidity index (Hematopoietic Cell Transplantation-Comorbidity Index, HCT-CI), developed by Sorror et al (⁸). Patients' comorbidities were analyzed to determine significant indicators of NRM. Patients with a HCT-CI score of 0, 1 or 2, and 3+ had 2-year NRM of 14%, 21%, and 41%, respectively. Increased pretransplant HCT-CI score has also been shown to predict the severity and mortality of acute GVHD (aGVHD) (⁹). A recent publication from the same group demonstrated that age greater than 40 years combined with the HCT-CI into a "composite comorbidity/age index" correlated with increased NRM for patients with a combined score of 3 or 4 (1 point was added to the HCT-CI for age greater than 40 years) (¹⁰). The results of this study need to be validated, but the data suggest that the HCT-CI/age index should be considered as part of the evaluation of any patient undergoing transplant. The HCT-CI score can be easily calculated using a validated web-based application (<http://www.hctci.org>).

At MDACC, all patients undergo an extensive evaluation prior to alloSCT. This includes a complete history and physical, pulmonary function tests (PFTs), echocardiogram, electrocardiogram (ECG), complete blood cell count, and chemistries. The performance status and HCT-CI are documented for each patient. Patients with a HCT-CI score of 0 to 2 are typically considered candidates for myeloablative transplant regimens, whereas patients with HCT-CI scores of 3 or greater are considered for reduced-intensity regimens. Regimen intensity is discussed further in the chapter. There is no specific cutoff for age in evaluating a patient for transplant; rather, a patient's HCT-CI, DRI, age, disease status, family and social support, and personal wishes are all taken into consideration when deciding on proceeding with transplant. A personalized multidisciplinary approach, with a thorough discussion of the risks and benefits of alloSCT, should be undertaken for each patient.

Donor

Most allografts are performed using hematopoietic progenitor cells obtained from an HLA-identical sibling. Transplants using cells procured from volunteer donors, mismatched family members, and cord blood are rapidly becoming more common. The most important factor in selecting an allogeneic donor is HLA compatibility, which is determined by HLA typing. The HLA compatibility is the single most important determinant for the occurrence of severe GVHD after alloSCT.

The HLA system is encoded by a series of genes on chromosome 6. For SCT HLA-A, HLA-B, HLA-C, and HLA-DR are routinely evaluated⁽¹¹⁾. In its strictest sense, *HLA identity* means that the donor and recipient are matched for the amino acid sequence encoded by all HLA loci. Identity is assumed in the setting of related transplant when segregation analysis demonstrates that the donor and recipient have inherited the same maternal and paternal haplotypes (genotypic HLA identity). Otherwise, HLA identity can be verified only by sequencing all HLA loci (phenotypic HLA identity), which is impractical and rarely done.

It is important to note that conventional typing techniques detect a limited number of HLA polymorphic sequences. Therefore, “HLA matched” may not actually be “HLA identical.” Conventional serologic typing is based on the complement-dependent microlymphocytotoxicity test and uses selected HLA-specific alloantisera or monoclonal antibodies to identify HLA antigens. A mismatch between cross-reactive antigens is considered minor, whereas a mismatch between non-cross-reactive antigens is considered major. For related patient–donor pairs, a single minor mismatch may be of little biological significance. Molecular typing relies on polymerase chain reaction (PCR) amplification of specific gene segments and can be performed (a) at a level corresponding to the specificities identified by serology (low resolution), (b) at a level where a limited number of alleles are possible (intermediate resolution), or (c) at a level where the specific allele is identified (high resolution). Sequence-based HLA typing is the most precise technique available.

At MDACC, we perform high-resolution typing at HLA-A, HLA-B, HLA-C, DR, DQ, and DP for all related and unrelated donor transplants. Only matching at HLA-A, -B, -C, and DR has been associated with improved survival⁽¹²⁾. However, patients with DP mismatch have decreased relapse rates, although this is negated by increased GVHD rates. Patients are considered “10/10” if they have identical tissue types for both alleles HLA-A, -B, -C, DR, and DQ, resulting in 10 alleles total. In general, the order of preference at MDACC is matched-related-donor (MRD) sibling, 10/10 matched-unrelated donor (MUD), followed by

either cord blood or haploidentical transplantation. The best alternative donor source has not been determined and is the subject of a randomized clinical trial (Bone and Marrow Transplant Clinical Trials Network [BMT CTN] 1101). Discussion of alternative stem cell sources is covered in detail in their respective chapters.

Once identified, the donor must undergo a thorough medical evaluation to determine that (a) he or she may donate safely, (b) the cells will be adequate for the recipient, and (c) the donor understands the risks and benefits of the procedure and provides cells voluntarily.

Preparative Regimen

Preparative regimens are high doses of chemotherapy or TBI administered prior to stem cell infusion with the dual purpose of eradicating the underlying malignancy and inducing a state of immune tolerance that allows for donor cells to engraft and expand. This second effect ultimately gives rise to the GVT effect mediated by donor T cells, which was initially discovered when using donor leukocyte infusions^(13, 14). Preparative regimens can be categorized into myeloablative conditioning (MAC) versus RIC. RIC can be defined using the CIBMTR criteria: reversible myelosuppression without stem cell support, typically resulting in mixed chimerism in a significant proportion of patients, accompanied by a somewhat decreased rate of nonhematologic toxicity⁽¹⁵⁾. The choice between MAC and RIC regimens is based on the underlying disease, the patient's age and comorbid condition(s), and the physician's preference.

Myeloablative Conditioning

Myeloablative conditioning regimens can generally be divided into chemotherapy-based protocols and TBI-based protocols. Total-body irradiation is both immunosuppressive and myeloablative. Single-dose TBI is associated with greater normal-organ toxicity, particularly pulmonary, compared with fractionated regimens⁽¹⁶⁾. Therefore, most modern regimens deliver a total dose of 10 to 15 Gy using a variety of fractionation schedules. There is some evidence that higher total doses of TBI may be more effective at preventing relapse, but these benefits are offset by increased NRM. High-dose cyclophosphamide (Cy), a potent immunosuppressive agent, is often given as 60 mg/kg IV on two consecutive days prior to fractionated TBI as part of a Cy-TBI regimen. Although efficacious, TBI is associated with a number of short- and long-term complications, including secondary malignancies, retarded growth and intellectual development, cataracts, and endocrine dysfunction.

The toxicities of TBI-based strategies led to the development of radiation-free conditioning regimens.

The most commonly used chemotherapy is the combination of busulfan and cyclophosphamide (BuCy). Busulfan was traditionally administered orally as 4 mg/kg/d divided into four daily doses and given on each of four successive days (total dose, 16 mg/kg), followed by Cy as depicted previously over 2 to 4 days. This was often complicated by excessive toxicity, including veno-occlusive disease (VOD)/sinusoidal obstruction syndrome (SOS), due to the unpredictable bioavailability of oral Bu combined with an adverse interaction with Cy. An intravenous formulation of Bu subsequently has allowed for once- or twice-daily dosing with more predictable systemic drug exposure, especially when coupled with pharmacokinetic targeted dose monitoring (TDM, or “targeted Bu”) (¹⁷). The combination of intravenous Bu and Cy was better tolerated and improved relapse and survival rates (¹⁸). Further large-scale comparisons of TBI-based versus intravenous Bu-based conditioning in North America and Europe conclusively demonstrated that intravenous Bu-based conditioning is safer and more efficacious than both TBI- and oral Bu-based conditioning for myeloid disorders (¹⁹⁻²¹). These and recently completed studies at MDACC led to targeted Bu becoming the new standard of care when Bu is used as part of an MAC regimen (²²).

Cyclophosphamide and its metabolites contribute to the development of hemorrhagic cystitis post-transplant and to serious, life-threatening or lethal liver toxicity of the preparative regimen. We sought

to substitute Cy with an immunosuppressive agent that would not utilize the GSH/GST and the hepatic cytochrome P450 (CYP450) pathways in its metabolism. The choice came to rely on nucleoside analogues, initially fludarabine (Flu), which replaced Cy in many conditioning regimens. Initial studies with the combination of Flu and Bu (BuFlu) produced high engraftment rates with low levels of toxicity, and this is now considered a standard of care MAC regimen at both MDACC (^{23, 24}) and other major transplant centers in North America. In these variant regimens, Flu is typically administered at a dose of 40 to 50 mg/m² on days (-7) -6 to -3, and each Flu dose is followed by intravenous Bu at a dose of 130 mg/m² over 3 hours on days -6 to -3, adjusted to an average daily systemic exposure (represented by an AUC of 4,000 to 6,000 $\mu\text{mol}\cdot\text{min}$, or total course AUC of 16,000 to 24,000 $\mu\text{mol}\cdot\text{min}$). Alternative regimens under investigation at MDACC include Bu, Flu, and clofarabine, which may result in increased antileukemic activity (²⁵). While both Cy-TBI and the variant BuCy regimens provide additive cytotoxic activity from the agents included in the regimen, the beneficial synergistic interaction between the nucleoside analogue Flu and the alkylating agent Bu is highly dependent on optimized sequencing. It is critical that Flu precedes intravenous Bu, both of which are administered once daily (²⁶). A summary of conditioning regimens, with disease-specific information and outcomes, can be found in [Tables 13-1](#) and [13-2](#).

Table 13-1 Outcomes of Standard MAC/RIC Regimens in Lymphoid Malignancies at MDACC^a

Disease Type	RIC MAC	Conditioning Regimen	OS	PFS	GVHD Rates
Relapsed/refractory Hodgkin lymphoma	RIC	Fludarabine/melphalan	64%	32%	aGVHD grade II-IV: 28%
	RIC	Gemcitabine, fludarabine/melphalan	87% (18 months)	49% (18 months)	NR
Relapsed CLL/NHL	RIC	Fludarabine, bendamustine, rituximab	90% (2 years)	75% (2 years)	aGVHD grade II-IV: 11% Extensive cGVHD: 26%
Relapsed follicular lymphoma	RIC	Fludarabine, cyclophosphamide, rituximab	85%	83%	aGVHD II-IV: 11% Extensive cGVHD: 36%
Acute lymphocytic leukemia	MAC or RIC	Busulfan (AUC 4,000 $\mu\text{M}/\text{min}$ RIC, AUC 5,500 $\mu\text{M}/\text{min}$ MAC), clofarabine	67%	54%	aGVHD II-IV: 38% Extensive cGVHD: 7%
Philadelphia chromosome-positive ALL	MAC or RIC	BuMel, Flu/Mel, or TBI based (multiple regimens)	33%	31%	aGVHD II-IV: 30%

Abbreviation: NR, not reported.

^aResults reported utilized MRD/MUD donors, with standard MDACC GVHD prophylaxis utilizing tacrolimus/minimethotrexate and ATG on days -3, -2, -1 for MUDs.

Table 13-2 Outcomes of Standard MAC/RIC Regimens in Myeloid Malignancies at MDACC^a

Disease Type	RIC MAC	Conditioning Regimen	OS	PFS	GVHD Rates
Chronic myelogenous leukemia (TKI resistant) ^b	MAC/RIC	MAC:BuFlu, BuFluClo RIC:FluMel, BuFlu based (±TKI, rituxan), others	Mutated: 44% Unmutated: 76%	Mutated: 36% Unmutated: 58%	aGVHD II-IV: 25% Extensive cGVHD: 20%
Acute myelogenous leukemia/MDS/CML	MAC	Busulfan, fludarabine	68% (CR1) 42% (CR2) 30% (PD)	68% 42% 30%	aGVHD II-IV: 40% cGVHD: 43%
	MAC	Clofarabine, fludarabine, once-daily busulfan ^c	50%	50%	aGVHD II-IV: 39%
Acute myelogenous leukemia/MDS	RIC	Fludarabine, melphalan	71%	68%	aGVHD II-IV: 25% Extensive cGVHD: 29%
Myelofibrosis ^d		Busulfan (dose dense), fludarabine	75%	61%	aGVHD II-IV: 22% cGVHD: 39%

Abbreviation: NR, not reported.

^aResults reported utilized MRD/MUD donors, with standard MDACC GVHD prophylaxis utilizing tacrolimus/minimethotrexate, and ATG on days -3, -2, -1 for MUDs. NR, not reported.

^bPatients were stratified based on unmutated or mutated BCR-ABL status.

^cPreliminary results: current phase II trial ongoing.

^dThis regimen is now a phase II trial open for all MPDs and myeloid malignancies.

Reduced-Intensity Conditioning

According to the CIBMTR, in 2011 approximately 3,200 RIC transplants were performed, two-thirds of which were in patients over the age of 50. The underlying principle of RIC preparative regimens lies in the immunosuppressive properties of the conditioning regimen to facilitate engraftment, which utilizes immunocompetent donor cells to establish a GVT effect rather than conditioning chemotherapy to attain disease control (²⁷). The intensity of the conditioning therapy is generally not enough to control the malignant disease but is sufficient to suppress recipient immunity, promote engraftment, and trigger a subsequent GVT effect. Patients with a history of extensive pretransplantation chemotherapy, prior radiotherapy to the chest or abdomen, prior malignancy, or underlying dysfunction of heart, lung, liver, or kidneys are at increased risk for NRM. This was reflected in the Sorror HCT-CI, in which patients were found to have higher NRM when the HCT-CI was greater than 3. A recent analysis by Sorror et al suggested that a composite HCT-CI/age comorbidity index may be employed, where patients with a score less than 3 had improved 2-year survival and could tolerate MAC or RIC regimens, and patients with HCT-CI of 3 or greater may benefit from a lower-intensity, non-myeloablative (NMA) regimen, although this hypothesis needs to be prospectively validated. At MDACC, patients with an HCT-CI of 3 or greater generally do not receive standard MAC and are offered an RIC program.

Multiple RIC regimens exist, and they vary in intensity from nearly myeloablative to completely NMA

regimens. Like MAC regimens, RIC regimens can be with chemotherapy only or be combined with TBI. Pre-clinical work in a canine model established that doses as low as 2 Gy were sufficient to allow engraftment of donor stem cells when used in conjunction with postgrafting immunosuppression (²⁸). A similar regimen piloted in patients with hematologic malignancies who were more than 50 years old or had significant medical contraindications to standard transplantation demonstrated a lower degree of treatment-related toxicity and a high rate of mixed chimerism by day 28 (²⁹). A substantial proportion (20%) of patients experienced graft rejection. A later modification to the conditioning regimen included Flu, which improved donor chimerism and decreased graft rejection (³⁰). Subsequently, Bu 3.2 mg/kg IV was added to decrease the risk of disease relapse (³¹). Other chemotherapy-based regimens include Bu/Flu, Flu/carmustine/melphalan (Mel), Flu/cytosan/TBI, and Flu/Mel (^{7, 32-35}). The RIC regimen typically used at MDACC, and implemented at many transplant centers, is the Flu/Mel regimen, utilizing Flu 25 mg/m² over 5 days and Mel 140 mg/m² (³³). A less-ablative regimen utilizes only 100 mg/m² of Mel. A summary of conditioning regimens, with disease-specific information and outcomes, is shown in Tables 13-1 and 13-2.

Sources of Stem Cells

Historically, stem cells used for transplantation were obtained through the harvest of bone marrow cells

from the posterior iliac crests of normal donors. Approximately 150 aspirations are necessary to yield 10 to 15 mL/kg of bone marrow, and the procedure is performed under general anesthesia, is associated with a low incidence of complications, and generally is done on an outpatient basis⁽³⁶⁾. Common sequelae of bone marrow harvest include pain and transient postoperative fever. Life-threatening complications occur in less than 1% of patients. In general, total nucleated cell (TNC) doses of 1 to 4×10^8 cells per kilogram of recipient weight are required to induce stable engraftment in patients treated with chemotherapy or TBI. Marrow cell dose is an important prognostic factor for survival in both sibling and unrelated donor transplantation⁽³⁷⁾.

Since the early 1990s, the use of peripheral blood-derived stem cells (PBSCs) has become increasingly common. The PBSCs are collected by utilizing recombinant growth factor granulocyte colony-stimulating factor (G-CSF), given for 4 to 6 days at doses of 6 to 16 $\mu\text{g/kg/d}$, to mobilize hematopoietic stem cells into the peripheral blood, where they may be collected by one or more leukapheresis procedures. A higher dose of CD34⁺ cells is required when utilizing PBSCs as a stem cell source, with CD34⁺ cells infused at an average of 2 to $10 \times 10^6/\text{kg}$, $4 \times 10^6/\text{kg}$ being the standard of care at MDACC, with a minimum dose of $2 \times 10^6/\text{kg}$.

The rationale for using PBSCs was derived from studies in the autologous setting demonstrating accelerated recovery of hematopoiesis as compared with traditional bone marrow transplantation (BMT)^(38, 39). Numerous studies, including randomized trials comparing peripheral blood and bone marrow, have now confirmed the efficacy and safety of this approach⁽⁴⁰⁾. For donors, this has eliminated the risks and morbidities associated with general anesthesia and bone marrow harvest. The PBSC transplantation offers a number of advantages to the recipient. The G-CSF-mobilized PBSCs are enriched for pluripotent CD34⁺ hematopoietic progenitors when compared with marrow grafts⁽⁴¹⁾. This has shortened the duration of neutropenia and thrombocytopenia in recipients by approximately 5 days, with median time to engraftment of 14 days⁽⁴⁰⁾.

Despite the benefits of more rapid engraftment with PBSCs, a major concern in many studies was an increased rate of GVHD in patients receiving PBSCs. In a major recent study, the incidence of chronic GVHD (cGVHD), but not aGVHD, was higher in recipients of MUD transplants from peripheral blood as opposed to marrow grafts (53% vs 41%, $P = .01$), although there was no difference in OS (51% vs 46%, $P = .29$)⁽⁴²⁾. The incidence of graft failure was higher in the bone marrow group versus the PBSC group (9% vs 3%, $P = .002$). At MDACC, the standard of care for MRDs is PBSC harvest. For MUDs, the standard of care is bone marrow harvest given the increased rates of cGVHD

with PBSC harvest. However, for patients who have marrow failure syndromes, particularly myelofibrosis, or for whom rapid engraftment is necessary, PBSC is sometimes utilized.

Umbilical cord blood (UCB) is increasingly utilized as a stem cell source, and its use is discussed in the chapter on alternative donors.

Graft-Versus-Host Disease Prophylaxis

Graft-versus-host disease is a multisystem immunologic disorder that greatly impacts long-term outcomes, including NRM, and quality of life after alloSCT. It continues to represent one of the major obstacles for allogeneic transplantation. The disease is mechanistically linked to the desired outcome of the GVT effect—a concept now universally accepted as a major reason for the success of allogeneic transplantation in reducing disease relapse. Diagnosis and treatment of GVHD are discussed in the section on posttransplant complications. Here, we will discuss the methods of prophylaxis against GVHD.

Two forms of GVHD, acute and chronic, are commonly distinguished based on the timing of occurrence and the clinical manifestations. Chronic GVHD typically presents more insidiously later in the posttransplant period and is associated with sclerosis of the skin, oral ulcerations, xerostomia/xerophthalmia, or bronchiolitis obliterans (BO). However, an “overlap” syndrome, with features of both acute and chronic GVHD, has increasingly been described.

Given the underlying morbidity and mortality associated with GVHD, multiple approaches to reduce the risk of both aGVHD and cGVHD have been implemented. These include posttransplant immunosuppressive chemotherapy (methotrexate, MTX), posttransplant Cy [post-Cy]), immune suppression through T-cell inhibition via calcineurin inhibitors (CNIs) (tacrolimus, cyclosporine), and T-cell depletion (ex vivo and in vivo with antithymocyte globulin [ATG]).

The two CNI inhibitors, tacrolimus and cyclosporine A (CsA), are closely related and are used in combination with MTX for MUDs and MRDs. Cyclosporine prevents T-cell activation by inhibiting the production of interleukin 2 (IL-2) and the expression of IL-2 receptors. It was discovered in the 1980s, initially in the context of aplastic anemia therapy, then in leukemia, that the combination of CsA and MTX was superior in reducing GVHD rates compared with CsA alone⁽⁴³⁾. The combination of CsA with MTX is initiated intravenously 1 to 2 days prior to stem cell infusion and converted to oral twice-daily dosing when possible. The risk of aGVHD increases when cyclosporine blood concentrations drop below a target level, typically 200 to 400 ng/mL. Cyclosporine has myriad

drug interactions, which may result in fluctuating levels. Tacrolimus (FK506) is a macrolide lactone closely resembling cyclosporine in mechanism of action, spectrum of toxicities, and pharmacologic interactions. It was found to be effective in the prevention of GVHD from MRDs and MUDs in the 1990s (⁴⁴). In a phase III trial, the combination of tacrolimus and MTX prophylaxis was superior to cyclosporine and MTX in reducing grade II to IV aGVHD and thus is the standard of care at MDACC (⁴⁵). Tacrolimus is initiated at day -2, with goal levels of 6 to 10 ng/mL. A third agent, sirolimus, inhibits the mammalian target of rapamycin (mTOR) pathway and has been utilized as an alternative to CNI. A combination of sirolimus with tacrolimus was equivalent to tacrolimus/mini-MTX for the prevention of GVHD (^{46,47}). At MDACC, sirolimus is typically used for patients unable to tolerate tacrolimus.

Chemotherapy approaches to GVHD prophylaxis include MTX combined with a CNI, or post-transplant cyclophosphamide (post-Cy). Chemotherapy, administered shortly after stem cell infusion but prior to engraftment, is thought to eradicate rapidly proliferating allo-reactive T cells, thus decreasing GVHD. Methotrexate at high doses has the potential for increased severity of regimen-related mucositis and delays in engraftment. These toxicities preclude full dosing of the drug. At MDACC, a modification of the cyclosporine and MTX regimen using mini-MTX was as effective as the full dose, with less toxicity (⁴⁸). Methotrexate was administered on days +1, +3, +6, +11 at a dose of 5 mg/m² in combination with methylprednisolone. Subsequently, it was determined that outcomes were identical without methylprednisolone. Thus, mini-MTX, in combination with a CNI, is the standard of care at MDACC for MRDs and MUDs.

In recent years, a calcineurin-free regimen, utilizing post-CY, based on initial success in the haploidentical

setting, has become an attractive potential alternative to standard CNI/MTX prophylaxis. Initial studies in the myeloablative setting with BuCy and BuFlu demonstrated comparable rates of GVHD when administering Cytoxan at 50 mg/kg on days +3 and +4 (^{49,50}). However, in a phase II study at MDACC, post-Cy utilized in the RIC setting resulted in increased mortality (unpublished data). Therefore, this regimen should still be considered experimental, and it is the subject of a randomized CTN trial (BMT CTN 1203).

In addition to prophylaxis with CNIs and chemotherapy, T-cell-depleting approaches have demonstrated some success in decreasing the rates of GVHD, both in vivo with ATG and ex vivo with T-cell depletion. The hypothesis is that by depleting allo-reactive T cells (thought to cause GVHD), rates of GVHD will be lower. The use of ATG resulted in decreased rates of severe aGVHD and extensive cGVHD in unrelated donors (^{51,52}). However, the use of ATG remains controversial. A meta-analysis published in 2012 from the Cochrane database showed that ATG did not improve OS, NRM, or relapse, but resulted in decreased incidence of grade II to IV aGVHD (⁵³). At MDACC, rabbit ATG is administered on days -3 through -1 (total dose of 4 mg/kg) for MUDs, in combination with mini-MTX/tacrolimus. The MRDs receive mini-MTX/tacrolimus prophylaxis without ATG. An alternate method is ex vivo T-cell depletion prior to marrow infusion; this effectively reduces the incidence and severity of GVHD. However, T-cell depletion also results in increased graft rejection, infectious complications, and relapse rates in a disease-specific manner. Selective depletion of T-cell subsets may be more effective in reducing the risk of acute GVHD while preserving the GVT effect but is not practiced at MDACC (^{54,55}). A summary of the approach to GVHD prophylaxis at MDACC is shown in Fig. 13-2.

FIGURE 13-2 Standard GVHD prophylaxis at MDACC using tacrolimus, “minidose” methotrexate (MTX), and antithymocyte globulin (ATG). (^aATG for mismatched-related and matched-unrelated donor recipients only.)

POSTTRANSPLANT SUPPORTIVE CARE

The basic principle underlying supportive care is prevention. Most transplant complications have a temporal relationship to the conditioning regimen and the transplant. Appropriate supportive care measures are therefore dependent on anticipated complications. The temporal relationship of common infectious complications is depicted in Fig. 13-3. A summary of post-transplant complications, diagnosis, and management is shown in Table 13-4 and is discussed next.

Infectious Disease Prophylaxis

Infection prophylaxis is provided to guard against bacterial, fungal, and viral pathogens. Based on the high risk of infectious complications and associated significant morbidities, a number of prophylactic and surveillance strategies have been developed. Patients are divided into “high-risk” and “low-risk” categories prior to stem cell transplantation. Standard prophylaxis for low-risk patients (MRD, low-risk MUD with lymphoma, aplastic anemia, myelofibrosis, CML, first and second remission [CR1/CR2] leukemia) is with fluconazole, levofloxacin, and valacyclovir, with trimethoprim/sulfamethoxazole for *Pneumocystis pneumonia* (PCP) prophylaxis. Higher-risk patients, particularly those with known fungal infections, may be treated with posaconazole/voriconazole. A summary of infectious prophylaxis strategies, including for patients being treated for GVHD, is shown in Table 13-3 (56-62).

Myelosuppression

Shortly after infusion, hematopoietic stem cells migrate to sites in the lungs, liver, spleen, and marrow. For most patients, a variably cellular marrow

can be demonstrated within 14 days. During the time period until growth of stem cells (engraftment), the patient is exposed to significant myelosuppression and pancytopenia as a result of conditioning chemotherapy. Engraftment is defined as the first of three consecutive days when the absolute neutrophil count is greater than $0.5 \times 10^3/\mu\text{L}$ and the platelet count is greater than $20 \times 10^3/\mu\text{L}$. This generally occurs 14 to 24 days after stem cell infusion. Prior to engraftment, patients require aggressive hematologic support with platelet and red blood cell transfusions. All blood products are routinely irradiated to minimize the possibility of graft-versus-host reactions mediated by donor T cells (63). For patients experiencing prolonged cytopenias, growth factors may be used to shorten the duration of aplasia without increasing the risk of GVHD or relapse (64).

Graft Failure

The failure to recover hematologic function or the loss of marrow function after initial hematopoietic reconstitution constitutes graft failure (rejection). Graft failure can be primary or secondary. Primary graft failure is the failure to reconstitute hematopoiesis after infusion of stem cells. Secondary graft failure is the loss of hematopoiesis after initial engraftment. Rates of graft failure can be as high as 5% to 10% in patients with HLA-mismatched grafts and as low as 0.1% in matched siblings (65). Graft failure generally occurs within 60 days of transplantation, although late graft failure may occur. Engraftment is followed by checking “chimerisms” to determine whether a patient’s circulating cells are 100% donor or mixed—a “mixed chimera.” Chimerism labs include checking for the presence of CD33 (granulocytes) and CD3 (T cells) as a measure of reconstitution of the bone marrow. Typically, patients are considered to be “full donor chimeras” if CD33 and CD3 are more than 95% donor, given an approximately 5% margin of error. Rapid development of full donor chimerism has been associated with decreased relapse and improved OS (66). At MDACC, chimerisms typically are checked at days +30, +100, +180, and 1 year.

Graft failure is due to immunologic graft rejection by the host immune system, infections, drugs, or an inadequate stem cell dose. A number of factors increase the risk of graft failure: a low nucleated cell count infused, T-cell depletion, bone marrow as stem cell source, increasing HLA disparity between donor and host (especially in cord and haploidentical transplantation), and inadequate immunosuppression of the host. Evidence now exists implicating host T cells as the mediators of an active host immune response against the minor alloantigens expressed by the donor cells (67).

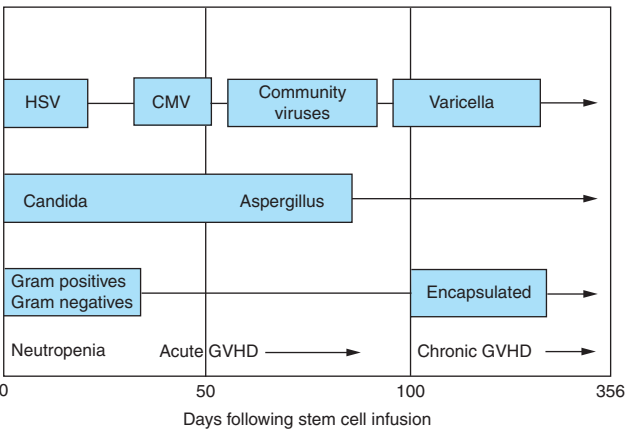

FIGURE 13-3 Timeline of common infectious and noninfectious complications of allogeneic transplantation. CMV, cytomegalovirus; HSV, herpes simplex virus.

Table 13-3 Infectious Disease Prophylaxis in the Allogeneic Transplant Patient

Risk Category	Antibacterial	Antifungal	Antiviral (HSV/VZV)	PCP
Low risk	Levofloxacin 500 mg IV or by mouth daily starting day -1 (or when ANC $<1 \times 10^3/\mu\text{L}$) until ANC $>1 \times 10^3/\mu\text{L}$	Fluconazole 400 mg IV or by mouth daily until off IST	Valacyclovir 500 mg by mouth daily ^a starting day -1 for 1 year or until off IST OR Acyclovir 250 mg/m ² or 5 mg/kg IV piggyback every 12 hours	Bactrim DS 1 tablet by mouth daily Monday, Wednesday, Friday or Bactrim SS daily starting by day +30 for 1 year and until off IST
High risk	Levofloxacin 500 mg IV or by mouth daily starting day -1 (or when ANC $<1 \times 10^3/\mu\text{L}$) until ANC $>1 \times 10^3/\mu\text{L}$	Voriconazole 200 mg IV or by mouth starting day -1 OR Posaconazole 200 mg by mouth three times daily with food starting day -2 For azole intolerant: Caspofungin 50 mg IV daily starting day -1 OR Micafungin 100-150 mg IV daily starting day -1 OR Liposomal amphotericin 3-5 mg/kg/d Continue until off IST	Valacyclovir 500 mg by mouth daily* starting day -1 for 1 year or off IST OR Acyclovir 250 mg/m ² or 5 mg/kg IV piggyback every 12 hours Continue for 1 year or until off IST	Bactrim DS 1 tablet by mouth daily Monday, Wednesday, Friday or Bactrim SS daily starting by day +30 for 1 year and until off IST ^c If sulfa intolerant: Pentamidine 4 mg/kg IV piggyback every 21 days OR Atovaquone 1,500 mg/d by mouth with fatty meal OR Dapsone 100 mg by mouth daily or 50 mg twice daily by mouth (check G6PD status)
aGVHD treatment on steroids	Continue quinolone until prednisone dose ≤ 0.25 mg/kg/d OR Azithromycin 250 mg by mouth daily (if need continued protection from pneumococcus) OR Penicillin V 500-750 mg by mouth twice daily	Continue antifungal until off IST	Continue antiviral until off IST	Continue PCP prophylaxis until off IST
cGVHD	Continue quinolone until prednisone dose ≤ 0.25 mg/kg/d OR Azithromycin 250 mg by mouth daily (if need continued protection from pneumococcus) OR Penicillin V 500-750 mg by mouth twice daily	Continue antifungal until off IST	Continue antiviral until off IST	Continue PCP prophylaxis until off IST

Abbreviation: ALT, alanine aminotransferase.

Low risk: MRD, MUD in CR1/CR2 AML, lymphoma, myelofibrosis, no active infections. High risk: haploidentical, cord blood transplant, active infection, history of invasive fungal infection.

^aConsider monitoring posaconazole levels after the first week to ensure adequate absorption. After day +90 if no evidence of infection, consider switching to fluconazole until off IST.^bALT $\geq 5 \times$ ULN, liver GVHD, intolerant to azoles.^cIn patients who receive alemtuzumab, cord transplants, or haploidentical transplant, duration of PCP prophylaxis should be guided by CD4 counts (continue until absolute CD4 counts are greater than 200 cells/mm³).

Table 13-4 Overview of Management of Major Noninfectious Complications After Allogeneic Stem Cell Transplantation at MDACC

Posttransplant Complication	Diagnosis	Management
Graft failure <i>Primary:</i> Failure to recover hematopoiesis after stem cell infusion <i>Secondary:</i> Loss of hematopoiesis after initial recovery	Bone marrow biopsy, chimerism studies Rule out infectious causes Review medications; stop stem cell toxic medications like ganciclovir	<ul style="list-style-type: none"> • Infusion of autologous backup cells if available • Second allogeneic transplant from same or another donor (Cy/ATG, Flu/ATG, alemtuzumab conditioning)
Cytopenias	Complete blood cell count	<ul style="list-style-type: none"> • Transfuse platelets if $<10 \times 10^9/L$ without bleeding and/or without possibility of engraftment • $<20 \times 10^3/\mu L$ for high risk of bleeding, moderate-severe mucositis, invasive procedures • Transfuse 1 unit PRBC if Hg B <8 g/dL • Transfuse 2 units if Hg B <7.5 g/dL
Veno-occlusive disease (VOD)/sinusoidal obstruction syndrome (SOS)	Two of the following: <ul style="list-style-type: none"> • Bilirubin >2 mg/dL • Painful hepatomegaly • Weight gain/fluid retention 	<ul style="list-style-type: none"> • Ursodeoxycholic acid 300 mg two or three times daily for prophylaxis • Supportive (maintain euvolemia, pain control) • Defibrotide for severe disease with MOF (investigational)
Acute GVHD (aGVHD)	See Table 13-6	<ul style="list-style-type: none"> • Topical steroids for grade 1 skin involvement only • 2 mg/kg IV or oral prednisone for grades II-IV aGVHD • Continue/resume CNI • Taper steroids first (initially to 1 mg/kg after 1 week, then slow taper thereafter) • Refractory aGVHD options: pentostatin, sirolimus, etanercept, clinical trial
Chronic GVHD	NIH 2005 criteria: <ol style="list-style-type: none"> 1. Exclude aGVHD 2. Presence of at least 1 diagnostic sign of cGVHD^a or biopsy of typical organ involvement confirming GVHD 3. Exclusion of other diagnoses 	<ul style="list-style-type: none"> • Prednisone 1 mg/kg daily; begin taper around 2 weeks if resolution of GVHD • If unable to taper steroids by ~2 months, consider adding CNI (sirolimus, CsA, tacrolimus) and taper steroids. Consider ECP, MMF
Bronchiolitis obliterans (BO)	<ul style="list-style-type: none"> • $FEV_1 <75\%$ of predicted • $FEV_1/FVC <0.7$ • $RV >120\%$ predicted CT: air trapping or bronchiectasis	FAM therapy: <ul style="list-style-type: none"> • Fluticasone inhaler 440 μg twice a day • Azithromycin 250 mg by mouth twice a day on Monday, Wednesday, Friday • Montelukast 10 mg by mouth daily • Treatment for GVHD with immunosuppression as indicated • Pulmonary consult
Relapse	<ul style="list-style-type: none"> • Bone marrow biopsy • Chimerisms • Flow cytometry (bone marrow/blood) 	<ul style="list-style-type: none"> • Consider immune withdrawal • Chemotherapy or disease-directed therapy (ie, TKIs, etc) • Hypomethylating agent +/- donor lymphocyte infusion (DLI) DLI alone (CML)

Cy/ATG, cyclophosphamide + antithymocyte globulin; FEV_1 , forced expiratory volume in the first second of expiration; Flu/ATG, fludarabine + antithymocyte globulin; FVC, forced vital capacity; Hg, hemoglobin; PRBC, packed red blood cells.

^aDiagnostic clinical manifestations specific to cGVHD over aGVHD include lichenification of the skin, mouth, or genitourinary tract and BO.

Veno-Occlusive Disease/Sinusoidal Obstruction Syndrome

One of the most serious complications of high-dose chemotherapy used in preparative regimens is VOD or SOS. This comprises a constellation of findings,

including fluid retention with weight gain, painful hepatomegaly, and hyperbilirubinemia. It is caused by endothelial damage to the hepatic sinusoids (⁶⁸). This leads to obstruction of blood flow through hepatic capillaries and venules, which may cause extensive centrilobular necrosis. The incidence of VOD has varied

widely. In a systematic review of 135 studies, the incidence was 13.7% ⁽⁶⁹⁾. The spectrum of disease is variable, ranging from mild and transient symptoms to multisystem organ failure (MOF) and death. In severe cases, portal hypertension may result in gastrointestinal (GI) bleeding; similarly, a low-perfusion state may result in prerenal azotemia or overt renal failure. The mortality rate for severe VOD (VOD with MOF) was 84.3%, with multisystem organ failure as the most frequent cause of death.

The diagnosis of VOD is based on clinical findings, requiring two of the following three features within 20 days posttransplant: (a) hyperbilirubinemia >2 mg/dL, (b) painful hepatomegaly, and (c) weight gain >2% of baseline body weight due to fluid retention ⁽⁷⁰⁾. A number of factors contribute to an individual patient's risk for VOD. Preexisting liver disease, elevated transaminases, and Bu/Cy/TBI increase the risk of VOD.

The treatment of VOD is primarily supportive, with management of fluid status, minimizing exposure to hepatotoxic agents, and pain/volume control with narcotics and paracentesis. In severe disease, defibrotide can be considered in addition to supportive care until normalization of bilirubin, although this is still considered investigational ⁽⁷¹⁾. Urodeoxycholic acid (UDCA or ursadiol) has been demonstrated to prevent VOD and is given 300 mg two or three times daily to all alloSCT recipients at MDACC and continued for 3 months after transplantation. The use of UDCA decreased the rate of VOD significantly (40% vs 15%) in one randomized study and in a meta-analysis ^(72,73).

Pulmonary Complications

Following alloSCT, patients are at risk for a wide range of pulmonary complications, including pulmonary edema, diffuse alveolar hemorrhage (DAH), and BO. Bronchiolitis obliterans, which may be thought of as "pulmonary cGVHD," affects 6% to 14% of patients undergoing alloSCT, with an OS of only 13% at 5 years ⁽⁷⁴⁾. It typically presents as increasing shortness of breath and can be detected as moderate-to-severe airflow obstruction on PFTs. Although many cases are deemed idiopathic or related to an aberrant systemic inflammatory response, the majority are likely related to viral infections. In recent years, the importance of respiratory syncytial virus (RSV), influenza virus, and parainfluenza in the pathogenesis of BO has become more apparent.

Once the diagnosis of BO is made, therapy with inhaled fluticasone, azithromycin, and montelukast (FAM) therapy has been shown to reverse and improve airflow obstruction ⁽⁷⁵⁾. Rapid intervention with FAM therapy or steroids in the setting of respiratory viruses in the posttransplant period may decrease the rate of BO, although this has not been demonstrated in any

clinical study. Respiratory infections are covered in the section on infections and are typically managed with antibiotics and supportive care.

INFECTIOUS COMPLICATIONS

Infectious complications result from profound humoral and cellular immune deficiencies that occur shortly after conditioning and may persist for years beyond transplant. Immune deficiencies can be exacerbated by the routine use of immunosuppressive agents for the treatment of GVHD. Immune deficiencies are broadly described in three phases ⁽⁷⁶⁾. Figure 13-3 demonstrates the three phases of posttransplant immune deficiency with associated infectious complications. [Table 13-5](#) discusses posttransplant infectious complications, their diagnosis, and treatment.

ACUTE GRAFT-VERSUS-HOST DISEASE

Acute GVHD typically presents within the first 3 months (100 days) after transplantation and is manifested as a maculopapular skin rash, elevation in liver function tests (LFTs), or GI distress (nausea/vomiting/diarrhea). It occurs in 20% to 70% of patients depending on the conditioning regimen ⁽⁷⁷⁾. Organs may be involved in isolation or simultaneously. A clinical grading system, the Glucksberg Scale, which allows for quantitative estimates of disease severity and response to therapy, is presented in [Table 13-6](#). Severity is described as grade I (mild) to grade IV (severe). Rates of grades II-IV aGVHD vary in different studies. With mini-MTX/tacrolimus prophylaxis with ATG for unrelated/mismatched donors at MDACC, they approach 20% to 30% (see Tables 13-1 and 13-2). Risk factors for aGVHD include MUD transplants, mismatched donors, acute leukemia, TBI, higher HCT-CI score, and female-into-male donor (especially if multiparous) ^(78,79). An increasingly recognized entity, delayed aGVHD, occurs after the 100-day period, yet still has features of aGVHD. In addition, an overlap syndrome with features of cGVHD and aGVHD occurs.

Acute GVHD can often be diagnosed based on clinical findings. Histologic confirmation can be valuable in excluding other possibilities, such as infection. Mild GVHD of the skin may demonstrate vacuolar degeneration and infiltration of the basal layer by lymphocytes. With more advanced disease, histologic findings of necrotic dyskeratotic cells with acantholysis may progress to frank epidermolysis. In the liver, early GVHD may be difficult to distinguish from hepatitis or other causes.

Mild aGVHD can be treated with topical steroids and slowing of immunosuppressive therapy (IST) taper.

Table 13-5 Overview of Diagnosis and Management of Infectious Complications After Allogeneic Stem Cell Transplantation at MDACC

Infection	Diagnosis	Management
Neutropenic fever	Temperature of 38°C on greater than 2 incidences 1 hour apart or $\geq 38.2^{\circ}\text{C}$ AND ANC $< 0.5 \times 10^3/\mu\text{L}$ or $< 1 \times 10^3/\mu\text{L}$ expected to fall below $0.5 \times 10^3/\mu\text{L}$ in the next 24 hours	<ul style="list-style-type: none"> • Blood cultures $\times 2$, urine analysis, chest x-ray • Empiric Abs: • Cefepime 2 g IV every 8 hours • Vancomycin 1 g IV every 12 hours • Meropenem 1 g every 8 hours or zosyn 4.5 g IV every 6 hours may be substituted for cefepime • Aztreonam 2 g IV every 8 hours + amikacin for true PCN allergy • Site-specific management, testing
Cytomegalovirus (CMV)	<ul style="list-style-type: none"> • CMV PCR (two subsequent positive tests) • CMV antigenemia • Follow weekly CMV PCR 	<p>Induction phase (until 1 week and CMV antigenemia negative $\times 2$):</p> <ul style="list-style-type: none"> • Ganciclovir 5 mg/kg IV every 12 hours • Valganciclovir 900 mg by mouth twice daily • Foscarnet 60 mg/kg IV every 8 hours (second line, if significant myelosuppression) • Consider 0.5 mg/kg IVIG for severe infection <p>Maintenance phase (2-3 weeks, longer if end-organ damage):</p> <ul style="list-style-type: none"> • Ganciclovir 5 m/kg IV every 24 hours • Valganciclovir 900 mg by mouth daily • Foscarnet 60 mg/kg IV every 24 hours • Infectious disease consultation

BK virus	<ul style="list-style-type: none"> • Cystitis, hematuria • Serum BK PCR nonspecific • Urine PCR more specific (with symptoms) 	<ul style="list-style-type: none"> • Supportive care • Ciprofloxacin • Leflunomide • Cidofovir • BK-specific cytotoxic T lymphocytes (investigational) • Taper IST if feasible
Adenovirus	<ul style="list-style-type: none"> • Typically in severely immunocompromised patients • Symptoms may include FUO, diarrhea/nausea/vomiting, cytopenias, fulminant hepatic failure • Check stool and serum adenovirus PCR. 	<ul style="list-style-type: none"> • Supportive care • Cidofovir • Adenovirus-specific CTLs (investigational) • Taper IST if feasible
Respiratory syncytial virus (RSV)	<ul style="list-style-type: none"> • Respiratory virus antigen screening • Testing for patients with symptoms of URI (rhinorrhea, fever, cough, SOB) 	<ul style="list-style-type: none"> • Supportive care if URI only • RSV pneumonia: ribavirin 2 g inhaled over 3 hours every 8 hours <p>AND</p> <ul style="list-style-type: none"> • IVIG 500 mg/kg IV every 48 hours for 3-5 doses
Influenza	<ul style="list-style-type: none"> • Influenza respiratory antigens 	<ul style="list-style-type: none"> • Oseltamivir 75 mg by mouth twice daily
<i>Clostridium difficile</i> colitis	<ul style="list-style-type: none"> • Stool sample PCR/ELISA in setting of diarrhea 	<ul style="list-style-type: none"> • Metronidazole 500 mg IV or by mouth every 8 hours $\times 10$-14 days • Vancomycin 125 mg by mouth every 6 hours for severe colitis, instability • Fidaxomicin 200 mg by mouth every 12 hours

(Continued)

Table 13-5 Overview of Diagnosis and Management of Infectious Complications After Allogeneic Stem Cell Transplantation at MDACC (Continued)

Infection	Diagnosis	Management
Epstein-Bar virus (EBV)/ posttransplant lymphoproliferative disorder (PTLD)	<ul style="list-style-type: none"> • EBV PCR monitoring in patients with high titer pretransplant or undergoing haploidentical/cord alloSCT • Any patient with new-onset fever, cytopenias, adenopathy • >3,000 copies/mL on 2 tests required for diagnosis • PET-CT scan 	<ul style="list-style-type: none"> • Rituximab 375 mg/m² IV weekly ×4 doses • EBV-specific CTLs (investigational) • Cidofovir • Taper IST if feasible
Invasive <i>Aspergillus</i>	<ul style="list-style-type: none"> • Bronchoscopy if pulmonary; otherwise, CT scan of affected area • FNA/biopsy of affected site 	<ul style="list-style-type: none"> • Infectious disease consult • Switch to voriconazole if on fluconazole
Mucormycosis	<ul style="list-style-type: none"> • Suspect with sinus infection • Obtain biopsy 	<ul style="list-style-type: none"> • Urgent ear, nose, and throat/infectious disease consult • Switch to posaconazole and/or initiate liposomal amphotericin 5 mg/kg IV daily
Other invasive fungal infection	<ul style="list-style-type: none"> • Blood cultures • Biopsy of affected site 	<ul style="list-style-type: none"> • Consultation with infectious disease personnel • Amphotericin 5 mg/kg IV daily • Echinocandin therapy for systemic yeast infection (caspofungin, anidulofungin)

ELISA, enzyme-linked immunosorbent assay; FNA, fine-needle aspiration; FUO, fever of unknown origin; IVIG, intravenous immunoglobulin; PCN, penicillin; SOB, shortness of breath; URI, upper respiratory infection.

Moderate-to-severe aGVHD (grades II-IV) requires systemic treatment. The mainstay of therapy has long been corticosteroid therapy. Methylprednisolone or prednisone, 2 mg/kg/d, achieves responses in 40% to 60% of patients⁽⁸⁰⁾. Steroid-refractory GVHD responds poorly to second-line therapies and is associated with increased mortality. Novel treatments showing efficacy

in preliminary studies include extracorporeal phototherapy, pentostatin, and sirolimus⁽⁸¹⁻⁸³⁾. Acute GVHD of the skin is most responsive to treatment, whereas GVHD of the liver is least responsive. The fatality rate for aGVHD may be as high as 50%. A discussion of MDACC protocols for the treatment of aGVHD is included in Table 13-4.

Table 13-6 Clinical Grading of Acute Graft-Versus-Host Disease (Days 1-100)

Extent of Organ Involvement			
Stage	Skin	Liver	Gut
1	Rash on <25% of skin ^a	Bilirubin 2-3 mg/dL ^b	Diarrhea >500 mL/d ^c or persistent nausea ^d
2	Rash on 25%-50% of skin	Bilirubin 3-6 mg/dL	Diarrhea >1,000 mL/d
3	Rash on >50% of skin	Bilirubin 6-15 mg/dL	Diarrhea >1,500 mL/d
4	Generalized erythroderma with bullae	Bilirubin >15 mg/dL	Severe abdominal pain +/- ileus
Grade ^e			
I	Stage I or II	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	–	Stage 2 or 3 or	Stage 2, 3, or 4
IV ^f	Stage 4 or	Stage 4	–

^aUse the "rule of nines" or burn chart to determine extent of rash.

^bRange given as total bilirubin. Downgrade one stage if additional causes of hyperbilirubinemia are documented.

^cVolume of diarrhea applies to adults. Downgrade one stage if additional causes of diarrhea are documented.

^dPersistent nausea with histologic evidence of GVHD in the stomach or duodenum.

^eCriteria for grading given as the minimum degree of organ involvement required to confer that grade.

^fGrade IV may also include lesser organ involvement but with decrease in performance status.

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD is the single most important factor affecting long-term outcome and quality of life after alloSCT. The incidence of cGVHD is difficult to quantify due to variability in cGVHD definitions and variability in transplant types and procedures. In general, most studies cited rates of 30% to 80%. Figures 13-1 and 13-2 describe the rates of cGVHD in commonly used regimens at MDACC. Chronic GVHD is an alloimmune process (donor graft vs recipient) that results in alloantibody formation as well as antihost T-cell responses and may have single-organ or multisystem involvement. The pathophysiology of cGVHD is incompletely understood, but impaired T-regulatory cell suppression of autoimmunity and loss of B-cell tolerance and B-cell hyperactivity have been implicated^(84, 85).

The classic definition of cGVHD was a syndrome that developed after day +100, with typical signs including skin, mucosal, or genital lichenification; BO; ocular complications; and significant sclerosis of skin and joints. Disease stage was originally defined as limited versus extensive⁽⁸⁶⁾. Limited disease was characterized as localized involvement, hepatic dysfunction, or both and was found to have a more favorable prognosis. Extensive disease was characterized by generalized skin involvement or localized skin involvement and hepatic dysfunction and ocular or salivary gland involvement or involvement of any other target organ. Patients with extensive cGVHD had a worse prognosis.

In 2005, a National Institutes of Health (NIH) consensus project developed a new definition of cGVHD, for use in future trials, given the inconsistent and incomplete staging using the limited/extensive system⁽⁸⁷⁾. The criteria eliminated the 100-day requirement. In addition, aGVHD was defined as the existence of classic clinical features (maculopapular rash, GI symptoms, elevated LFTs) within 100 days, or greater than 100 days, with the absence of cGVHD symptoms.

The definition of cGVHD must fulfill the following criteria:

1. Exclusion of acute GVHD
2. Presence of at least one diagnostic clinical sign of cGVHD or presence of at least one distinctive manifestation confirmed by biopsy or other testing
3. Exclusion of other diagnoses

Clinical manifestations of cGVHD, which differentiate it from aGVHD, include lichenification of the skin, mouth, or genitourinary tract and BO.

The management of cGVHD is similar to aGVHD, with immune-suppressant agents as the standard therapies. Treatments include systemic and topical steroids, CNIs, mTOR inhibitors, extracorporeal phototherapy, mycophenolate mofetil, and anti-tumor

necrosis factor agents. The goal of cGVHD therapy is to relieve symptoms and prolong life long enough for immune tolerance to develop. Once treatment of cGVHD is initiated, the median duration of treatment is typically 2 years⁽⁸⁸⁾.

The treatment of cGVHD has been outlined by a cGVHD working group series of publications⁽⁸⁹⁾. Mild cutaneous involvement of cGVHD can be managed with topical steroids alone. Mild manifestations of cGVHD, such as transaminitis, should be managed with systemic corticosteroids, using the lowest effective dose possible. Typically, patients should remain on systemic steroids for 4 to 8 weeks, with tapering doses based on clinical symptoms.

Moderate and severe cGVHD require systemic immunosuppression. The standard first-line therapy is corticosteroids, with a dose of 1 mg/kg/d of prednisone, or equivalent, as the standard of care. Management of corticosteroids and tapering regimens vary widely and are often done on a “trial-and-error” basis. Steroid taper is started 2 weeks after clinical improvement. A dose of 1 mg/kg every other day is continued until resolution of GVHD symptoms. Thereafter, steroids can be tapered by 10% to 20% per week. If symptoms recur, an increase in steroids may yield a response, and a slower taper thereafter is required. If no response is achieved by 3 months, alternative treatments should be considered.

The most frequent clinical problem encountered in the treatment of cGVHD is steroid-dependent or refractory cGVHD, as 50% of patients undergoing therapy for cGVHD will be refractory or dependent on steroids. These patients not only have a worse overall prognosis but also are subject to the long-term effects of high doses of corticosteroids. Second-line treatment of cGVHD is largely focused on reducing steroid requirements and improving quality of life and symptoms⁽⁹⁰⁾. Steroid-refractory cGVHD was defined by the working group as progression on prednisone 1 mg/kg/d for 2 weeks, stable disease on more than 0.5 mg/kg/d of prednisone for 4 to 8 weeks, or the inability to taper prednisone below 0.5 mg/kg/d. Individual treatments should be tried for at least 4 weeks before being deemed a failure; cutaneous/sclerotic manifestations may require up to 6 months to achieve improvement. Once disease achievement has been improved with the addition of immunosuppressant agents, steroid weaning should be attempted due to the increased toxicities associated with prolonged use.

Multiple agents have been considered in the setting of high-risk or steroid-dependent cGVHD, but as in primary cGVHD, there are limited randomized trial data to justify their use. The most common agents used include CNIs (tacrolimus, cyclosporine), mycophenolate mofetil, mTOR inhibitors (sirolimus), and extracorporeal phototherapy^(88, 91, 92). These are typically used in combination with prednisone, or with

each other, and achieve responses ranging from 35% to 80%. The heterogeneity, combination of drugs, retrospective nature, and lack of randomization in the trials make it difficult to interpret the data; however, there is a clear benefit. Other agents, such as thalidomide, hydroxychloroquine, rituximab, etanercept, azathioprine, and imatinib, have demonstrated a beneficial effect in cGVHD. The optimal treatment regimen in this disease remains to be elucidated. Table 13-4 describes the MDACC approach to cGVHD.

LATE COMPLICATIONS

Patients at MDACC are evaluated annually for several delayed toxicities resulting from alloSCT. These include endocrine toxicities such as hypothyroidism, hypogonadism, or growth hormone deficiency in younger patients. Pulmonary effects may include obstructive lung disease or pulmonary fibrosis. Late infectious complications can occur, including viral reactivation and late fungal infections. These complications are more common in patients who have received alternative donor sources, long-term steroids for GVHD, or both. Patients undergoing alloSCT experience an increased risk for secondary malignancies, about 10% to 13% at 15 years posttransplant^(93,94). The spectrum of second malignancies includes NHL, myelodysplastic syndrome (MDS), skin cancer, head and neck cancers, and other solid tumors. Older patient age and IST for chronic GVHD were significantly correlated with the risk of developing a secondary malignancy. The intensive treatment and prolonged recovery from alloSCT can have profound psychosocial implications for patients and their families, and patients often are managed with antidepressants (selective serotonin reuptake inhibitors) to control anxiety and depressive symptoms.

RELAPSE

The major benefit of alloSCT is the reduction in the relapse rate compared with conventional chemotherapy. However, despite aggressive chemotherapy, conditioning, and alloSCT, some patients still relapse. This remains the primary cause of treatment failure after alloSCT and improvement in improving relapse rates remains a priority of the American Society for Bone Marrow Transplantation⁽⁹⁵⁾.

The management of relapsed disease is complicated and disease and patient specific. Typically, relapse is approached as follows: withdrawal of immune suppression, immune therapy (donor lymphocyte infusions [DLIs] or other immunotherapy), and systemic therapy. In the absence of severe GVHD, immune suppression can be more rapidly weaned in an effort to potentiate the GVT effect⁽⁹⁶⁾. This may be helpful when there are small amounts (ie, minimal residual

disease) or in CML, but is unlikely to result in remission in cases of florid relapse or other more immune-resistant disease types. Systemic therapy options, including chemotherapy, tyrosine kinase inhibitors (TKIs), and other small molecules, are disease specific and often can result in remissions, but without regaining immunologic control are unlikely to result in long-term curative therapy. These approaches are covered in the disease-specific chapters.

Immunotherapy utilizing chimeric antigen receptor T cells is discussed in the novel immune therapies chapter and has demonstrated success in treating relapsed/refractory disease. Immunotherapy in the form of DLIs is frequently used and can result in durable remissions. Donor lymphocyte infusion is an infusion of donor-derived T cells (typically 3×10^7 to 4.5×10^8 CD3⁺ T cells/kg) aimed to create a GVT effect and regain disease control. This infusion was initially utilized in CML⁽¹³⁾. It is most effective in CML, but also is effective in other disease types. In the European Bone Marrow Transplant-95 survey, achieving CR with DLI was noted in 80% of patients with CML and cytogenetic relapse, 77% with hematologic relapse, and 36% with transformed CML. In AML/MDS, 26% achieved CR with DLI, whereas only 15% of ALL patients achieved CR⁽⁹⁷⁾. Donor lymphocyte infusion has been used in combination with chemotherapy, typically lower doses of chemotherapy or hypomethylating agents such as azacitidine, with OS of 29% at 2 years in a recent study⁽⁹⁸⁾. The most frequent complication of DLI is GVHD, with rates of approximately 50%. At MDACC, DLI is utilized in CML in cases of molecular relapse with detectable BCR-ABL by PCR. It is sometimes utilized in the setting of relapsed leukemia in combination with a hypomethylating agent such as azacitidine. These approaches are not standardized, and there is scant literature to guide our management. Second alloSCT can be considered, particularly in AML/MDS, with potential cure rates around 25% in patients with good performance status⁽⁹⁹⁾.

Aside from treating active relapse, novel approaches are being investigated to prevent relapse. One of the most promising approaches is a maintenance approach; after transplant, a low dose of an anticancer agent is administered to prevent relapse. This has demonstrated remarkable efficacy in the postautologous transplant setting in MM⁽¹⁰⁰⁾. At MDACC, low-dose azacitidine given as maintenance has demonstrated preliminary efficacy in decreasing relapse rates in AML and MDS⁽¹⁰¹⁾. In the setting of molecular or florid relapse of CML, DLI-refractory CML, or Philadelphia chromosome-positive ALL, selective Bcr-Abl TKIs (dasatinib, nilotinib, imatinib) are effective at a lower dose than pretransplant to regain remission^(102, 103). Table 13-7 describes the management of specific diseases at relapse, as well as maintenance therapy in certain disease types.

Table 13-7 Indications and Current Results of Allografting for Hematologic Malignancies at MD Anderson Cancer Center (MDACC)

Disease/ Stage	Risk Category ^a	Allograft Recommended	Current Results DFS at 5 Years	Standard Conditioning Regimen Agents ^a	Comments
AML CR1	Good	No	N/A		
	Intermediate	Yes	50%-60%	Bu/Flu or Flu/Bu/Clo Flu/Mel (RIC alternative) for high HCT-CI or advanced age Haploidentical/cord blood transplant if no MRD/MUD	Consider maintenance therapy with azacitidine
	Poor (Including FLT3 ITD positive)	Yes	30%-40%	Bu/Flu Flu/Bu/Clo Flu/Mel (RIC alternative) for high HCT-CI or advanced age Haploidentical/cord blood transplant if no MRD/MUD	Consider FLT3 inhibitor as maintenance therapy, ie, sorafenib for FLT3+ AML
AML >CR1		Yes	30%-50% if in remission 10%-20% if active disease	Bu/Flu or Flu/Bu/Clo Flu/Mel (RIC alternative) for high HCT-CI or advanced age Haploidentical/cord blood transplant if no MRD/MUD	Consider maintenance therapy with azacitidine
MDS good risk	IPSS risk: low, intermediate-1	No	N/A		
MDS poor risk	IPSS risk: intermediate-2, high	Yes	35% if in remission 10%-30% if active disease	Bu/Flu or Flu/Bu/Clo Flu/Mel (RIC) for high HCT-CI or advanced age Haploidentical/cord blood transplant if no MRD/MUD	
ALL CR1	Ph+, T-ALL, MRD+ after induction	Yes	40%-50%	Bu/Clo Etoposide-TBI	Consider maintenance TKI (dasatinib, imatinib) if BCR-ABL positivity post-transplant
ALL >CR1		Yes	30% if in remission, 10%- 20% if active disease	Bu/Clo Etoposide-TBI RIC regimens for older patients	
CML CP1		No			
CML >CP1	T315I mutation failure/ intolerance of 2 TKI	Yes	60%-80% if chronic phase 30%-40% accelerated phase 10%-20% blast crisis	Bu/Flu or Bu/Flu/Clo Flu/Mel (RIC alternative) for high HCT-CI or advanced age Haploidentical/cord blood transplant if no MRD/MUD	Consider maintenance TKI (dasatinib/imatinib) if BCR-ABL+ posttreatment. Usually lower doses are effective to eliminate MRD t
NHL/CLL CR1		No	N/A		

NHL first relapse		Autograft not feasible or Less than partial remission to salvage therapy	N/A	RIC regimens (FC, FB) Add rituximab for B-cell malignancies Alternative regimen Flu/Mel Appropriate for alternative stem cell donor transplants (unrelated, mismatched, and cord blood)	
NHL/CLL > first relapse		Yes	10%-50% depending on disease status and chemosensitivity	RIC regimens (FC, FB). Add rituximab for B-cell malignancies Alternative regimen Flu/Mel Appropriate for alternative stem cell donor transplants (unrelated, mismatched, and cord blood)	
Hodgkin disease		Autograft failures	20%-30%	RIC regimens for older patients Flu/004Del/gemcitabine Appropriate for alternative stem cell donor transplants (unrelated, mismatched, and cord blood)	
Myeloma	17p deletion, failure of autotransplant, multiple lines of therapy	Yes only on clinical trial	10%-15%	Bu/Flu Flu/Mel RIC Alternative stem cell donor transplants (unrelated, mismatched, and cord blood) only for patients with high-risk disease	

ALL, acute lymphocytic leukemia; AML, chronic myelogenous leukemia; CLL, chronic lymphocytic leukemia; CR1, first complete remission; DFS, disease-free survival; IV, intravenous; MDS, myelodysplastic syndromes; NHL, non-Hodgkin lymphoma. Bu, busulfan; FBR, fludarabine/bendamustine/rituximab, FCR, fludarabine/cyclophosphamide/rituximab; Flu, fludarabine; IPSS, International Prognostic Scoring System; Mel, melphalan; TKI, tyrosine kinase inhibitor. *Bu/Flu can be administered as a myeloablative regimen (AUC 6,000) or an RIC regime (4,000-5,000); selection of intensity of conditioning regimen is determined based on disease status, patient age, HCT-CI, and risk of relapse.

DISEASE-SPECIFIC CONSIDERATIONS

The primary benefit of alloSCT is reduction in the risk of disease relapse, and subsequent cure, mediated by the GVT effect in patients for whom cure is unlikely or impossible with standard chemotherapy alone. Given the risk of NRM associated with alloSCT, it is important to distinguish the patients who will most benefit from alloSCT. As discussed, initial considerations include the patient's overall performance status, age, and comorbidity status. Equally important is a consideration of the disease type and status. Table 13-7 provides an overview of disease-specific indications for transplant, disease-specific conditioning regimens, and disease-specific considerations.

In considering an alloSCT, the risk of relapse is weighed against the potential benefits from the GVT effect and potentially curative therapy. Each disease type has a risk classification, typically divided into low-, intermediate-, and high-risk disease. These schemes are outlined in Table 13-7. In general, patients

with intermediate- or high-risk disease have an indication for alloSCT, whereas low-risk patients benefit from a watch-and-wait approach. Any relapsed disease, particularly leukemia, is incurable with standard therapies and therefore is high risk. The effectiveness of alloSCT is greatest when the burden of disease is low, given that it takes 3 to 6 months for the full GVT effect to occur given the presence of GVHD prophylaxis/immunosuppression.

Therefore, patients should receive therapy prior to alloSCT to reduce the disease burden. For leukemias, a 5% blast value has historically been the threshold for transplant, although in recent years, given improved detection methods, the current optimal patient has a bone marrow free of aberrant blasts and, increasingly, free of low-level minimal residual disease, with no detectable cytogenetic abnormalities^(104, 105). For lymphomas, the goal is negative positron emission tomographic/computed tomographic (PET/CT) scanning or evidence of decreasing size of lymph nodes (<3 cm) and marrow free of disease (<10% involvement in the case of CLL/indolent lymphoma) in response to chemotherapy. For patients with higher levels of disease

FIGURE 13-4 Relative intensity and use of most commonly reported ablative, reduced intensity, and nonablative conditioning regimens. AML, acute myelogenous leukemia; BEAM, carmustine + etoposide + cytarabine + melphalan; Bu16/Cy, busulfan, 16 mg/kg + cyclophosphamide; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; Cy/thymic XRT, cyclophosphamide + thymic irradiation; Cy/TBI, cyclophosphamide + total body irradiation; Cy/TT/TBI, cyclophosphamide + thiotepa + total body irradiation; F/Bu8/ATG, fludarabine + busulfan, 8 mg/kg + antithymocyte globulin; FC, fludarabine + cyclophosphamide; FLAG/Ida, fludarabine + cytarabine + granulocyte colony-stimulating factor + idarubicin; FM, fludarabine + melphalan; F/TBI, fludarabine + total body irradiation; LCL, large-cell lymphoma; LGL, low-grade lymphoma; MM, multiple myeloma; TBI, total body irradiation.

prior to alloSCT, the rates of relapse and OS are high. It is increasingly recognized that patients with no detectable residual disease or evidence of leukemia have superior outcomes.

In general, patients who receive MAC have decreased relapse rates and improved survival. Patients with more active or higher-risk disease often receive MAC for this reason. However, there are exceptions to this rule. Patients with indolent lymphoma (follicular lymphoma, CLL) or NHL generally benefit more from a RIC regimen given the disease is slow growing, and there is more time to allow for the GVT effect to develop. In addition, patients with higher HCT-CI of 3+ typically receive RIC regardless of disease status, given that MAC comes at a risk of higher NRM. **Figure 13-4** provides a graphical representation of disease type and conditioning intensity. Tables 13-1 and 13-2 provide a breakdown of disease-specific indications by myeloid and lymphoid disease, with survival rates, GVHD rates, and standard-of-care conditioning regimens utilized at MDACC ^(25, 35, 106-114). Table 13-7 provides a more broad consideration of each disease type and outcomes.

CONCLUSIONS

Allogeneic stem cell transplantation provides an important therapeutic approach for the management of hematologic malignancies. Over the past decade, advances in alternative donor transplantation, GVHD prophylaxis, conditioning therapy, supportive care, risk stratification, and management and prevention of disease relapse have advanced the field of transplantation at a time when candidate patients have increasingly high-risk disease, older age, and more comorbidities. The goal of future investigations will be to decrease NRM and relapse to fully harness the GVT effect and provide optimal therapy for patients with otherwise incurable disease.

Alternative Donor Transplants: Cord Blood Transplant

Rohtesh S. Mehta
Betul Oran
Elizabeth J. Shpall

BACKGROUND

The numbers of allogeneic stem cell transplants (SCTs) performed in the United States have increased steadily, from about 7,500 in 1994-1995 to over 13,500 in 2010-2011, in patients above the age of 20 years (¹). Donor identification has been a constant challenge, and only 30% of patients who need allogeneic SCT have a matched sibling donor. The National Marrow Donor Program (NMDP) and its cooperative international registries have about 16 million volunteer donors. It is estimated that 75% of white patients, but only 16% of African Americans and other minority patients, will be able to find a suitably matched unrelated donor (MUD) and proceed to transplantation (²). Mismatched related (often haploidentical), cord blood (CB) or mismatched unrelated donors (MMUDs) with either peripheral blood (PB) or bone marrow (BM) graft sources are potential options for patients in need of a SCT but lacking a matched related donor (MRD) or unrelated donor.

Using CB as the graft source provides many advantages; CB units are easy to collect with little or no risk to the mother or newborn. Cord blood units can be rapidly obtained for 80% to 95% of the patients 20 years and older across all races and in almost 100% of younger patients (²). This is particularly advantageous in cases where urgent transplant is mandated. Owing to rapid procurement of CB units, patients can receive CB transplantation (CBT) 4 or 5 weeks earlier than those receiving SCT with a MUD (³). Further, CBT is associated with low risk of infection transmission,

requires less-stringent human leukocyte antigen (HLA)-matching criteria, and has relatively lower risk of graft-versus-host disease (GVHD) with preserved graft-versus-malignancy effects. However, it is associated with a greater risk of graft rejection, delayed engraftment, and delayed immune reconstitution, leading to heightened risk of infection or nonrelapse mortality (NRM) (⁴⁻⁷). Many of the adverse outcomes noted after CBT are attributed to the naïveté of CB T lymphocytes and the low numbers of total nucleated cells (TNCs) and CD34⁺ cells in the graft.

CELL DOSE AND HUMAN LEUKOCYTE ANTIGEN MATCHING

The outcomes of CBT depend on the impact of cell dose and the degree of HLA match (⁸). The TNC dose available for CBT is a fraction of what is typically used in the PB or BM setting. The median TNC dose obtained from a BM harvest is about 3×10^8 TNCs/kg; the granulocyte colony-stimulating factor (G-CSF)-mobilized PB can yield a median of 7×10^8 TNCs/kg (⁹). In contrast, about one-fourth of the CB units contain less than 0.25×10^8 TNCs/kg, and two-thirds of the units have between 0.25×10^8 to 1×10^8 TNCs/kg (⁸). The recommended minimum cell dose is typically 2×10^7 TNCs/kg for successful engraftment after a CBT.

The HLA matching criteria between the CB units and the recipient are less stringent compared with other donor sources. Therefore, while unrelated adult donors are selected to be closely matched to recipients

at HLA-A, -B, -C, and -DRB1 by high-resolution testing^(10,11), CB units are selected using lower-resolution HLA typing (antigen level) for HLA-A and -B and at the allele level for HLA-DRB1⁽¹²⁾. In a study of single CBT, Barker et al showed that recipients of 6/6 matched CB units had the lowest transplant-related mortality (TRM) regardless of the dose, followed by 5/6 matched CB units with TNC dose greater than $2.5 \times 10^7/\text{kg}$ or 4/6 matched units with TNC dose greater than $5.0 \times 10^7/\text{kg}$, and 5/6 matched units with lower TNC dose ($<2.5 \times 10^7/\text{kg}$)^(8,13). These findings support the notion that both TNC dose and HLA-matching level should be taken into account for CB unit selection.

Although the standard HLA-matching criteria do not require high-resolution typing at class I antigen in CBT, a recent study by the Center for International Blood and Marrow Transplant Research (CIBMTR) and the Eurocord reported better outcomes in single CBT after myeloablative conditioning (MAC) with improved allele-level matching for 4 HLA loci (-A, -B, -C, and -DRB1)⁽¹⁴⁾. The investigators showed that the frequency of neutrophil recovery was lower for recipients of mismatches at three to five but not at one or two alleles compared with those of HLA-matched units. Nonrelapse mortality was higher with units mismatched at one to five alleles compared with matched units. This retrospective study confirmed the clinical importance of selecting better HLA allele-matched units for single CBT, an observation already well described for BM and PB progenitor cell transplantation. The effect of HLA matching by high-resolution testing is unclear after double CBT (dCBT) and should be investigated.

SINGLE VERSUS DOUBLE CORD BLOOD TRANSPLANTATION

The relatively low number of progenitor cells in a single CB unit resulting in delayed hematopoietic recovery, and engraftment failure limited the use of CBT in adults. Most adults do not have access to a single CB unit containing the recommended nucleated cell dose of 2.5×10^7 TNCs/kg⁽¹⁵⁾. To overcome the cell-dose limitation, investigators pioneered an approach by which two partially HLA-matched CB units were used to augment the progenitor cell dose when a single unit was considered inadequate and confirmed its feasibility⁽¹⁵⁾. A recent CIBMTR analysis investigated the relative risks and benefits of transplanting double CB units compared with an adequately dosed single CB unit. The investigators observed no differences in clinical outcomes after dCBT or adequately dosed

single CBT. Both transplant approaches had comparable outcomes with 78% (95% CI, 72-83) versus 81% (95% CI, 74-88, $P = .83$) probabilities of neutrophil engraftment by day 42, and 68% (95% CI, 62-74) versus 63% (95% CI, 53-72; $P = .34$) probabilities of platelet recoveries at 6 months, respectively. There were no differences for grades III or IV acute GVHD (18% [95% CI, 11%-26%] versus 14% [95% CI, 10%-19%], $P = .64$), 2-year probabilities of chronic GVHD (31% [95% CI, 26-37] versus 24% [95% CI, 15-34], $P = .27$), treatment-related mortality (hazard ratio [HR] 0.91; $P = .63$), risk of relapse (HR 0.90, $P = .64$), and overall mortality (HR 0.93, $P = .62$)⁽¹⁶⁾.

A unique feature after a dCBT is evidence of mixed chimerism from both the CB units observed during the initial posttransplant period.⁽¹⁷⁾ In the early post-dCBT period (day +21), both CB units contribute to hematopoiesis in 40% to 50% of patients, but by day +100 one unit predominates in a vast majority^(18,19). The factors leading to unit dominance are not well defined. It is however recognized that there is no association with the TNC or CD34⁺ cell doses, HLA match, gender match, ABO typing, or the order in which CB units are infused^(15,18-21). This current lack of evidence is a major limitation to dCBT, and identifying predictive factors for unit dominance would optimize CB unit selection algorithms by allowing for the selection of two CB units with a high probability of long-term engraftment.

CONDITIONING REGIMENS

Myeloablative Conditioning Regimens

High-intensity MAC regimens are reserved for young and otherwise-fit patients who can tolerate the associated regimen morbidity. Such regimens lead to a low risk of relapse at the expense of a high TRM compared with reduced-intensity conditioning (RIC) regimens.

One of the largest registry studies comparing single-unit CB ($n = 165$) to PB ($n = 888$) or BM ($n = 472$) transplants in adults with acute leukemia using MAC regimens from 2002 through 2006 showed promising outcomes with CBT. Total body irradiation (TBI) constituted part of the preparative regimen in about half of patients in the CB group and about two-thirds in the comparative groups. Despite a significantly higher number of patients with fully HLA-matched PB or BM grafts (70%) compared to CB grafts (6%), the rates of disease-free survival (DFS) and relapse were similar among the groups, while the risks of acute or chronic GVHD were significantly lower with CBT. Also, TRM was similar with CBT compared with mismatched PB

or BM grafts, but higher in contrast to fully matched PB (HR 1.62; 95% CI, 1.18-2.23; $P = .003$) or BM transplants (HR 1.69; 95% CI, 1.19-2.39; $P = .003$). This was offset by a significantly lower incidence of chronic GVHD compared with fully matched PB (HR 0.38; 95% CI, 0.27-0.53; $P = .001$) or BM transplants (HR 0.63; 95% CI, 0.44-0.90; $P = .01$)⁽⁴⁾. Therefore, in the absence of matched PB or BM donors, CBT potentially offers better outcomes compared with mismatched alternative donor transplants.

Similar encouraging results were noted in a study that compared 4-6/6 matched dCBT exclusively (using the MAC regimen including fludarabine 75 mg/m², cyclophosphamide 120 mg/kg, and TBI 1,200 to 1,320 cGy [Flu/Cy/TBI]) to 8/8 MRD or MUD, or 1 allele-MMUD donors⁽⁷⁾. This study also noted lower risk of relapse, higher TRM, lower GVHD, and comparable DFS after CBT compared to other groups. The risk of relapse was significantly lower after dCBT (15%, 95% CI, 9%-22%), compared with MRD (43%, 95% CI, 35%-52%) or MUD (37%, 95% CI, 29%-46%) transplants. Higher NRM was noted after dCBT (34%, 95% CI, 25%-42%) compared to MRD (24%, 95% CI, 17%-39%) or MUD (14%, 95% CI, 9%-20%) transplants, which resulted in comparable 5-year DFS between CB (51%, 95% CI, 41%-59%), MRD 33% (95% CI, 26%-41%), and MUD (48%, 95% CI, 40%-56%) transplants. The cumulative incidence of grades II to IV GVHD at day 100 after DCBT, MRD, and MUD was 60% (95% CI, 50%-70%), 65% (95% CI, 57%-73%), and 80% (95% CI, 70%-90%), respectively. The rate of chronic GVHD at 2 years was 26% (95% CI, 15%-35%), 47% (95% CI, 39%-55%), and 43% (95% CI, 34%-52%) respectively⁽⁷⁾.

In adults with high-risk acute lymphoblastic leukemia (ALL), CBT leads to similar overall survival (OS), TRM, and relapse risk, with significantly lower risk of acute or chronic GVHD, compared with PB or BM transplants. This was demonstrated in a recent registry study that compared outcomes after single or double 4-6/6 matched CB ($n = 116$) and 7-8/8 matched PB ($n = 546$) or BM ($n = 140$) transplants after MAC regimens⁽²²⁾. More than half of the patients in the CBT group received Flu/Cy/TBI as the conditioning regimen, while about 75% of the patients in the PB or BM groups received TBI/Cy-based regimens. There were no differences in the 3-year OS rates (44%, 44%, and 43%, respectively); relapse risk (22%, 25%, and 28%, respectively); or TRM (42%, 31%, and 39%, respectively) among the groups. However, the risk of acute grades II to IV GVHD (27%, 47%, and 41%, respectively) or grades III and IV acute GVHD (9%, 16%, 24%, respectively) was appreciably lower after CBT compared with 8/8-matched and 7/8-matched PB or BM transplants, respectively⁽²³⁾.

Reduced-Intensity Conditioning Regimens

The advent of RIC regimens extended the utility of CBT to older patients and those with comorbid conditions that otherwise restrict the use of the MAC regimens. It is noteworthy that a majority of trials in MRD or MUD transplants used an arbitrary age definition of greater than 55 to 60 years (to define "older patients") as a threshold of using an RIC regimen. However, age greater than 40 to 45 years is generally chosen as a threshold for RIC in the CBT setting.

Barker et al reported that the RIC with fludarabine 200 mg/m², cyclophosphamide 50 mg/kg, and 2-Gy TBI (Flu/Cy/2Gy TBI) was well tolerated, with rapid neutrophil recovery, a sustained donor engraftment rate of 94%, and a low incidence of TRM⁽²³⁾. This regimen was associated with significantly better DFS compared with other RIC regimens (51% vs 28%, $P = .0002$, HR 0.53)⁽²⁴⁾. Multiple studies supporting the use of RIC CBT in patients who would not be able to tolerate more intensive preparative regimens have subsequently been reported^(6, 18, 19, 25-27).

A retrospective single-center study compared the outcomes in patients older than 55 years who underwent CB and MRD SCT with RIC (primarily of Flu/Cy/2Gy TBI). There were no differences in TRM at 180 days (28%, 95% CI, 14%-41% vs 23%, 95% CI, 11%-36%); 3-year DFS (34%, 95% CI, 19%-48% vs 30%, 95% CI, 16%-44%); or 3-year OS (34%, 95% CI, 17%-50% vs 43%, 95% CI, 29%-58%) between the groups⁽⁶⁾. These findings were confirmed by a registry analysis of patients with acute leukemia comparing the outcomes after CB ($n = 161$), 8/8-matched (313) and 7/8-matched PB (111) transplants with RIC regimens. Patients with CBT following a Flu/Cy/2 Gy TBI regimen had comparable results with 8/8 HLA-matched PB donors. However, higher TRM and lower OS and LFS were observed in recipients of CBT if they were treated with alternative RIC regimens, including busulfan plus melphalan, or cyclophosphamide with fludarabine and in vivo T-cell depletion with anti-thymocyte globulin (ATG)⁽²⁷⁾. Similar findings were reported by Eurocord and the European Group for Blood and Marrow Transplantation (EBMT) in patients with lymphoid malignancies. When patients with CB units ($n = 104$) were compared with 8/8-matched PB MUD ($n = 541$) transplants, no difference was noted in NRM (29% vs 28%), PFS (28% vs 35%), or OS (56% vs 49%) at 3 years (Fig. 14-1). Further, the risk of chronic GVHD was significantly lower in the CBT group (26% vs 52% at 3 years; $P = .0005$)⁽²⁶⁾. These studies supported the use of CBT with RIC as a suitable alternative for patients who may benefit from RIC SCT and who do not have a suitable related or unrelated volunteer donor in the time period transplantation is needed.

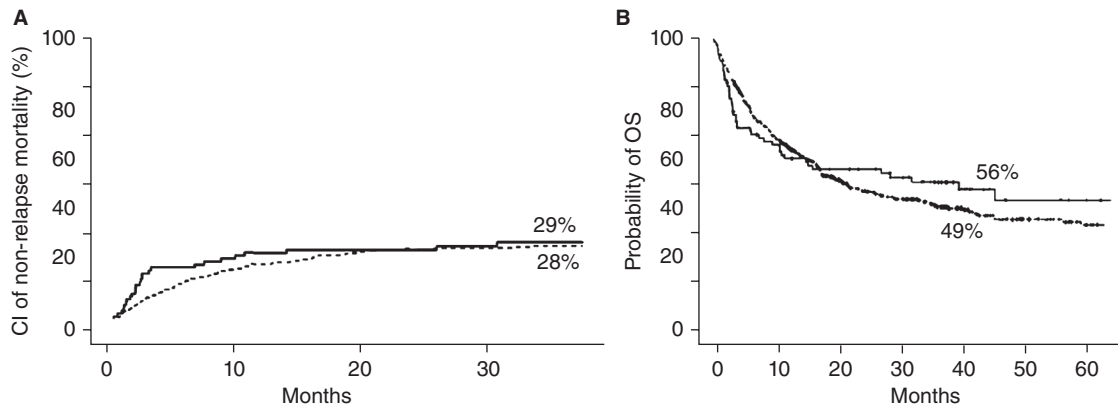

FIGURE 14-1 Comparison of cord blood (solid line) and matched unrelated donor transplants (dotted line) for lymphoid malignancies. **A.** Nonrelapse mortality (NRM). **B.** Overall survival (OS). There were no differences in NRM or OS at 3-years between the two groups. [Reproduced with permission from Rodrigues CA, Rocha V, Dreger P, et al. Alternative donor hematopoietic stem cell transplantation for mature lymphoid malignancies after reduced-intensity conditioning regimen: similar outcomes with umbilical cord blood and unrelated donor peripheral blood. *Haematologica*. 2014;99(2):370-377.]

POSTTRANSPLANT COMPLICATIONS

Disease relapse is the most common cause of mortality after allogeneic SCT, while GVHD and infections are the two leading causes of NRM. Treatment options after SCT relapse include withdrawal of immunosuppression, chemotherapy, or donor lymphocyte infusion (DLI). Although DLI is currently unavailable for CBT patients outside clinical trials, a study showed that in adults who have acute myelogenous leukemia relapse following CB or MRD transplants, DLI in the latter group did not have an impact on OS (19% CB vs 28% MRD at 1 year; $P = .36$), and relapsed patients had poor prognosis independent of the donor source⁽²⁸⁾.

In the CBT setting, infections are the leading cause of early 100-day NRM (27%), while GVHD contributes to most (20%) of the delayed NRM (beyond 100 days)⁽⁴⁾. The reported probabilities of acute grades III and IV GVHD at day 100 (10%-25%) and chronic GVHD (25%-35%), TRM (20%-50%), risk of relapse (20%-50%), DFS (30%-35%), and OS (30%-45%) at 2 to 3 years varied depending on the conditioning regimens and the study population^(7, 16, 19, 22, 24, 27). The rates of posttransplant complications are comparable after the use of dCBT and single CBT⁽²⁹⁾.

Early infections (within 100 days) are primarily due to neutropenia and mucosal damage caused by conditioning regimens. Delayed infections are related to the speed of cell-mediated immune reconstitution and use of immunosuppressants. Most early infections are bacterial; more than half of the invasive fungal infections and 45% of cytomegalovirus (CMV) infection occur beyond day +100⁽³⁰⁾.

The heightened risk of infections in CBT is partly explained by the naïveté of CB T cells and delayed

T-lymphocyte immune reconstitution and neutrophil engraftment in contrast to other donor sources^(4,7,27,31,32). Although significant B-cell recovery starts within 3 to 4 months and may approach normal numbers by 6 months after transplant, T-cell reconstitution is substantially prolonged⁽³²⁾. The CD4⁺ and CD8⁺ T-cell counts are strikingly reduced after CBT, remain low for up to 6 months, and approach normal values by 1 year. The PB T cells after CBT are more dysfunctional as compared with other types of allogeneic SCTs. Patients also fail to recover thymic function after CBT, in contrast to other allogeneic SCT recipients⁽³³⁾ (Fig. 14-2).

A retrospective registry analysis from the CIBMTR comparing CB ($n = 150$) with matched ($n = 367$) or antigen-mismatched ($n = 83$) BM transplants reported higher risk of early (within 100 days) infection-related deaths after CBT compared to other groups (45%, 21%, and 24%, respectively; $P = .01$)⁽²⁹⁾. In another study, the risk of severe infection, especially bacterial infections in the first 100 days, was significantly higher after CBT in contrast to BM or PB graft (85% vs 69%, $P < .01$). The risk of infection-related mortality did not differ at day 100 or at 3 years. In multivariate analysis for CBT, CMV-seropositive recipient, prolonged neutropenia beyond day 30, and low cell dose ($< 2 \times 10^7/\text{kg}$) were the predictors for infection-related mortality⁽³⁰⁾.

MD ANDERSON APPROACH TO CORD BLOOD TRANSPLANTATION

At the MD Anderson Cancer Center, patients with various hematological malignancies who do not have an MRD or MUD but require SCT are considered for CBT and a search for a CB unit is initiated (Fig. 14-3).

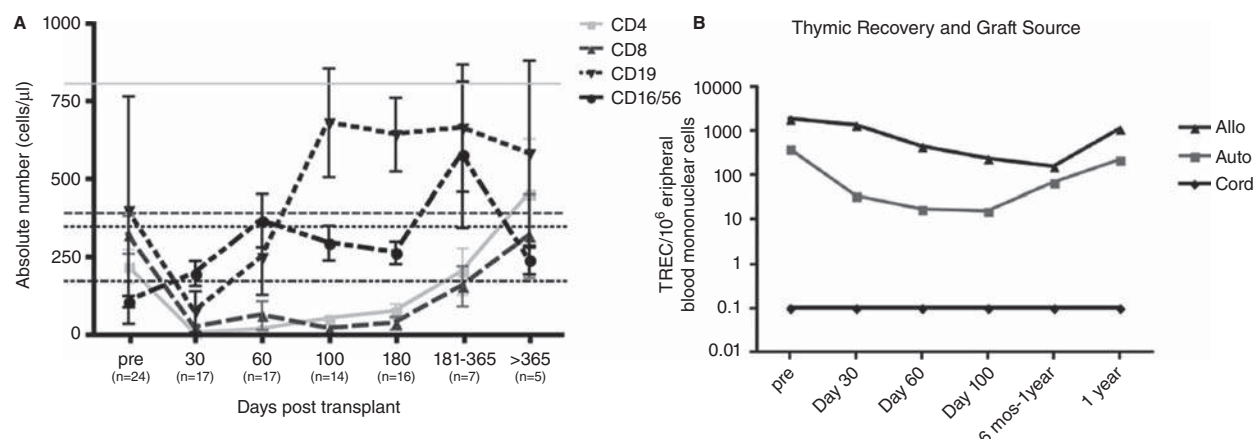

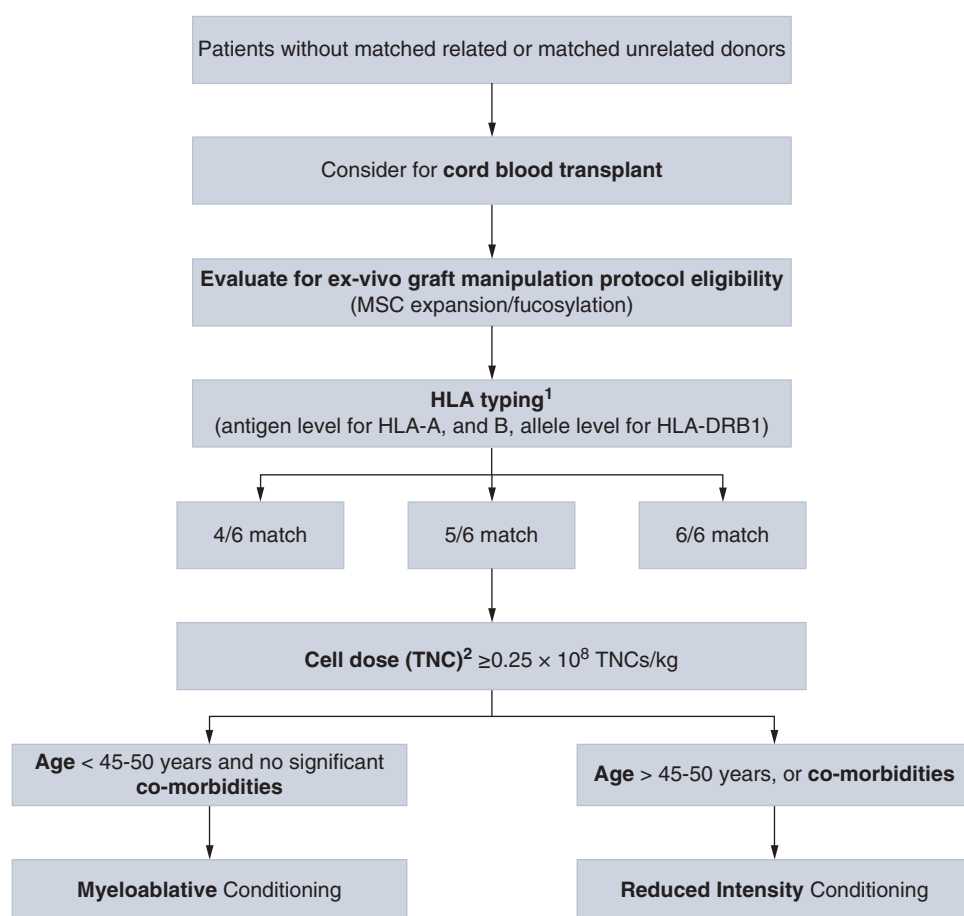

FIGURE 14-2 A. Delayed immune reconstitution after cord blood transplant (CBT). After CBT, NK cells (CD16/CD56) and B cells (CD19) recover early; there is significant decline in CD4 and CD8 T cells, which gradually recovers over several months. Horizontal lines depict normal values. B. Thymic regeneration failure after CBT compared to autologous and allogeneic SCT recipients as determined by the measurement of peripheral recent thymic emigrants by determining the number of T-cell receptor excision circles (TRECs). After CBT, most patients have an undetectable thymopoiesis. [Reproduced with permission from Komanduri KV, St John LS, de Lima M, et al. Delayed immune reconstitution after cord blood transplantation is characterized by impaired thymopoiesis and late memory T-cell skewing. *Blood*. 2007;110(13):4543-4551.]

¹Avoid HLA-DRB1 mismatch

²Prefer higher TNC dose for lower degree of match

FIGURE 14-3 Approach to a patient for cord blood transplant.

Unit Selection

Within the first days to weeks of the initial donor search, coordinators determine the likelihood of obtaining a suitably matched donor based on the patient's ancestry, the preliminary search results, and review of the HLA typing. If the likelihood of finding a matched donor is deemed to be low, we proceed with confirmatory HLA typing of CB units. Alternatively, we may delay typing of CB units if multiple 10/10 HLA-A, -B, -C, -DRB1, -DQ allele-MUDs are probable or if the transplantation is not urgent. If an unrelated donor collection is delayed because of problems with donor health or availability, a prompt decision is made whether to abandon the unrelated donor search in favor of CB.

To maximize the chance of identifying optimal CB unit(s), we conduct a global search while being aware that there is no global regulatory oversight of CB-banking standards. It is important to know which banks are included in the NMDP consortium of banks, in the Netcord, and in the NMDP Cooperative Registries. We give equal consideration to domestic and international units as the primary units of the graft, whereas we prefer domestic units for backup.

Our current institutional policy is to use a double-unit graft in an effort to augment engraftment and reduce TRM. Given that either unit may engraft after a double-unit CBT, each unit of a double-unit graft is equally important. We give a strong priority to HLA match over precryopreservation TNC threshold of about $2.0 \times 10^7/\text{kg}$ for each unit of a double-unit graft. This approach gives strong priority to HLA match but augments the chance of engraftment by infusing two units with at least an adequate dose in each.

We use novel ex vivo graft manipulation techniques pioneered at the MD Anderson Cancer Center, such as ex vivo CB expansion with mesenchymal stromal cells (MSCs) ⁽³⁴⁾ and ex vivo CB fucosylation ⁽³⁵⁾. With these, remarkable improvement in engraftment is noted compared with historical controls. The median time to neutrophil engraftment is 15 (range, 9 to 42) days with MSC expansion ⁽³⁴⁾ and 14 (range 12-28) days with fucosylation, which is significantly faster than the 24 (range 12-52) days noted in the CIBMTR controls ($P < .001$) ⁽³⁵⁾. Similarly, platelet engraftment is 42 (range 15-62) days with MSC expansion and 33 (range 18-100) days with fucosylation, compared with 49 (range 18-264) days in the CIBMTR controls ($P = .03$) ^(34, 35). We are investigating the impact of CB unit KIR (killer immunoglobulin-like receptor) genotype on transplant outcomes with an aim to integrate KIR information into the CB unit selection algorithm.

Conditioning Regimens

We have investigated various MAC regimens for CBT, which include combinations of (a) melphalan, fludarabine, and thiotepe; (b) busulfan and fludarabine; (c) busulfan, clofarabine, fludarabine, and low-dose TBI given 9 days after chemotherapy; and (d) busulfan, clofarabine, fludarabine, and low-dose TBI given immediately after the chemotherapy ⁽³⁶⁾. The most favorable outcomes appear to be associated with the latest regimen, which is well tolerated and associated with prompt engraftment and effective disease control. This regimen consists of fludarabine 10 mg/m²/d (days -7 through -4), clofarabine 30 mg/m²/d (days -7 through -4), busulfan at a dose calculated to deliver a daily area under the curve (AUC) of 4,000 μmol/min for 4 days (days -7 through -4) based on an outpatient test dose of 32 mg/m², and 2-Gy TBI on day -3. Our preferred RIC regimen consists of fludarabine 40 mg/m²/d (days -5 through -2) and melphalan 140 mg/m² (day -2) in addition to the Flu/Cy/2Gy TBI for patients older than 50 years or not medically fit to tolerate an MAC regimen.

Prophylaxis

Prophylaxis against GVHD is provided with mycophenolate mofetil (MMF) and tacrolimus. We start MMF from day -3 at a dose of 15 mg/kg (maximum of 1 g orally twice daily) and continue it through day +100. Tacrolimus is started from day -2 and taper started at day 180 in the absence of GVHD. We use rabbit ATG 3 mg/kg infused over 2 days on days -4 and -3 in all patients. Patients on azole antifungals require appropriate dose adjustments for tacrolimus. Other drug interactions and creatinine clearance need be considered while calculating the dosing.

Filgrastim is administered from day 0 until neutrophil engraftment and blood products are transfused as indicated. Standard infectious disease prophylaxis with antibacterial (levofloxacin), antiviral (valacyclovir), and antifungal (voriconazole, posaconazole, or caspofungin—the choice depending on risk factors) and against *Pneumocystis jiroveci* pneumonia are also provided for all CBT patients. The surveillance for CMV using quantitative polymerase chain reaction (qPCR) (or antigenemia assay if absolute neutrophil count is $>1 \times 10^9/\text{L}$) is performed routinely twice weekly for the first 100 days after CBT or longer if any complications are present. We routinely perform Epstein-Barr viremia testing using qPCR every 2 weeks from day +30 until day +100. Other viruses, including adenovirus, BK virus, respiratory syncytial virus, influenza, human herpes virus 6, and parainfluenza, are tested as clinically indicated.

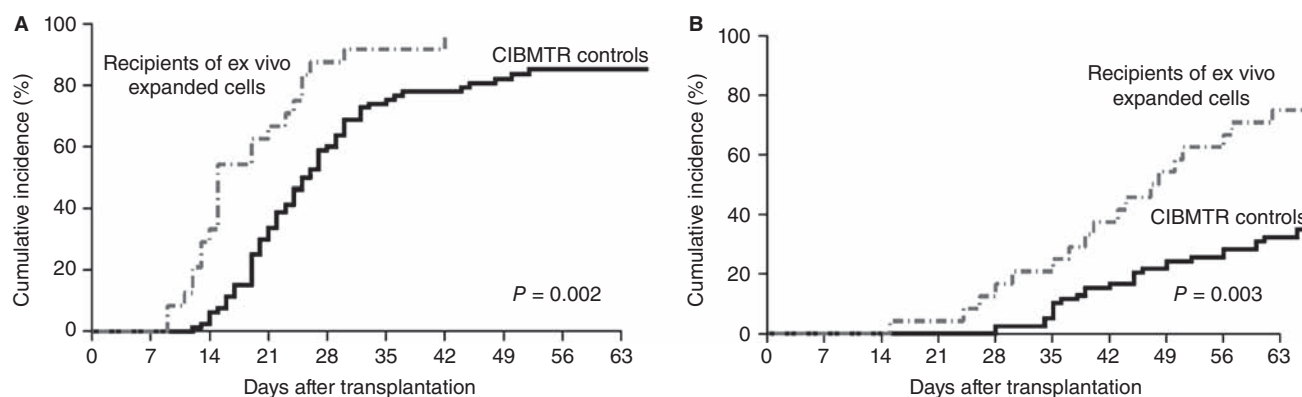

FIGURE 14-4 Cumulative incidences of (A) neutrophil and (B) platelet engraftments after ex vivo CB expansion with mesenchymal stromal cells (MSCs) compared with CIBMTR historical controls. Both neutrophil and platelet engraftments are significantly faster, and a higher proportion of patients engrafts after MSC expansion. [Reproduced with permission from de Lima M, McNiece I, Robinson SN, et al: Cord-blood engraftment with ex vivo mesenchymal-cell coculture, *N Engl J Med* 2012 Dec 13;367(24):2305-2315.]

Novel Strategies to Improve Cord Blood Transplantation Outcomes

To increase CB cell dose, a variety of ex vivo expansion techniques have been developed that yield significantly higher final numbers of TNCs. These include coculturing the CB cells with cytokine support or MSCs to simulate the BM “hematopoietic niche” ex vivo⁽³⁴⁾ or using nicotinamide analogs⁽³⁷⁾ or copper chelators (such as tetraethylenepentamine)⁽³⁸⁾ and targeting the *Notch* signaling pathway⁽³⁹⁾, all of which block the differentiation of early progenitor cells, leading to expansion of hematopoietic stem cells. Apart from augmenting the cell dose, ex vivo graft manipulation techniques are being explored to improve the inherent homing capacity of CB cells, with an aim to accelerate engraftment. Different methods are being tested in clinical trials, such as fucosylation of the CB progenitor cells⁽⁴⁰⁾ or the use of prostaglandin E₂ derivatives⁽⁴¹⁾ or dipeptidyl peptidase-4 inhibitors. Many of these techniques have demonstrated significantly improved time to neutrophil engraftment (13-17 days) comparable to other donor types (Fig. 14-4).

Ex vivo graft manipulation permitted the generation and clinical use of antiviral and antitumor adoptive immunotherapies as well as cellular therapies for GVHD prevention. A variety of “designer” CB lymphocytes can now be engineered and expanded ex vivo. For instance, these include T cells with specific cytotoxicity against tumors or viruses⁽⁴²⁻⁴⁴⁾, chimeric antigen receptor (CAR) T cells⁽⁴⁵⁾, natural killer (NK) cells⁽⁴⁶⁾, and regulatory T cells (T_{Regs})⁽⁴⁷⁾, which are being tested in clinical trials.

CONCLUSION

Cord blood transplantation is an attractive option for patients who lack a matched PB or BM donor. To overcome the limitation of low cell doses in single-CB units, dCBT has been adopted for many patients and is associated with outcomes comparable to those with other donor sources. There are promising strategies to improve engraftment with ex vivo expansion or homing and to enhance immune reconstitution with the infusion of CB-derived NK cells and cytotoxic T lymphocytes with antiviral and antileukemic specificities. Prospective multicenter clinical trials are needed to determine the efficacy of these promising technologies.

Alternative Donor Transplants: Haploidentical Hematopoietic Stem Cell Transplantation

Sameh Gaballa
Richard E. Champlin
Stefan O. Ciurea

INTRODUCTION

Haploidentical stem cell transplantation (haploSCT) from a first-degree-related haplotype-mismatched donor (siblings, children, parents) could expand allogeneic stem cell transplantation (SCT) to a large proportion of patients with hematologic malignancies without an HLA-matched donor (¹). As the average family size continues to shrink, the likelihood of finding an HLA-matched related sibling donor continues to decrease (²). Moreover, as the population continues to age, finding a young, healthy sibling donor becomes increasingly less likely. The use of matched unrelated donors (MUDs) is limited by the long time to SCT (median 3-4 months), which makes it difficult to treat patients with more advanced disease in rapid need of SCT. The ethnicity/race of the recipient can also limit MUD transplantation as approximately 30% of Caucasians, 70% of Hispanics, and 90% of African Americans do not have a MUD in the worldwide registries (³).

In contrast to unrelated donor stem cells, haploidentical (or “half-matched”) donors can be available immediately, and there are no costs associated with an unrelated donor search, maintaining a registry, or coordinating logistics with distant donor centers. This is an especially valuable option for the non-Caucasian and mixed-race individuals (³). This approach might also be particularly useful in developing countries that may not have the resources to procure unrelated donor transplants or maintain complex unrelated donor registries. Moreover, haploidentical donors offer the possibility to easily collect donor cells for cellular therapy posttransplant. Over the recent decade, significant

breakthrough advances in controlling alloreactivity have been made and important steps taken toward graft engineering and posttransplant cellular therapy, approaches that changed dramatically the landscape of haploSCT. Improved haploidentical transplant outcomes represent a major advance in SCT that has practically eliminated the limitation of donor availability for allogeneic SCT.

COMPLETE T-CELL DEPLETION: CONTROL OF GRAFT-VERSUS-HOST DISEASE WITH A HIGH TREATMENT-RELATED MORTALITY

Historically, unmanipulated T-cell-replete haploSCT grafts with conventional graft-versus-host-disease (GVHD) prophylaxis used in the late 1970s were associated with intense bidirectional alloreactivity and unacceptably high morbidity and mortality rates due to hyperacute GVHD and graft rejection (⁴⁻⁶). This led in the 1980s to the development of complete ex vivo depletion of T cells using CD34-selected grafts. Complete T-cell depletion has been associated with a lower incidence of acute GVHD (aGVHD); however, this caused delayed immune recovery and was associated with a high nonrelapse mortality (NRM) from infections and higher disease relapse rates given the decreased graft-versus-leukemia effect, as well as a higher rate of graft rejection (⁷⁻⁹). While graft rejection was partially overcome with “megadoses” of CD34 cells (typically $>10^7$ CD34⁺ cells/kg) and a myeloablative conditioning

Table 15-1 Current Approaches to HaploSCT

Approach	Rationale	Stage of the Clinical Development
High-dose posttransplantation cyclophosphamide	<ul style="list-style-type: none"> Eliminating only the alloreactive T cells Rapid immune recovery with low infectious complications Acceptable rates of GVHD Lower cost 	Phase II/III

regimen (including total-body irradiation [TBI], cyclophosphamide, thiotepa) with severe T-cell depletion of the graft, immune recovery remained delayed, leading to high NRM rates in excess of 40% (¹⁰). Improved results with this approach have been reported in some centers with selective depletion of alpha-beta T cells. T-cell depletion strategies have been most successful in children (¹¹). We have used this approach with a different conditioning regimen (fludarabine, melphalan, and thiotepa) and showed that most patients died of NRM related to infectious complications (¹²).

During the last decade, several advances enabled investigators to selectively deplete alloreactive T cells and successfully control GVHD rates while maintaining memory T cells in the graft to accelerate immune recovery and prevent significant infectious complications posttransplant. Table 15-1 summarizes the major contemporaneous approaches to haploSCT. These advances have improved significantly outcomes of patients treated with haploidentical donors, with outcomes now similar to matched transplants

(Fig. 15-1) (^{12a}). Here, we summarize the recent developments with this type of transplant, focusing on advances made at the MD Anderson Cancer Center (MDACC).

BALANCING GRAFT-VERSUS-HOST DISEASE, IMMUNE RECOVERY, AND THE CONCEPT OF SELECTIVE ALLODEPLETION: POSTTRANSPLANT CYCLOPHOSPHAMIDE

The introduction of high-dose posttransplant cyclophosphamide (HDPTCy) for GVHD prevention represented a major turning point for haploSCT. The concept of inducing immune tolerance with posttransplant cyclophosphamide was introduced by Berenbaum and Brown in 1963, showing that the life of a skin allograft can be prolonged with the use of HDPTCy administered 1 to 3 days after the graft (¹³). Mayumi et al demonstrated that microchimerism and

FIGURE 15-1 Progression-free survival at 3 years for patients with haploidentical ($n = 192$) and 8/8 matched unrelated donor ($n = 1,982$) with myeloablative conditioning (left) and reduced-intensity conditioning (right) transplantation.

robust tolerance to minor histocompatibility antigens can be achieved in mice receiving allogeneic splenic cells by intraperitoneal high-dose cyclophosphamide administered on day 2 or 3 posttransplant (¹⁴). This concept found its best applicability in allogeneic transplantation, particularly in haploidentical transplantation, where HDPTCy induces bidirectional immune tolerance by selectively eliminating the highly dividing alloreactive donor and recipient T cells generated early posttransplant in the setting of a human leukocyte antigen (HLA) mismatched transplant, with decreased rates of GVHD and graft rejection (¹⁵). HDPTCy spares stem cells (due to high levels of aldehyde dehydrogenase present in the cells), which reconstitute the recipient's hematopoiesis (¹⁶), and nondividing T cells, including memory T cells. This results in a more rapid immune recovery compared to T-cell-depleted approaches, leading to lower NRM (lower rates of infections) compared with T-cell-depleted haploSCT, as shown by our group (¹⁷).

We have used HDPTCy since 2009, soon after the first human trials showed the safety of this approach (¹⁸). Initial studies used a nonmyeloablative conditioning regimen with fludarabine, cyclophosphamide, and 2-Gy TBI, which was associated with a low incidence of grades 2 to 4 aGVHD (35%) and NRM (15%) at 1 year. However, a higher relapse rate was observed (¹⁸). We then hypothesized that more intense conditioning is needed and can be tolerated, especially for patients with leukemia, and used our melphalan-based conditioning regimen (with fludarabine 120 mg/m², melphalan 100 to 140 mg/m² with thiotepa 5 to 10 mg/kg [subsequently changed to 2-Gy TBI]) previously used in T-cell-depleted haploSCT, which had been effective in inducing remission in most patients with leukemia even with advanced disease (^{12,17}). Updated results for the first 100 patients treated with this regimen showed 3-year PFS rates of 56% to 62% for patients with myeloid malignancies (acute myelocytic leukemia [AML] in complete remission 1/2, myelodysplastic syndrome and chronic myelocytic leukemia in chronic phase) and lymphoma, and 1-year NRM rates of 12% and 22%, respectively (¹⁹).

With haploSCT, outcomes improved significantly; we and others have subsequently compared transplant outcomes of patients treated with a haploidentical versus a matched related donor or a MUD (²⁰⁻²²). These single-institution studies uniformly showed similar outcomes with haploidentical transplant with HDPTCy and HLA-matched donor SCT (²⁰⁻²²). To confirm these findings, we compared outcomes of haploidentical with MUD transplants using the Center for International Blood and Marrow Transplant Research (CIBMTR) database. This retrospective analysis of 2,174 patients with AML showed similar 3-year PFS with haploidentical transplants performed

with HDPTCy and MUD transplants (41% vs 42% for myeloablative, $P = .87$; 35% vs 37% for reduced-intensity conditioning [RIC], $P = .89$, respectively) (see Fig. 15-1). The incidence of grades 2 to 4 aGVHD was lower for haploidentical compared with MUD transplants (21% vs 42% for myeloablative, 25% vs 35% for RIC) (²³). Our group has proposed a large prospective multicenter study comparing transplant outcomes using haploidentical and MUDs to the Bone and Marrow Transplant Clinical Trials Network group.

GRAFT ENGINEERING

Several research strategies are being investigated to optimize the haploidentical graft, maximize immune recovery, and minimize GVHD posttransplant. One promising approach is changing complete T-cell depletion to selective depletion of alpha/beta T cells capable of eliciting GVHD while preserving in the graft memory T cells and gamma-delta T cells (¹¹). It is currently thought that the gamma-delta T cells possess innate and adaptive immune responses and can function without requiring antigen processing or HLA presentation, making them unlikely to generate GVHD (²⁴). Methods to deplete alpha-beta T cells and leaving the gamma-delta subsets intact are being investigated, with encouraging results (²⁵). Other novel approaches involve depletion of naïve T cells (CD45RA⁺) thought to play a major role in the development of GVHD in mouse models (²⁶⁻²⁸) or administration of T-regulatory cells along with the T-cell-depleted graft. These may further reduce the risk of aGVHD and reduce the rate of relapse (²⁹). Future trials will explore these approaches at MDACC, as they may control GVHD and facilitate rapid immune recovery without posttransplant immunosuppression.

POSTTRANSPLANT CELLULAR THERAPY TO PREVENT DISEASE RELAPSE

With significant improvements in NRM, disease relapse remains the major cause of death in patients undergoing haploSCT. Several approaches are under investigation at our institution to prevent and treat disease relapse posttransplant (Table 15-2).

Unmodified Donor Lymphocyte Infusion

The readily available haploidentical donors can be sources of posttransplant donor lymphocyte infusion (DLI) administered to prevent or treat early relapse. There is a theoretical higher risk of inducing severe aGVHD with haploidentical DLI; however, the

Table 15-2 Posttransplant Cellular Therapies Aimed at Decreasing Disease Relapse in HaploSCT

Approach	Rationale	Pitfalls
Unmodified donor lymphocyte infusion (DLI)	<ul style="list-style-type: none"> To fight disease relapse via harnessing graft-versus-malignancy effect 	<ul style="list-style-type: none"> Limited experience in haploSCT Potential for GVHD precipitation Not targeted to specific antigen(s)
Engineered donor lymphocytes with a safety suicide switch	<ul style="list-style-type: none"> To fight disease relapse via harnessing graft-versus-malignancy effect Safety switch allows T-cell suicide in case of GVHD development 	<ul style="list-style-type: none"> Not targeted to specific antigen(s) Clinical efficacy not yet demonstrated
Gamma-delta DLI	<ul style="list-style-type: none"> Infusion of selected gamma-delta T cells No GVHD potential 	<ul style="list-style-type: none"> Graft-versus-malignancy effect not yet demonstrated
T cells with chimeric antigen receptors (CAR-T)	<ul style="list-style-type: none"> T cells engineered to recognize specific antigens (eg, CD19) provide graft-versus-malignancy effect without GVHD 	<ul style="list-style-type: none"> Clinical efficacy after haploSCT not yet demonstrated
Infusion of ex vivo expanded NK cells	<ul style="list-style-type: none"> Potential graft-versus-malignancy effect without GVHD 	<ul style="list-style-type: none"> Clinical efficacy has not yet been demonstrated

incidence of GVHD was not higher than in matched transplants, possibly due to the tolerizing effect of HDPTCy⁽³⁰⁾. Among 40 patients with hematological malignancies relapsed after a haploSCT who received unmodified haploidentical DLI ($1 \times 10^6/\text{kg}$ CD3⁺ T cells), aGVHD was noted in 25% (grades III-IV aGVHD in 15%). A third of patients achieved a complete response with a median duration of response of 12 months. Most patients received cytoreductive therapy prior to the DLI infusion. Thus, cellular therapy with haploidentical DLI can be effective posttransplant, and future approaches should improve the safety and efficacy of DLI.

Modified Donor Lymphocyte Infusion Using T Cells With a Safety Switch (Suicide Gene)

One approach to control aGVHD post-DLI would be to insert a suicide gene in the haploidentical donor T cells. If significant aGVHD occurs, a “safety off switch” can “turn off” these T cells and avoid excessive aGVHD. This approach has so far been investigated to boost posttransplant immune recovery after T-cell-depleted haploidentical grafts. Ciceri et al infused DLI engineered T cells to express herpes simplex virus–thymidine kinase suicide gene (can be triggered by ganciclovir to induce apoptosis)⁽³¹⁾. The aim was to boost posttransplant immune reconstitution by adding back T cells after a complete or partial T-cell-depleted haploSCT. Grades 1 to 4 aGVHD developed in 20% of patients and was successfully terminated by inducing the suicide gene with ganciclovir. However, ganciclovir may not be the ideal drug in this setting given that it is commonly used posttransplantation to control cytomegalovirus reactivation. Another approach is to use DLI engineered to express an inducible caspase-9

transgene⁽³²⁾. This gene can be induced by a synthetic dimerizing drug, leading to rapid cell death. In a preliminary experience in ten patients, aGVHD developed in five patients and was rapidly reversed with the use of the dimerizing drug.

Chimeric Antigen Receptor T Cells

While the DLI offers nonspecific antitumor activity, the effect is nontargeted. A potential game changer has been the introduction of T cells engineered to express a chimeric receptor, with an extracellular domain that can recognize a specific antigen and an intracellular domain that can activate the cytotoxic T cell. This approach has demonstrated significant activity in tumors expressing CD19, such as acute lymphoblastic leukemia (ALL) or B-cell lymphomas. Maude et al used autologous chimeric antigen receptor (CAR) T cells against CD19 (CTL019) in 30 patients with relapsed-refractory ALL, and complete remission occurred in 90% of patients. They demonstrated that CTL019 cells proliferated in vivo and were detectable in the blood, bone marrow, and cerebrospinal fluid of patients who responded⁽³³⁾. We are exploring the use of CAR T cells early after haploidentical transplantation to prevent disease relapse, part of a multiarm clinical trial⁽³⁴⁾. Our center is the only center so far using CAR T cells after haploidentical transplantation. Four patients (three with ALL and one with diffuse large B-cell lymphoma) received CAR T cells generated using the Sleeping Beauty system. The lymphoma patient achieved remission for the first time after transplant and infusion of CAR T cells. Three of these four patients remained in remission at last follow-up. These results are promising and showed that allogeneic CAR T-cell therapy can be safely given without significant GVHD.

Natural Killer Cells and Killer Immunoglobulin-Like Receptor Mismatch

Natural killer (NK) cells are part of the innate immune system and normally are involved in identifying and killing tumor cells or virally infected cells. The NK cells recognize and target “foreign” cells that lack one or more HLA class I alleles specific to the inhibitory receptors (killer immunoglobulin-like receptors, KIRs) ⁽³⁵⁾. The NK cells do not contribute to GVHD as they target hematopoietic cells sparing other body organs, making them ideal in the transplant setting. This was first observed in the T-cell-depleted setting, where patients with a KIR “mismatch” had a lower incidence of relapse ⁽³⁶⁾. There is great interest in this field to identify haploSCT donors with a KIR mismatch to possibly maximize the graft-versus-tumor effects. Several studies suggested a lower risk of relapse with donors who possess specific activating KIR genes, such as KIR2DS1, KIR2DS2, or the KIR “B” haplotype ⁽³⁷⁻³⁹⁾. We are exploring infusion of ex vivo expanded NK cells using the mb-IL21 method developed at MDACC in haploidentical transplants (protocol 2012-0708) to prevent disease relapse posttransplant in patients with myeloid malignancies ⁽⁴⁰⁾.

DONOR SELECTION FOR HaploSCT AND RISKS FROM DONOR-SPECIFIC ANTIBODIES

Multiple donors may be available to choose from in haploSCT. Several factors are considered when choosing the best donor ⁽⁴¹⁾. One of the most important factors to evaluate in these patients is the presence of anti-HLA donor-specific antibodies (DSAs) ^(42, 43). Patients may develop antibodies against foreign HLA antigens, particularly parous women or multiply transfused patients. We have shown for the first time that patients with high levels of complement fixing anti-HLA antibodies against donor HLA antigens are at high risk of graft failure ⁽⁴³⁾.

Routine evaluation of all donors with HLA mismatches has now been incorporated into standard practice worldwide. Research is currently ongoing to optimize donor selection to improve outcomes ⁽⁴⁴⁾. In general, younger donors are preferred. There is controversy whether the parent gender is important if a parental donor is needed. Some studies suggested using donors selected for maximal NK cell alloreactivity to maximize the graft-versus-malignancy effects. This includes selecting donors with KIR:KIR ligand mismatch or using KIR B haplotype donors (enriched for activating KIR) to exploit the NK cell alloreactivity and decrease relapse rate posttransplant ⁽³⁷⁾.

CONCLUSIONS AND FUTURE DIRECTIONS

The field of haploidentical stem cell transplantation has advanced significantly over the past decade with the introduction of HDPTCy and novel methods of partial T-cell depletion. These newer techniques effectively control strong alloreactive reactions in haploSCT and are associated with robust immune recovery, translating into fewer infections and lower NRM. Data from multiple retrospective studies suggested that outcomes are now comparable to MUD SCT, and this type of transplant is expanding worldwide ⁽²³⁾. Controlled clinical trials are needed to address whether haploidentical transplants are preferred over unrelated donors, at least in some clinical settings. Cellular therapy posttransplant represents a great opportunity to further modulate GVHD and graft-versus-malignancy effects. Future studies will prospectively compare haploSCT to other alternative donor sources and the incorporation of cellular therapy in the treatment of these patients.

Cellular Therapy in Allogeneic Hematopoietic Cell Transplantation

Philip A. Thompson
Katayoun Rezvani
Partow Kebriaei

INTRODUCTION

The efficacy of allogeneic hematopoietic cell transplantation (HCT) in hematologic malignancies can in large part be attributed to a graft-versus-tumor (GVT) effect, by which the donor immune system achieves immunologic control of the tumor. As such, it is the prototype of cellular therapy. The human leukocyte antigen (HLA) system is fundamental to transplant biology. The HLAs are highly polymorphic proteins that have a key role in antigen presentation and immunoregulation. Class I HLAs are expressed on the surfaces of all nucleated cells; class II are expressed on specialized antigen-presenting cells (APCs), such as macrophages, dendritic cells, and B cells.

Peptides derived from microbes are presented on class I HLAs to CD8⁺ T cells and result in immunologic destruction of infected cells; class II HLAs are recognized by CD4⁺ T cells. T-cell activation requires costimulatory signals from the APC, specifically CD80/86 binding to CD28 or LFA-3 binding to CD2 (¹). Absence of a costimulatory signal results in T-cell anergy, which is a key mechanism of peripheral immune tolerance to self-antigen in normal immunoregulation. Early posttransplantation, there is a “cytokine storm”; release of proinflammatory cytokines, such as tumor necrosis factor alpha (TNF- α) and interleukin 6 (IL-6), is induced by tissue damage from the conditioning regimen, activating the host innate immune system (Fig. 16-1). Donor T cells interact with host APCs and recognize foreign peptides; helper T cells produce further cytokines, especially IL-2, and prime host APCs

via CD40:CD40L interaction. Differentiation of naïve donor T cells into effector cells subsequently occurs, resulting in immunologic attack on host tissues and the potential development of graft-versus-host disease (GVHD) (²). Increasing numbers of HLA mismatches are associated with higher incidence of GVHD and transplant-related mortality (TRM) (³). However, even in a fully HLA matched HCT, GVHD still occurs due to donor T cells directed against minor histocompatibility antigens (MiHAs), polymorphic peptides displayed on host HLA molecules.

There are three key barriers to successful HCT: GVHD, infectious complications, and relapse due to failure of immunologic control of the underlying disease. Herein, we review these issues in greater detail with an emphasis on recent cellular therapeutic approaches to address these complications.

ENHANCING GRAFT-VERSUS-TUMOR EFFECT TO OVERCOME TUMOR ESCAPE

Pathophysiology of the Graft-Versus-Tumor Effect

The GVT effect occurs due to a predominantly T-cell-mediated immunologic attack on tumor cells. In HLA-identical transplants, GVT effect is mediated by naïve T cells; for development of effector function, these must first be primed by host APCs. This requires the following: presentation of MiHAs or tumor-specific antigens

FIGURE 16-1 Pathogenesis of GVHD. In phase I, chemotherapy or radiotherapy as part of transplant conditioning causes host tissue damage and release of inflammatory cytokines such as $\text{TNF}\alpha$, IL-1, and IL-6, with resulting priming of host antigen-presenting cells (APCs). In phase II, host APCs activate mature donor cells, which subsequently proliferate and differentiate; release of additional effector molecules, such as $\text{TNF}\alpha$ and IL-1, mediates further tissue damage. Lipopolysaccharide (LPS) that has leaked through damaged intestinal mucosa triggers additional $\text{TNF}\alpha$ production. The $\text{TNF}\alpha$ can damage tissue directly by inducing necrosis and apoptosis in the skin and gastrointestinal tract through either TNF receptors or the Fas pathway. Tumor necrosis factor alpha plays a direct role in intestinal GVHD damage, which further amplifies damage in the skin, liver, and lung in a “cytokine storm.” The process culminates in death of host cells through CD8-positive cytotoxic T-cell-mediated apoptosis. [Reproduced with permission from Ferrara JL, Levine JE, Reddy P, Holler E. Graft-versus-host disease. *Lancet*. 2009;373(9674):1550-1561].

on HLA; appropriate costimulatory molecules, including CD28, OX40, CD40L, and 41BB; and an appropriate “third signal,” provided by IL-12, interferon gamma ($\text{IFN}\gamma$) or adjuvant (⁴). Restraining influences limiting the degree of immune activation are present to protect the host from an excessive immune response and include expression of CTLA4 (which competes with CD28 for binding to CD80/86) and programmed cell death protein 1 (PD1) and its interactions with its ligand PDL1, which limit T-cell activation and expansion during normal, pathogen-directed immune responses.

Soon after transplant, there is activation and expansion of MiHA-reactive T cells, followed by a decline,

similar to that seen in pathogen-directed immune reactions. This may in part relate to the development of peripheral tolerance/anergy and also to replacement of host hematopoiesis, with resulting loss of host APCs. For tumor-associated antigen presentation to continue, there must be cross presentation on donor APCs. In addition, the initial alloresponse to MiHAs results in recruitment of T cells targeting either tumor-associated antigens or nonpolymorphic genes, which are either overexpressed or aberrantly expressed by the tumor (⁴).

Some tumor-associated antigens of importance include pathogenesis related protein (PR1), an epitope shared by proteinase-3 and elastase proteins, which is expressed in

normal neutrophils and overexpressed in myeloid leukemias; and PR1-specific CD8⁺ T-cell responses, which can be detected in a range of myeloid and nonmyeloid malignancies post-HCT and correlate with outcome in chronic myelogenous leukemia (CML) (⁶). CD8⁺ T-cell responses to WT1, which is frequently overexpressed in acute myelogenous leukemia (AML), can be induced with vaccination strategies in both the autologous and allogeneic settings (⁶⁻⁸). Clinical responses from tumor vaccines have thus far been suboptimal.

Natural killer (NK) cells can also mediate antitumor effects; this is discussed in further detail in this chapter.

Tumor Escape From Immunologic Destruction

Tumors utilize numerous mechanisms to escape immunological destruction, including the following:

- Induction of regulatory T cells
- Production of inhibitory cytokines
- Downregulation of costimulatory molecules (⁹) and HLA I (¹⁰)
- Induction of coinhibitory molecules
- Induction of myeloid-derived suppressor cells in the microenvironment that inhibit immune responses through multiple mechanisms.
- Invasion of immunologically privileged sites (¹¹).

Cellular therapeutic approaches are designed with the intent to abrogate these escape mechanisms.

Cellular Therapy to Induce Graft-Versus-Tumor Effect

Donor Lymphocyte Infusions

Donor lymphocyte infusion (DLI) may induce remissions in patients with molecular or overt relapse of their malignancy and can reverse CD8⁺ T-cell exhaustion. (¹²). However, the likelihood of success varies significantly according to the underlying disease. Chronic myelogenous leukemia is most sensitive; follicular lymphoma (FL) and Hodgkin lymphoma (HL) are also highly responsive (^{13, 14}). Responses to DLI in AML or myelodysplastic syndrome (MDS) are less frequent, and durability is often poor. Acute lymphoblastic leukemia (ALL) is the least responsive to DLI. Reported response rates are 60% to 73% in CML, 15% to 29% in AML, and 0% to 18% in ALL (^{15, 16}).

Problems and Challenges Associated With Donor Lymphocyte Infusion

Development of Graft-Versus-Host Disease

Graft-versus-host disease occurs in 40% to 60% of patients with HCT (^{15, 16}) and is more likely to occur

in unrelated donor recipients (¹³). Lympho-depleting chemotherapy given prior to DLI enhances alloreactive T-cell proliferation, potentiating the GVT effect but increasing GVHD (¹⁷). Approaches to reduce the GVHD incidence include the following:

1. Reducing T-cell dose. A dose-response relationship exists for both GVT and GVHD effects. In CML, no increased response is seen with cell doses greater than 4.5×10^8 CD3⁺ cells/kg. In AML, response rates plateau beyond 1.5×10^8 /kg; higher doses increase GVHD. Gradual dose escalation schedules have been successfully utilized in relapses of indolent diseases. Follicular lymphoma appears highly sensitive to DLI after T-cell-depleted HCT, responding to low-dose DLI at doses from 1 to 10×10^6 /kg with less than 20% incidence of clinically significant acute GVHD (aGVHD) and chronic GVHD (cGVHD) (¹⁴). A similar strategy has shown success in HL, mainly in the setting of low-volume disease detected on surveillance positron emission tomographic (PET) imaging (¹⁸). More sensitive surveillance techniques, such as deep sequencing, to detect low-volume disease may allow earlier institution of DLI and maximize efficacy; utilization of these techniques remains experimental.
2. Transduction of donor lymphocytes with a suicide gene (¹⁹).
3. Selection of T cells to target tumor-associated antigens/antigens with restricted or differential expression (analogous to the use of viral-specific T cells [VSTs]). Infusion of MiHA-specific T cells was effective at eradicating tumor in mouse models (²⁰). In addition, tumor-infiltrating lymphocytes (TILs) recognizing tumor-associated antigens have been successfully used for selected metastatic solid tumors (²¹). However, the technology to isolate TILs remains restricted to a few specialized centers and is yet to be applied in large-scale clinical studies.

Marrow Hypoplasia

If there is insufficient residual donor hematopoiesis prior to DLI, eradication of host hematopoiesis by the infused lymphocytes can result in marrow aplasia; chimerism studies should therefore be performed prior to DLI to ensure adequate donor hematopoiesis (²²).

Delayed Onset of Action

Responses to DLI may not be seen for up to 2 months (¹¹). In indolent diseases (eg, FL), this may not be problematic, but in overt relapse of aggressive diseases (eg, AML), chemotherapy may be required first to achieve disease control (²³).

Prophylactic Donor Lymphocyte Infusion in High-Risk Patients

The delayed onset of action of DLI has led to the use of preemptive DLI to prevent relapse in high-risk patients. Mixed donor/recipient chimerism within the T-cell lineage is frequently seen in T-cell-depleted transplants and is associated with higher rates of relapse in CML (²⁴), FL (¹⁴), and HL (¹⁸), likely due to development of bidirectional tolerance with resulting tumor escape from immunologic control. Donor lymphocyte infusion can induce full donor chimerism in both FL and HL, and subsequent relapse rates are low; no formal comparison to similar groups not receiving DLI has been performed.

Bi-Specific T-Cell-Engaging Antibodies

The topic of bi-specific T-cell-engaging antibodies has been discussed in detail elsewhere. Bi-specific T-cell-engaging antibodies are single-chain antibodies that engage T cells via CD3 and direct them to an antigenic target present on tumor cells, typically CD19, resulting in T-cell redistribution, activation, expansion, and perforin-mediated killing of target cells (²⁵). Blinatumomab is highly efficacious in ALL in the setting of persistent MRD (²⁵), overt relapse, or refractory disease (²⁶).

Chimeric Antigen Receptor-Modified T Cells

The ideal cellular therapy for a malignant disease should expand and persist in vivo and selectively target cancer cells. This can be achieved by modifying autologous T cells with a chimeric antigen receptor (CAR). The CAR consists of a single-chain monoclonal antibody (scFv) targeted to a tumor-associated antigen, which is thus recognized in a major histocompatibility complex (MHC)-independent fashion (unlike unmodified T-cell-mediated GVT effect); the scFv is coupled via an extracellular hinge domain and transmembrane domain to an intracellular signaling domain, typically the CD3 ζ chain (Fig. 16-2) (²⁷). Autologous T cells are collected from peripheral blood (PB) via a steady-state blood draw or apheresis procedure and transduced with the CAR construct via a lentiviral or retroviral vector or using electroporation and a transposon/transposase system (²⁸). Cells are cultured and expanded ex vivo using either CD3/28 beads (²⁹) or artificial APCs (³⁰) and specific cytokines prior to infusion. The persistence and clinical activity of CAR T cells (CAR-T) in vivo can be enhanced by the addition of a costimulatory molecule to the CAR construct (³¹), usually CD28 (^{31,32}). An initial report in a patient with highly refractory CLL treated with an anti-CD19 CAR-T utilizing CD137 (4-1BB) as the costimulatory domain generated great excitement (³³): Infused T cells expanded more than 3 log,

FIGURE 16-2 Schematic of basic chimeric antigen receptor (CAR) construct. The CAR consists of a single-chain monoclonal antibody (scFv) targeted to a tumor-associated antigen, and the scFv is then coupled via an extracellular hinge domain and transmembrane domain to an intracytoplasmic signaling domain, typically the CD3 ζ chain.

the patient developed a cytokine-release syndrome (CRS) and tumor lysis syndrome (TLS), and achieved complete remission (CR); long-term persistence of CAR-T and persistent normal B-cell aplasia (a predictable, on-target effect when targeting CD19) were demonstrated.

Subsequent results in CLL have been heterogeneous; updated results from the University of Pennsylvania showed that 5 of 24 patients treated achieved durable CRs, 7 had partial responses (PRs), and 12 had no response (³⁴). The variables underlying response to treatment are not well understood, but in vivo CAR-T expansion is a prerequisite and appears to be more important than the dose of infused cells (³⁰). In ALL, results have been particularly impressive, with a CR rate of 86% in children treated for relapsed/refractory disease; patients were MRD negative even when tested with highly sensitive deep-sequencing techniques (³⁴). Long-term survival rates are not yet known, particularly as in many cases the treatment has been used as a “bridge to transplant.” At least two patients with ALL have relapsed with CD19-negative disease (³⁴). Similarly impressive CR rates have been reported by the groups at the National Institutes of Health (³⁵) and Memorial Sloan Kettering Cancer Center (³⁶). All three groups reported a similar toxicity profile (see Table 16-1). It is unclear whether this treatment can replace HCT in a proportion of patients; long-term survival outcomes in

Table 16-1 Summary of Reported Studies Using Chimeric Antigen Receptor (CAR) T Cells Directed Against CD19 in Hematologic Malignancies

Reference	Cancer	CAR Endodomains	Number of Patients	Clinical Outcome	Toxicities

Abbreviations: CLL, chronic lymphocytic leukemia; DLBCL, diffuse large B-cell lymphoma; CR, complete response; CRI, complete response with incomplete count recovery; NE, not evaluable; NHL, non-Hodgkin lymphoma; NR, no objective response; PMBCL, primary mediastinal B-cell lymphoma; PR, partial response; SD, stable disease; SIRS, systemic inflammatory syndrome; SMZL, splenic marginal zone lymphoma, TLS, tumor lysis syndrome.

patients ineligible for HCT will be important in answering this question. The CAR-T targeting CD19 have now been used in a range of B-cell malignancies, with responses seen in both aggressive and indolent lymphomas, CLL, and ALL (Table 16-1).

While this therapy shows great promise, many aspects require optimization. Due to the heterogeneity in technique for CAR-T production, it is difficult to compare across trials to determine optimal manufacturing methods. The controversies are numerous: First, while it has been shown that addition of a costimulatory domain to the CAR enhances expansion and persistence ⁽³¹⁾, it is unclear whether CD28 or 4-1BB, or both, is superior. Second, lympho-depleting chemotherapy may enhance CAR-T expansion and persistence ⁽³²⁾, but the optimal drugs and schedule are unknown. Third, the epitope targeted by the antibody fragment

is likely important, in terms of both the spatial location of epitope binding and binding affinity. Fourth, the hinge and transmembrane domains are important in determining interaction with antigen and formation of the immunologic synapse, but little is known about optimizing this aspect of the CAR design. Fifth, the method of T-cell transduction (viral vs transposon) may be important in determining efficacy. Sixth, the ex vivo culture technique and duration (eg, CD3/28 beads vs artificial APCs and which supplemental cytokines to provide) may be important; for example, culture after transduction using the Sleeping Beauty system is relatively prolonged, which is problematic in kinetically active diseases such as ALL ⁽³⁷⁾. The dose and composition (unselected vs specific ratios of CD4/8 cells) of T-cell product infused are also variables requiring consideration. Finally, the bulk of tumor present at the

time of CAR-T infusion may potentially affect the in vivo proliferation of the infused CAR-T, and the ideal time of infusion (eg, in an MRD state vs overt relapse) has not been elucidated.

Adverse Events and Optimizing Safety

All responding patients have had some degree of CRS and have developed B-cell aplasia⁽³⁸⁾. Cytokine-release syndrome is characterized by fever with variable systemic symptoms, including hypotension, and high levels of inflammatory cytokines, of which IL-6 appears particularly important⁽³⁷⁾. Macrophage activation syndrome (MAS) may accompany CRS. Major neurological symptoms, including seizures, have occurred. The mechanism of neurological events is unclear; it may be cytokine mediated, associated with MAS, or due to direct CAR-T infiltration. Unexpectedly, CD19 CAR-T have been found in the cerebrospinal fluid of some patients without central nervous system disease⁽³⁷⁾. Cytokine-release syndrome can be managed with the anti-IL-6 antibody tocilizumab, with prompt responses in the majority of patients⁽³⁷⁾. Corticosteroids, while potentially efficacious in managing CRS/MAS, are toxic to the infused cells and may limit efficacy.

Unanticipated on-target toxicity may occur; for example, a toxic death occurred in a patient treated with a CART-T directed against Human Epidermal Growth Factor Receptor 2, or ErbB2, due to unanticipated low-level pulmonary epithelial expression⁽³⁹⁾. The inclusion of a suicide gene within the CAR, such as inducible caspase 9 (iCaspase9), which could be triggered in the event of severe toxicity, would provide an added safety measure.

Most human trials to date have focused on CD19 as a target in B-cell diseases, but a number of novel targets show potential in different diseases.

Adoptive Transfer of Natural Killer Cells to Enhance Antitumor Effect

In contrast to T and B lymphocytes, NK cells do not express rearranged, antigen-specific receptors; rather,

NK effector function is dictated by the integration of signals received through germ-line-encoded receptors that can recognize ligands on their cellular targets. Functionally, NK cell receptors are classified as activating or inhibitory. Natural killer cell function, including cytotoxicity and cytokine release, is governed by a balance between inhibitory receptors, notably the killer immunoglobulin-like receptors (KIRs) and the heterodimeric C-type lectin receptor (NKG2A), and activating receptors, in particular the natural cytotoxicity receptors (NCRs) NKp46, NKp30, NKp44, and the membrane protein NKG2D⁽⁴⁰⁾. Inhibitory receptors bind to HLA class I molecules, expressed on the surface of normal cells, resulting in signals that block NK cell triggering and inhibit killing. In the setting of malignancy or viral infection, HLA class I is often downregulated or has altered peptide expression, resulting in failure of KIR-mediated recognition by the NK cell and resultant cell killing⁽⁴⁰⁾. Activating receptors, such as NKG2D, bind ligands that are induced by cellular stress (eg, viral infection and malignant transformation); binding results in NK cell activation and target lysis⁽⁴¹⁾ (Fig. 16-3).

Early NK cell recovery (within 30 days) postallogeic stem cell transplant has been associated with reduced rates of both relapse and aGVHD, with resultant improved survival⁽⁴²⁾. This dual benefit makes allogeneic NK cells an attractive option for adoptive cellular therapy peritransplant. Adoptive transfer of NK cells has previously been limited by the small numbers of circulating NK cells (5%-15% of the total lymphocytes) and consequently the low numbers obtained in an apheresis procedure⁽⁴³⁾.

Use of allogeneic NK cells may be more efficacious than autologous NK cells due to inhibition of autologous NK cell activity by recognition of host HLA. Adoptive transfer of ex vivo-expanded haploidentical NK cells after lympho-depleting chemotherapy is safe. High-dose, but not low-dose, chemotherapy facilitates in vivo NK cell expansion, likely due to both prevention of host T-cell-mediated rejection and reduction in

FIGURE 16-3 Selective killing of transformed cells by NK cells: In normal cells, the inhibitory signals triggered by KIR-HLA-I molecule engagement overrides activating signals. In the context of cancer, expression of stress ligands for activating receptors, in conjunction with low expression of HLA-I molecules, attenuates the triggering of inhibitory receptors and results in an activating signal.

competition for cytokines, particularly IL-15. Persistence for at least 4 weeks has been achieved in some patients and responses have been observed in high-risk AML without inducing GVHD (⁴⁴). The NK cell expansion *ex vivo* has traditionally included culture with cytokines (IL-2 or IL-15) and cell selection (CD3 depletion) (⁴⁴); the use of “feeder cells” (Epstein-Barr virus [EBV]–transformed lymphoblastic cell lines or gene-modified, irradiated K562 cells), and large-scale expansion flasks have dramatically increased NK cell yield and activation status. Clinically relevant NK cell numbers can be obtained from both cord blood (CB) and adult donors (⁴³). The CB-derived NK cells show a similar phenotype and are similarly active against leukemic targets as PB-derived NK cells (⁴⁵).

There are several potential limitations of NK cell adoptive transfer, particularly limited persistence and the potential for passenger lymphocyte-related complications. The NK cells may rapidly develop exhaustion *in vivo* after adoptive transfer, despite initial expansion and activity (⁴⁶). In part, this may relate to NK cells’ exquisite sensitivity to cytokines such as IL-2 and IL-15. *In vivo* use of IL-2 (which can expand NK cell numbers) can lead to severe toxicity and to T-regulatory (T-reg) expansion, which limits NK cell activation (⁴⁷). In contrast, IL-15/IL-15R α complexes promoted NK cell activation and enhanced function without the detrimental effects of IL-2 (⁴⁸). Whether *in vivo* use of IL-15/IL-15R α will rescue NK cells from this phenomenon is not known. Lymphocyte contamination of the infused product can be avoided by proper selection techniques. T-cell contamination should be limited to less than 1 to 5×10^5 /kg (⁴⁹) to minimize the risk of GVHD; this can be achieved by CD3 depletion (⁴⁴). Addition of CD56⁺ selection reduces B-cell contamination to less than 1%, minimizing passenger B-lymphocyte-mediated EBV-posttransplant lymphoproliferative disorder (PTLD) and acute hemolytic anemia (⁵⁰).

Optimizing Natural Killer Cell Efficacy

The NK cells have a range of highly polymorphic KIRs, which are divided into inhibitory and activating subtypes. The KIRs are inherited as haplotypes (KIR-A and KIR-B). The KIR-A haplotypes, found in one-third of adult Caucasians, have one activating receptor, while the KIR-B haplotypes have 2 or more. Transplantation in AML from a KIR-B haplotype donor is associated with lower relapse rates and superior survival (⁵¹). Donor KIR2DS1 (an activating KIR) and recipient HLA-C type influence relapse risk. The KIR2DS1-associated reduction in the rate of AML relapse is restricted to donors with HLA-C1/C1 or C1/C2, in whom KIR2DS1-expressing NK cells are presumed to be “educated,” and the benefit was eliminated in transplants from donors with HLA-C2/C2,

where KIR2DS1-expressing NK cells are expected to be tolerized in the setting of self HLA-C2 (⁵²). Selection of adult or CB donors for *ex vivo* NK cell expansion based on KIR genotype may therefore enhance NK cell efficacy.

Other future strategies to enhance NK cell tumor killing include the use of immunomodulatory drugs such as lenalidomide and the use of bi-specific killer engagers (BiKEs), which consist of a single-chain Fv against CD16 and a tumor-associated antigen. A CD16x33 BiKE has been shown to have activity in refractory AML (⁵³).

PD1/PDL1 Antibodies

Interaction of PD1/PDL1 induces T-cell dysfunction in CLL (⁵⁴). Anti-PD1 antibodies are efficacious in a subset of patients with metastatic solid tumors as monotherapy and in combination with the anti-CTLA4 antibody ipilimumab (⁵⁵). They have also shown remarkable activity in relapsed/refractory HL (⁵⁶).

The potential importance of immune checkpoints has been demonstrated in AML. CD8⁺ T-cell responses directed against the MiHA Liver receptor homolog-1 (LRH-1) have resulted in remission post-DLI. Despite persistence of CD8⁺ T-memory cells specific for LRH-1, subsequent relapse with LRH-1-positive blasts occurs, unaccompanied by LRH-1-specific T-cell expansion, suggesting anergy/functional impairment. LRH-1-specific T cells from patients with relapsed AML have elevated levels of PD-1. The addition of anti-PD1 antibody to a coculture system resulted in marked LRH-1-specific T-cell expansion, IFN- γ production and cytotoxicity, suggesting a specific inhibitory effect induced by the PD-L1/PD1 interaction (⁵⁷). Blockade of the PD-L1/PD1 axis may therefore represent an immunomodulatory target for patients with persistent/relapsed AML post-alloHCT.

REDUCING GRAFT-VERSUS-HOST DISEASE

Cellular Therapy for Prevention of Graft-Versus-Host Disease

Grades II-IV aGVHD occur in 25% to 60% of matched related donors and 45% to 70% of MUDs (⁵⁸). Corticosteroid-based therapy for grades II-IV aGVHD is unsatisfactory, with fewer than 50% of patients showing a durable complete response (⁵⁹). Increasing severity of aGVHD is associated with incremental TRM and inferior survival. Corticosteroid-refractory GVHD has a poor prognosis. Numerous additional agents have been studied in combination with corticosteroids or as second line therapies and showed uniformly poor response rates and numerous complications,

particularly viral reactivation⁽⁵⁹⁾. Prevention of GVHD is therefore of paramount importance.

T-Cell Depletion

A T-cell-replete transplant usually contains 1 to 5×10^7 T cells/kg recipient weight⁽⁵⁸⁾. T-cell depletion is the most potent method of preventing aGVHD but is associated with increased rates of graft rejection; delayed immune reconstitution; infectious complications, including EBV-driven PTL; and increased relapse risk⁽⁵⁸⁾. T-cell depletion can be accomplished *ex vivo* immunologically (T-cell antibodies, positive CD34 selection) or by the use of physical separation (eg, density gradients) or *in vivo* by the use of anti-T-cell antibodies such as antithymocyte globulin (ATG) or alemtuzumab. *In vivo* T-cell depletion with ATG reduces severe aGVHD and extensive cGVHD without increasing relapse but does not reduce TRM or improve survival⁽⁶⁰⁾, likely due to increased infection risk. Alemtuzumab-based GVHD prophylaxis achieves low rates of severe aGVHD and extensive cGVHD, but results in high rates of mixed chimerism and viral infections, particularly cytomegalovirus (CMV) reactivation⁽⁶¹⁾.

T-Cell Depletion With Planned Postengraftment Donor Lymphocyte Infusion Utilizing a “Suicide Gene” in the Infused T Cells

Transduction of donor T cells with a “suicide gene,” which can be activated in the event of developing severe aGVHD, may enhance the safety of adoptively transferred cellular therapy products. One method involves incorporating a herpes simplex virus thymidine kinase (HSV-TK) within the cellular product. Ganciclovir, a prodrug, is then administered, activated by HSV-TK and incorporated into replicating DNA, inhibiting DNA polymerase and resulting in cell death. Patients given HSV-TK-transduced DLI from haploidentical donors who developed GVHD had prompt resolution of GVHD after ganciclovir administration⁽⁶²⁾.

A more recent technique involves T-cell transduction with an inducible human caspase 9 protein, modified to remove its endogenous caspase activation and recruitment domain and conjugated to a sequence of human FK-binding protein, which binds to an otherwise-inert dimerizing agent, AP1903. Dimerization of the iCaspase9 protein by AP1903 activates the intrinsic apoptotic pathway and induces apoptosis. A pilot study using this technique in patients undergoing haplo-HCT showed robust *in vivo* expansion of gene-modified T cells and 90% and 99% killing of transduced cells within 30 minutes and 24 hours of AP1903 administration, respectively^(19, 63). Concurrently, manifestations of aGVHD in both skin and liver rapidly resolved. Intriguingly, alloreactive T cells were

preferentially eliminated by the dimerizing agent, potentially due to greater expression of the transgene in these cells. There was relative sparing of antiviral T cells, with polyclonal CD3/19⁺ transduced T cells with antiviral specificity detectable within 1 to 2 weeks postadministration of AP1903.

Adoptive Transfer of Regulatory T Cells

The level of CD4⁺CD25⁺FOXP3⁺ T-reg cells in the graft and after HCT correlates inversely with aGVHD and cGVHD⁽⁶⁴⁾. Adoptive transfer of T-reg cells could therefore ameliorate GVHD.

The most efficient method for obtaining a pure T-reg population is sorting based on flow cytometry. Some effector T cells will be present in the product if CD4⁺/CD25⁺(high) cells are selected. Removal of CD127 (IL-7R)-positive cells, which are not expressed on T-reg cells, achieves a more purified product⁽⁶⁵⁾. Following sorting, T-reg cells can be expanded using CD3/28-coated microbeads and IL-2 and maintain suppressive function^(66, 67). Murine xenogenic GVHD models have shown that infusion of human CB-derived T-reg cells confers protection from aGVHD and improves survival⁽⁶⁸⁾.

Potential concerns with T-reg cell infusions relate to impairment of immune reconstitution and GVT effect. However, by inhibiting GVHD-mediated thymic destruction⁽⁶⁹⁾, T-reg cells may actually facilitate functional immune reconstitution⁽⁷⁰⁾. Indeed, immune function is preserved in murine models of T-reg cell infusion⁽⁷¹⁾. Data from mouse models regarding impairment of GVT effect is contradictory. Tumor regression after IL-2–diphtheria toxin–mediated T-reg cell depletion was seen in one model, suggesting that T-reg cells may adversely affect disease control⁽⁷²⁾.

In contrast, simultaneous adoptive transfer of T-reg cells and unselected donor T cells in a mismatched murine transplant model showed protection from GVHD without impairing tumor control⁽⁷³⁾. Timing of adoptive transfer is likely important; efficacy may be greatest if infused peritransplant to limit initial alloreactive T-cell expansion rather than if infused to treat established aGVHD⁽⁷⁴⁾. An early-phase clinical trial has shown posttransplant adoptive transfer of T-reg cells to be safe, with a reduction in risk of grades II–IV aGVHD relative to historical controls and similar disease-free survival⁽⁷⁵⁾. In this study, there did not appear to be an excess risk of disease relapse or infection.

PREVENTING AND TREATING INFECTION

Delayed recovery of cellular and humoral immunity results in morbidity and mortality from infection. Figure 16-4 shows the approximate time course of

FIGURE 16-4 Time course of numeric cellular immune recovery posttransplant. [Reproduced with permission from Mackall C, Fry T, Gress R, et al. Background to hematopoietic cell transplantation, including post transplant immune recovery. *Bone Marrow Transplant.* 2009;44(8):457-462.]

numeric recovery of immune cells post-HCT; Fig. 16-5 shows the time course of infections.

Cellular Therapy for the Prevention and Treatment of Infectious Complications Postallogeneic Stem Cell Transplantation

Viral infection is a major cause of mortality post-HCT, resulting from cellular and humoral immune deficiency;

risk factors include umbilical CB transplantation, T-cell depletion, and GVHD requiring systemic immunosuppression. Viral infections of particular relevance post-HCT are CMV, EBV, the polyoma virus BK, adenovirus (ADV), and human herpesvirus 6 (HHV-6). Pharmacotherapy for these infections has limited efficacy and substantial toxicity^(76,77). Consequently, adoptive immunotherapy for the treatment and prevention of viral reactivation/infection postallograft is attractive.

FIGURE 16-5 Time course of infections posttransplant. [Reproduced with permission from Mackall C, Fry T, Gress R, et al. Background to hematopoietic cell transplantation, including post transplant immune recovery. *Bone Marrow Transplant.* 2009;44(8):457-462.]

General Principles of Generating Viral-Specific T Cells

Generation of VSTs is most straightforward from an immune-experienced, adult donor who will have viral-specific memory T cells specific in their PB. The VSTs from such donors can be generated in two ways ⁽⁷⁸⁾:

1. T-cell coculture, in the presence of specific cytokines, with an artificial APC modified to express the immunodominant antigens of the target virus and costimulatory molecules. Rapid culture techniques using overlapping peptide pools rather than live virus have shortened culture time to 7 to 14 days.
2. Rapid selection strategies without ex vivo culture. These rely on the presence of sufficient numbers of VSTs in the donor PB and hence are limited to CMV and EBV ⁽⁷⁹⁾.

Generation of VSTs from immunologically naïve donors (eg, CB) is more challenging. However, multivirus-specific T cells against EBV, CMV, and ADV can be generated from naïve CB cells by genetically modifying EBV lymphoblastoid cell lines transduced with an adenoviral vector expressing the CMVpp65 transgene ⁽⁷⁹⁾. These are highly active against virus, despite recognition of noncanonical CMV and EBV epitopes ⁽⁷⁹⁾, and early clinical results are encouraging ⁽⁸⁰⁾.

Third-party, banked VSTs from adult donors could also be used to treat viral reactivation in patients without an available adult donor or in whom rapid disease progression precludes waiting for generation of VSTs from their donor. Suitable lines (which are dependent on the recipient expressing immunodominant viral peptides on an HLA antigen shared by a donor VST line) are available in approximately 90% of patients and can be rapidly identified and made available. In an early-phase clinical trial, these VSTs demonstrated high response rates in patients with refractory CMV, ADV, and EBV-related PTLD ⁽⁸¹⁾. Interestingly, despite the theoretical risk of inducing GVHD due to HLA mismatch, no severe cases of de novo aGVHD were seen in initial studies, and re-treatment was successful in several cases despite initial immunologic rejection of the transferred cells ⁽⁸¹⁾.

Five virus-specific T cells (EBV, CMV, ADV, BK, and HHV-6) can now be produced from adult donors after culture with a peptide mix containing immunodominant antigens of the FIVE viruses ⁽⁸²⁾.

Treatment of Specific Infections With Viral-Specific T Cells

Epstein-Barr Virus Reactivation and Posttransplant Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder related to EBV occurs in the setting of severe transplant-related immunosuppression when the EBV-specific T-cell

response is insufficient to control latent EBV infection within recipient or donor B cells. The biology and pathology of EBV-related PTLT have been reviewed previously ⁽⁸³⁾. Risk factors for infection predominantly relate to the degree of immunosuppression in recipients of T-cell-depleted transplants. Patients typically present with high fever and lymphadenopathy, with an elevated serum lactate dehydrogenase ⁽⁸³⁾.

Initial therapy for EBV reactivation is reduction in immunosuppression ⁽⁸³⁾. However, there are no randomized studies to guide the best therapy of established EBV-associated PTLT. In patients with frank PTLT, the largest study ⁽⁸⁴⁾ showed a 70% CR/CRu rate with four weekly doses of rituximab monotherapy, but there were poor responses to subsequent treatment (chemotherapy, DLI, or both) in nonresponders. Chemotherapy is associated with greater toxicity in HCT recipients and may increase infection risk.

Cellular therapy shows great promise in the management of EBV-related PTLT. Unmanipulated donor T-cell infusions can control established PTLT in approximately 70% of patients but can induce severe or fatal GVHD ⁽⁸⁵⁾. Therefore, when available, VSTs are preferred. The EBV-specific or polyvirus-specific cytotoxic T lymphocytes (CTLs) can be generated as described previously and have proven successful in overt PTLT in over 80% of patients, including patients with rituximab-refractory disease ⁽⁷⁶⁾. **Figure 16-6** demonstrates a dramatic clinical response in a patient with chemorefractory PTLT to infusion of EBV-specific CTLs.

Cytomegalovirus Infection

Risk factors for CMV reactivation and disease post-HCT include receiving umbilical CB grafts, T-cell-depleted grafts, T-cell antibody therapy for GVHD prophylaxis, or high-dose steroids ⁽⁸⁶⁾. In addition, CMV-seropositive patients with seronegative donors are at particularly high risk due to the lack of memory T cells against CMV from the seronegative donor ⁽⁸⁶⁾. While ganciclovir prophylaxis reduces the risk of CMV disease, it prolongs neutropenia, increases invasive bacterial and fungal infections, and does not improve survival ⁽⁸⁶⁾. Close monitoring for CMV reactivation in blood, followed by preemptive therapy with ganciclovir when assays in blood become positive, reduces the incidence of CMV disease. Overall, rates of CMV disease have declined from 30% to 35% to 8% to 10% with ganciclovir prophylaxis or preemptive therapy ⁽⁸⁶⁾. Gastrointestinal disease, pneumonia, and retinitis are the most common manifestations; pneumonia has a high mortality despite treatment with ganciclovir or foscarnet and CMV-immunoglobulin ⁽⁸⁶⁾. Given the toxicity and expense associated with pharmacological interventions and their imperfect efficacy, cellular

FIGURE 16-6 A patient with posttransplant EBV PTLD treated with allogeneic, most closely HLA-matched CTL against multivirus (EBV, adenovirus, CMV) (⁸¹). Left panel: pretreatment; right panel: posttreatment.

therapy as treatment or prophylaxis of CMV in high-risk patients is attractive.

Adenovirus Infection

Adenovirus infection occurs in up to 21% of transplant recipients, with manifestations of adenovirus disease in 20% to 89% of infected patients (⁸⁷). Four clinically significant syndromes are seen: pneumonitis, nephritis, hemorrhagic colitis, and hemorrhagic cystitis. Disseminated disease with multiorgan failure also occurs and has a poor outcome despite antiviral therapy; most successfully treated cases are respiratory or urinary tract infections. The ADV-specific T cells can now be generated from both CB (^{79, 80}) and adult donors (⁸⁸), with a high clinical response rate in cidofovir-refractory cases. Rapid isolation strategies are not applicable for generation of ADV-specific CTLs due to the low numbers of circulating ADV-specific T cells in donor blood.

BK Virus Infection

BK virus reactivation occurs in 5% to 68% of hematopoietic stem cell transplantation recipients. It can cause severe hematuria, urinary obstruction, renal failure, and increased mortality. It is more frequent in patients with grades III and IV aGVHD and Umbilical cord blood transplant (UCBT) recipients (⁸⁹). Pharmacologic therapy is toxic and poorly efficacious. BK virus-specific CTLs can be generated from PB, but rapid overnight generation is not possible due to the low frequency of BK virus-specific T cells in PB; hence, culture with peptide mix or APCs is required for generation.

Human Herpes Virus 6 Infection

Infection with HHV-6 is virtually universal before age 2 years (⁹⁰). Reactivation occurs in more than 50% of allograft recipients and can result in encephalitis, delayed engraftment, and increased rate of GVHD, with increased mortality (⁹⁰). Production of HHV-6 VSTs using a peptide mix and 10-day culture with IL-4 and IL-7 is possible from adult donors with prior exposure (⁹⁰). Production of HHV-6-specific VSTs has yet to be performed from CB, and rapid isolation methods are not possible given the low frequency of VSTs in blood. Clinical studies of five virus-specific CTLs (EBV, CMV, ADV, BKV, and HHV-6) are ongoing (NCT 01570283).

CONCLUSION

Allogeneic HCT, initially performed in a twin patient with leukemia by Dr. E. Donnall Thomas in the late 1950s, was one of the first elegant demonstrations of the power of cellular therapy. Much has been learned since then, and our increased understanding of the immune system has translated into exciting new therapeutic approaches, especially relevant to transplantation, leading to continued better outcomes for patients.

INTRODUCTION

Small cell lung cancer (SCLC) is an aggressive bronchogenic carcinoma diagnosed in 14% of all patients with lung cancer, accounting for approximately 30,000 new cases annually in the United States ⁽¹⁾. It is distinguished from non-small cell lung cancer (NSCLC) by its rapid doubling time, high proliferative fraction, and early development of metastases. Regional lymph node involvement or distant metastasis is present in 90% or more of patients at diagnosis. Historically, SCLC has been staged as limited disease (LD), which is confined to the ipsilateral thorax of origin and regional nodes, versus extensive disease (ED). The recent International Association for the Study of Lung Cancer (IASLC) staging project and American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) seventh edition suggest use of the tumor, node, metastasis (TNM) system for the staging of SCLC ⁽²⁾. Clinically, the limited- and extensive-stage classification is practical given that most patients present with advanced disease (stages III-IV) and are only rarely candidates for resection.

Standard treatment for LD (stages I-IIIb) includes both chemotherapy and radiation; chemotherapy is the mainstay of treatment for ED (stage IV). Although a dramatic response to initial therapy is usually observed, greater than 95% of patients with ED and 80% to 90% of those with LD eventually suffer relapse and die of their disease.

Despite extensive research, no substantive advances in the systemic treatment of SCLC have been made for

decades. Molecular profiling and preclinical models of SCLC have increased our understanding of the biology and genomic changes in the pathogenesis of SCLC. Translation of preclinical research to the clinical arena has resulted in recent promising data with targeted therapies, providing hope that improved outcomes for patients is on the horizon.

EPIDEMIOLOGY

Small cell lung cancer is uncommon in never smokers, who constitute only 3% to 5% of cases, and is commonly associated with intense tobacco exposure ⁽³⁾. However, transformation to SCLC has been recently documented in never smokers with epidermal growth factor receptor (*EGFR*)-mutation positive adenocarcinoma of the lung, in the setting of resistance to tyrosine kinase inhibitors ⁽⁴⁾. The original *EGFR* mutation is maintained in the SCLC, supporting the notion that the tumor evolved from transformation and is not a second primary cancer.

The incidence of SCLC has steadily declined, as illustrated by an analysis of the Surveillance, Epidemiology, and End Results (SEER) database ⁽¹⁾, in which the proportion of SCLCs decreased from 17% in 1986 to 13% in 2002. However, this decrease was accompanied by an increase in SCLC cases arising in women (28% in 1973 vs 50% in 2002), attributed to increasing tobacco use among women starting in the 1960s. The reduced incidence may be related, in part, to changes in the pathologic criteria leading to the classification of

cases as large cell neuroendocrine carcinoma (LCNEC) that would have been previously classified as SCLC.

RISK FACTORS

Of all lung cancer subtypes, SCLC shows the strongest association with tobacco exposure, which represents the most important risk factor⁽³⁾. The risk is related to both the duration (>40 years) and intensity of tobacco use (>30 cigarettes/day). This risk is lower in former smokers versus current smokers, although the risk in former smokers still exceeds that of non-smokers⁽³⁾. Additional risk factors include exposure to asbestos, benzene, coal tar, and radon gas, usually as cocarcinogens with tobacco. Smoking cessation should be encouraged as a method of primary prevention. Patients with LD who continue to smoke during or after chemoradiation experience increased toxicity, have a high risk of second lung cancers, and have shorter survival than those who quit⁽⁵⁾.

NATURAL HISTORY

The natural history of SCLC was documented in the placebo arm of a randomized trial from the Veterans Administration Lung Cancer Study Group (VALSG) reported in 1969, testing the effect of three doses of intravenous cyclophosphamide⁽⁶⁾. In this trial, the median survival for patients in the placebo arm was 6 weeks for those with ED and 12 weeks for those with LD, based on primitive staging studies at that time. Due to stage shift with modern staging techniques, outcomes in both groups would be likely better today. Cyclophosphamide increased the median survival by 75 days in both groups, tripling the survival of patients with metastases and doubling that of patients with LD. This was the first observation foretelling the important role chemotherapy would come to play in management of SCLC.

The use of effective combination chemotherapy and, in the case of patients with tumor amenable to definitive radiation, the use of multimodality treatment have improved survival of SCLC patients. For patients with LD, 5-year survival was less than 5% in 1973 and improved to 10% in 2000. In the same period of time, 2-year survival for patients with ED improved from 1.5% to 4.6%⁽¹⁾.

PROGNOSTIC FACTORS

The most important prognostic factor for SCLC is the stage, as patients with LD have improved survival compared with those with ED⁽⁷⁾. Among patients with LD,

good performance status (PS), age less than 70, female gender, and normal lactate dehydrogenase (LDH) are predictive of a favorable outcome⁽⁷⁾. Among these patients, a small subgroup with very LD (no mediastinal involvement) was found to have a longer median survival when treated with surgery⁽⁸⁾. In patients with ED, normal LDH, multidrug regimen treatment, and a single metastasis predicted better outcomes. Liver or cerebral metastases confer significantly shorter survival compared to bone, soft tissue, or bone marrow involvement⁽⁹⁾. Paraneoplastic syndromes (PNSs) may also predict outcome. Patients with the syndrome of ectopic corticotrophin (ACTH) secretion producing clinical Cushing syndrome have a dismal prognosis, with a low response to chemotherapy and poor control of hypercortisolism following treatment⁽⁷⁾. Lambert-Eaton myasthenic syndrome (LEMS), an autoimmune PNS, confers a more favorable prognosis, presumably due to immunity against the cancer⁽¹⁰⁾.

PATHOBIOLOGY

Small cell lung cancer is defined by light microscopy as a malignant epithelial tumor consisting of small cells, with round-to-fusiform shape, scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli⁽¹¹⁾. Nuclear molding and necrosis are frequent, and mitotic rates are high (Fig. 17-1). Tumors usually grow in diffuse sheets, but rosettes, peripheral palisading, organoid nesting, streams, ribbons, and rarely, tubules or ductules may be present. Typically, diagnosis is made from small biopsies and cytology specimens, as surgery is rarely performed. Due to significant crush artifact, biopsies are sometimes more problematic in diagnosis than cytology specimens.

FIGURE 17-1 Light microscopic images of SCLC. Note the small, round, and spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm.

Combined small and large cell carcinoma is histologically a tumor with a mixture of SCLC and at least 10% larger cells that morphologically fall under the definition of NSCLC. Additional variants exist, including combined SCLC with squamous cell, adenocarcinoma, spindle cell, or giant cell carcinoma. The frequency of combined SCLC varies according to tumor sample size, number of histological sections analyzed, type of specimen, and interpretation. SCLC is a “small, round, blue cell tumor” using a hematoxylin and eosin (H&E) stain, and the differential diagnosis includes other small, round, blue cell tumors, including lymphomas and small cell sarcomas. Histologically, identical tumors can arise in other organs (eg, nasopharynx, larynx, genitourinary or gastrointestinal tract, and cervix) and are termed extrapulmonary small cell carcinomas. Both pulmonary and extrapulmonary small cell carcinomas have similar biological features and clinical behavior, with high potential for widespread disease. However, malignant cells from extrapulmonary small cell carcinomas do not exhibit 3p deletions, which are common in SCLCs, indicating, at least in part, differences in carcinogenesis ⁽¹²⁾.

Immunohistochemical (IHC) markers are valuable in differential diagnosis of SCLC. Positive pancytokeratin (AE1/AE3) staining helps to identify the tumor as a carcinoma rather than a lymphoma or sarcoma ⁽¹¹⁾. Neural cell adhesion molecule (CD56), chromogranin, and synaptophysin are the most useful markers. While CD56 expression is detectable in approximately 90% to 100% of cases, SCLC may be negative for expression of neuroendocrine markers, such as chromogranin and synaptophysin ⁽¹³⁾. Small cell lung cancer (SCLC) is a primitive undifferentiated high-grade neuroendocrine tumor (NET) and does not typically express these proteins as intensely as low-grade, well-differentiated NETs do, such as carcinoids. In 10% of cases, all neuroendocrine markers may be negative, and the diagnosis can still be established if the morphology is diagnostic. Thyroid transcription factor 1 (TTF-1) is expressed in 70% to 90% of SCLCs; however, this marker may also be expressed in extrapulmonary small cell carcinomas and thus does not reflect lung origin ⁽¹⁴⁾. The Ki-67 staining index, reflecting proliferation, is generally greater than 50% in SCLC and can be used to differentiate SCLC from lower-grade NETs ⁽¹⁵⁾.

GENOMIC AND PROTEOMIC ALTERATIONS

Small cell lung cancer is characterized by genomic alterations, biology, and clinical behavior that are distinct from the intermediate- and low-grade pulmonary NETs. It appears that SCLC is driven more by mutations and deletions of tumor suppressor genes

than by alterations in oncogenes. Loss of function of tumor protein 53 (*TP53*) occurs in 75% to 90% of SCLCs ⁽¹⁶⁾. Loss of the retinoblastoma 1 (*RB1*) gene at 13q14 occurs in virtually all patients with SCLC ⁽¹⁶⁾. Haploinsufficiency due to allele loss in multiple areas on chromosome 3p, including 3p21.3, 3p12, 3p14.2, and 3p24.4, leads to absent or lower expression of several tumor-suppressor genes in greater than 90% of SCLCs and is an early event in tumorigenesis ⁽¹²⁾. Deletion of the *TGFBR2* gene, encoding the transforming growth factor beta type II receptor, has been described in SCLC ⁽¹⁷⁾. The tumor suppressor gene *FUS1*, in the 3p21.3 region, was not expressed in 100% of SCLCs examined in one series ⁽¹⁸⁾. *RASSF1A* encodes a protein involved in cell cycle, apoptosis, and microtubule stability and is inactivated in 90% or more of SCLC ⁽¹⁹⁾.

Cells may acquire immortality by compensating for the loss of telomeric repeats through telomerase reactivation. Telomerase RNA subunit (hTR) and telomerase activity are upregulated in 98% or more of SCLC ⁽²⁰⁾. Increased expression of cKit, and its ligand stem cell factor, is detected in up to 80% to 90% of SCLCs ⁽²¹⁾. Amplification of MYC family members (v-myc avian myelocytomatosis viral oncogene homolog, MYC, MYCL1, and MYCN) is detected in 20% of SCLCs ⁽¹⁶⁾. Loss of phosphatase and tensin homolog (PTEN) is observed in 2% to 4% of tumors ⁽²⁰⁾; however, the Phosphoinositide 3-kinase (PI3K) pathway alteration rate (PI3K) pathway alteration rate may be overall higher and may promote SCLC tumorigenesis in preclinical models. The BCL-2 family proteins exert an antiapoptotic effect and may be upregulated in 75% to 95% of SCLC ⁽¹⁶⁾.

Two comprehensive genomic profilings of SCLC confirmed common DNA alterations and their relation with tobacco exposure ⁽²²⁾ and identified novel potential therapeutic targets, including SOX2 (sex-determining region Y box 2) amplifications and RLF-MYCL1 fusions ⁽²³⁾. Proteomic profiling has identified differences in protein expression between SCLC or LCNEC and other NSCLC cancers, including the DNA repair protein poly(ADP-ribose) polymerase 1 (PARP1), checkpoint kinase 1 (Chk1), and chromatin modulator enhancer of zeste 2 polycomb repressive complex 2 subunit (EZH2) ⁽²⁴⁾. **Table 17-1** describes common genomic and proteomic alterations that occur in SCLC.

CLINICAL PRESENTATION

Small cell lung cancer typically arises in the central airways and infiltrates the submucosa, with a tendency to narrow the bronchial lumen through extrinsic or endobronchial spread, in contrast to squamous cell carcinomas, where polypoid luminal occlusion is common. Rapid intrathoracic tumor growth, lymphatic and distant spread, and manifestation of PNSs can

Table 17-1 Representative List of Common or Potentially Targetable Genomic and Proteomic Alterations According to Percentage in Small Cell Lung Cancer

Genes	Mutation Frequency (Type of Mutation)
<i>TP53</i>	75-90% Loss of function (mutation, LOH, deletion)
<i>RB1</i>	~100% Loss of function (mutation, LOH, deletion)
<i>PTEN</i>	~5% Loss of function (mutation, LOH, deletion)
<i>MYC</i>	18-31% MYC family alterations overall Gain of function (amplification or transcriptional dysregulation)
<i>SOX2</i>	27% Gain of function (amplification)
<i>FGFR1</i>	<10% Gain of function (amplification, mutation)
<i>CCNE1</i>	<10% Gain of function (amplification)
<i>EPHA7</i>	<10% Gain of function (amplification)
<i>PARP1</i>	>50% (overexpression of protein target)

CCNE1, cyclin E1; EPHA7, ephrin receptor A; FGFR1, fibroblast growth factor receptor 1; MYC, v-myc avian myelocytomatosis viral oncogene homolog; PARP, poly(ADP-ribose) polymerase 1; PTEN, phosphatase and tensin homolog; RB1, retinoblastoma 1; SOX2, sex-determining region Y box 2; TP53, tumor protein 53.

cause severe and progressive symptoms that lead to diagnosis generally within 3 months from onset. Common clinical manifestations include cough, dyspnea, weight loss, and debility. Hemoptysis and postobstructive pneumonia are relatively uncommon due to the submucosal growth pattern of the tumor. Bulky involvement of mediastinal lymph nodes is a hallmark of SCLC, and syndromes resulting from mass effects are commonly seen, including superior vena cava syndrome, hoarseness (from recurrent laryngeal nerve compression), phrenic nerve palsy, dysphagia (from esophageal compression), and stridor (from tracheal compression). Small cell lung cancer is the most common malignant cause of superior vena cava obstruction. Radiographically, a large hilar mass with bulky mediastinal adenopathy is commonly observed (Fig. 17-2), although occasional peripheral satellite nodules may be found.

Most patients present with overt metastatic disease (60%-70%); common sites of metastasis include liver, adrenals, bone, bone marrow, and brain. Symptoms of metastatic disease can include bone or right upper quadrant abdominal pain, headache, seizures, fatigue, and anorexia. Occasionally, patients may present with

**FIGURE 17-2** Bulky involvement of mediastinal adenopathy (black arrow) at computed tomographic scan of chest in a patient with extensive-stage SCLC.

PNSs, such as syndrome of inappropriate antidiuretic hormone (SIADH) or LEMS.

STAGING

The two-stage system originally proposed by the VALSG in the late 1950s and later modified by the IASLC is currently used for simplicity and practicality. Limited disease (LD) is defined as a tumor confined to one hemithorax, with involvement of regional nodes, including contralateral mediastinal or ipsilateral supraclavicular nodes, that can be included in a single tolerable radiotherapy (RT) port (TNM stages I-IIIb). Extensive disease (ED) is defined as a tumor beyond the boundaries of LD, including distant metastases, malignant pericardial or pleural effusions, and contralateral supraclavicular and contralateral hilar node involvement (TNM stage IV, any T, any N, M1a/b). More recently, IASLC proposed changes to the TNM NSCLC staging system, mainly in T and M descriptors and stage groupings. These changes have been incorporated into the AJCC seventh edition, which recommends TNM staging for SCLC and NSCLC (²). However, the two-stage system continues to be used in clinical practice, as most patients present with advanced disease (stages III-IV) and are only rarely candidates for surgery. This system has prognostic significance and clinical implications because patients with LD are candidates for chemoradiation with curative intent, while patients with ED receive chemotherapy alone and palliative radiation as clinically indicated. Approximately 30% to 40% of patients with SCLC present with LD; the remainder will have ED (¹).

The initial clinical evaluation should include history and physical examination, chest radiograph, pathology review, baseline laboratory tests, including complete

blood cell count, a comprehensive metabolic profile, LDH measurement, computed tomographic (CT) scans of the chest and abdomen with intravenous contrast, and brain magnetic resonance imaging (MRI) or CT scan with intravenous contrast. Brain MRI is more sensitive than CT in identifying metastases and is preferred. If LD is suspected, a positron emission tomography (PET)–CT scan may be indicated because it can identify distant disease and guide mediastinal evaluation. For most metastatic sites, a PET-CT scan is superior to other imaging modalities; however, it is inferior to MRI or CT of the brain for detection of brain metastases. Despite the fact that PET-CT may improve staging accuracy of SCLC, pathologic confirmation is still recommended for lesions depicted at PET-CT scan that may alter staging. If PET-CT scan is not available or is equivocal, bone imaging with a whole-body bone scan should be used to stage the skeleton.

Staging should not focus only on symptomatic sites of disease or on altered laboratory data. For example, bone scans may be positive in up to 30% of asymptomatic patients without abnormal alkaline phosphatase. The goal of complete staging is to identify those patients with LD who are candidates for definitive therapy. In the presence of obvious ED, staging may be clinically directed. Brain imaging should be obtained in all patients, given the morbidity of uncontrolled central nervous system (CNS) disease. Imaging of the CNS reveals brain metastases in 10% to 15% of patients at diagnosis, with 30% of these individuals asymptomatic.

In patients with apparent stage I disease (T1-2N0) surgical resection should be considered if mediastinal staging is negative⁽⁸⁾. This can be obtained by conventional mediastinoscopy, transesophageal endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA), endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA), or video-assisted thoracoscopy (VATS). If a pleural effusion is present in a patient with otherwise LD, thoracentesis should be performed and fluid sent for cytology. If the fluid is exudative or if malignant cells are present, the patient should be considered to have ED (stage IV: M1a). While most pleural effusions in lung cancer are related to the malignancy, there may be a few instances in which multiple cytopathological examinations are negative for malignancy and the pleural fluid is not an exudate. When these elements and clinical judgment indicate that a pleural effusion is not malignant, the effusion should be excluded as a staging element. Pericardial effusion is classified according to the same criteria.

Sampling of cerebrospinal fluid is indicated if leptomeningeal spread is suspected. Pulmonary function tests should be performed in patients who are candidates for definitive chemoradiation therapy. Severe anemia, nucleated red blood cells on peripheral smear,

neutropenia, or thrombocytopenia, in the absence of other obvious etiologies, are selection criteria for bone marrow aspiration and biopsy. The presence of tumor cells in a marrow biopsy identifies ED. Treatment should be initiated as quickly as possible after diagnosis is confirmed, given the rapid rate of progression. If the patient is significantly symptomatic or the staging evaluation prolonged, staging should be completed while chemotherapy is started.

TREATMENT

Limited Disease

Patients with SCLC rarely survive more than a few months without treatment. The disease is generally highly responsive to both chemotherapy and radiation, and patients with LD are treated with curative intent. In LD, the overall response rates (RRs) to combined chemoradiation are typically 80% to 90%, including 50% to 60% complete RRs. Median overall survival (OS) is approximately 17 months, and the 5-year survival rate is approximately 12%.

Surgery

An autopsy series on patients who died from postoperative complications revealed that 90% of patients with SCLC had mediastinal metastasis within 30 days following surgical resection⁽²⁵⁾. A randomized trial evaluating surgery versus thoracic RT (TRT) in patients with resectable disease revealed that the TRT group had significantly longer OS⁽²⁶⁾, suggesting that, even in absence of diagnosed metastases, surgery alone is an inadequate therapeutic strategy. However, surgery may play a role in multimodality therapy for those patients (5%) with early T stage and without nodal involvement (T1-T2N0M0, very LD). A 5-year survival of 48% has been reported in patients with very LD when surgery was followed by adjuvant chemotherapy⁽⁸⁾. Adjuvant chemotherapy with four courses of etoposide/cisplatin (EP) should be considered for all patients with surgically resected SCLC. If nodal involvement is found at the time of surgery, chemoradiation and chemotherapy are recommended.

Combined Chemoradiation Therapy

Based on the results of a British Medical Research Council trial demonstrating surgery to be inferior to RT for the treatment of LD⁽²⁶⁾, TRT became standard of care for local control for these patients. Although early studies indicated that RT could increase local control compared to chemotherapy alone, these studies did not consistently show significant survival benefits to combination therapy over chemotherapy⁽²⁷⁾. Because

of this controversy, randomized trials were performed. Two meta-analyses were performed that showed a significant 2-year survival benefit of 5.4% with the addition of RT to systemic chemotherapy for patients with LD^(27,28). It is noteworthy that the best outcomes from these older trials included concurrent as opposed to sequential approaches; in addition, the regimens used in this era were anthracycline- and alkylator-based therapies and were associated with excessive in-field toxicity when administered with concurrent radiation. The development of the EP regimen was critical to improving the tolerance and feasibility of concurrent chemoradiation. Etoposide/cisplatin can be given at full dose with RT, leading to improved disease control.

An anthracycline-based regimen (cyclophosphamide, epirubicin, and vincristine [CEV]) was compared in a phase III trial to EP in patients with SCLC⁽²⁹⁾. Patients received RT concurrently with the third cycle of chemotherapy, and prophylactic cranial irradiation (PCI) was administered to those who achieved complete remission (CR). The results showed that, in patients with LD, EP was superior to CEV for survival rates at 2 and 5 years (14% and 5% vs 6% and 2%, respectively; $P = .0001$), as well as median OS (14.5 vs 9.7 months; $P = .001$). In patients with ED, no survival difference was noted.

The addition of other cytotoxins to the EP regimen—either as a triplet with paclitaxel or alternating therapy with cyclophosphamide, doxorubicin, and vincristine—has also been studied, but to date a new standard in the treatment of LD has not emerged^(30,31).

Radiation Intensity

Based on the radiobiology of SCLC, the Intergroup (INT) trial 0096 studied accelerated hyperfractionated RT (AHRT) compared to conventional fractionation in a phase III trial⁽³²⁾. Over 400 patients were randomized between the two arms. All patients received four cycles of EP, and TRT was administered concurrently, starting with the first cycle of chemotherapy. All patients received 45 Gy, either in once-daily 1.8-Gy fractions for 5 weeks or twice-daily 1.5-Gy fractions for 3 weeks. Patients in the twice-daily RT group had an improved median OS (23 vs 19 months) and 5-year survival (26% vs 16%), at the cost of increased weight loss and grade 3 esophagitis (27% vs 11%). Local failure rates were lower in the twice-daily RT arm, presumably the major reason for improved survival.

Intergroup trial 0096 convincingly showed an OS benefit to concurrent chemoradiation with hyperfractionation. However, because of concerns for side effects and the logistical difficulties involved in twice-daily treatment, the regimen has not been widely used in the community⁽³³⁾. The control arm of the INT 0096 study used a relatively low total RT dose, and since

the results of INT 0096 have become available, conventionally fractionated radiation in higher doses has also been studied. The Cancer and Leukemia Group B (CALGB) trial tested the regimen paclitaxel and topotecan for two cycles, followed by TRT with 70 Gy in 35 daily fractions with concurrent carboplatin/etoposide (CE; total of three cycles) in a phase II study⁽³⁴⁾. Median OS was 22.4 months, comparable to that found with AHRT in the INT 0096 study.

Another schedule of TRT tested was concomitant boost, in which patients received once-daily radiation through most of their course, then received hyperfractionated therapy at the end of treatment, so that RT was accelerated without the need for twice-daily administration throughout the treatment course. The Radiation Therapy Oncology Group (RTOG) tested this approach in the phase II trial 0239. Patients received 61.2 Gy over 5 weeks, with twice-daily RT in the final 9 days⁽³⁵⁾. Radiotherapy started on day 1 of chemotherapy with four cycles of EP. Two-year survival rate was 37%, somewhat less than that found in both INT 0096 and the CALGB trial (2-year survival rates of 41% and 48%, respectively).

A prospective INT study of chemoradiation for patients with LD (RTOG 0538/CALGB 30610) is currently active. Originally, this trial included the concomitant boost regimen, but that arm has been dropped after an interim analysis. The trial currently compares 70 Gy once daily with AHRT (45 Gy twice daily) from the INT 0096 study. In both arms, concurrent EP and RT commence with the first cycle of chemotherapy (NCT [National Clinical Trial] 00632853). The primary end points are median OS and 2-year survival rates.

Timing of Chemotherapy

Sequential, concurrent, and alternating chemotherapy have all been tested with TRT. Early studies did not show a survival benefit to concurrent chemotherapy; however, this was likely due to the increased toxicity when using cyclophosphamide- or doxorubicin-based chemotherapy. Etoposide/cisplatin is far better tolerated than these earlier regimens when administered concurrently with RT.

The National Cancer Institute of Canada reported a phase III trial of alternating CAV (cyclophosphamide, anthracycline, vincristine)/EP with TRT in either the second or sixth cycle of chemotherapy⁽³⁶⁾. The patients receiving early RT experienced improved OS (21.2 vs 16 months). The Japan Clinical Oncology Group (JCOG) compared RT (45 Gy in twice-daily 1.5-Gy fractions) starting with either the first cycle of EP or following completion of the chemotherapy course⁽³⁷⁾. More myelosuppression was noted in the patients in the concurrent arm, but there was a significant reduction in risk of death for early concurrent therapy, with

a hazard ratio (HR) of 0.70 ($P = .02$). Although not all trials have consistently shown a benefit for concurrent chemoradiation, the data strongly support this and its early integration in treatment when the regimen is EP, as contrasted with anthracycline- or alkylator-based regimens. Furthermore, efficacy outcomes are consistently better with EP in the treatment of LD.

Given that SCLC is such a rapidly dividing malignancy, it has been hypothesized that accelerated proliferation of tumor clonogens can affect outcome, and that treatment should be delivered in a condensed fashion⁽³⁸⁾. A meta-analysis examined the impact of a novel parameter, time from the start of any treatment to the end of RT, on OS in LD. A shorter SER was found to be a significant predictor of better outcome. For each week that the SER was lengthened, OS at 5 years showed an absolute decrease of almost 2%⁽³⁸⁾. The data from INT 0096 had a strong influence on this result.

Carboplatin is frequently used in ED due to a more favorable toxicity profile, whereas cisplatin is preferred in patients with LD with curative intent. The efficacy of cisplatin versus carboplatin regimens in LD was evaluated in a meta-analysis of four trials⁽³⁹⁾, which revealed no significant difference in terms of efficacy. Similar results were found in a subset analysis based on the two randomized trials conducted in patients with LD^(40, 41), where no differences were seen in RRs or median survival time for EP versus CE, although less toxicity was reported in the carboplatin-containing arm. Nevertheless, due to its use in trials for which the best 5-year survival has been observed

in LD, EP should be given unless there is a significant contraindication to cisplatin use. Notably, the dose of cisplatin in INT 0096 was only 60 mg/m². **Figure 17-3** illustrates the treatment algorithm for management of limited-stage SCLC.

Extensive Disease

Systemic chemotherapy represents the primary therapeutic modality for patients with ED. Prophylactic cranial irradiation decreases the incidence of symptomatic brain metastases in responders to systemic chemotherapy, although its impact on OS is uncertain. Currently, TRT is utilized for symptom palliation; however, a potential role for radiation in patients with limited systemic disease and a good response to initial therapy has been suggested. Chemotherapy prolongs survival compared with best supportive care (BSC)⁽⁶⁾. From the time of diagnosis, the median OS for patients with ED is 8 to 13 months, the 5-year survival is 1% to 2%, and the 2-year survival is 4% to 5%⁽¹⁾. **Figure 17-4** shows representative coronal PET-CT images in a patient with extensive-stage SCLC (ED).

Chemotherapy

In an early study, patients with SCLC had a highly significant improvement in survival with intravenous cyclophosphamide compared to placebo, increasing median survival from 12 weeks to almost 5 months⁽⁶⁾. As new cytotoxins became available, combination therapy was studied, and the CAV regimen became

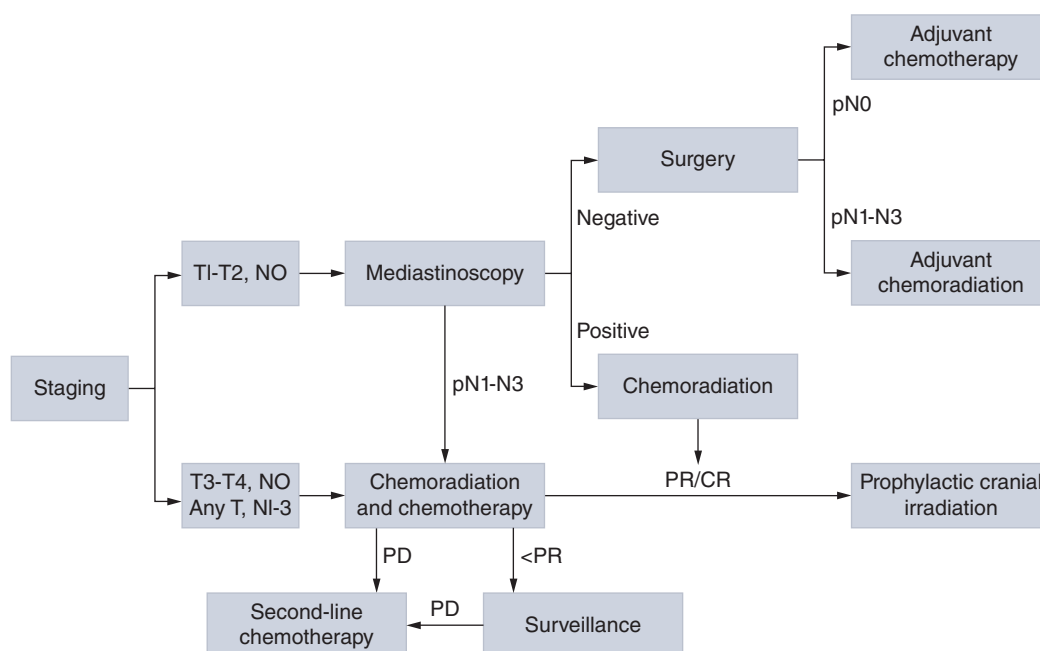

FIGURE 17-3 Treatment algorithm for management of limited-stage SCLC.

FIGURE 17-4 Representative PET-CT images in a patient with extensive-stage SCLC. Coronal PET (left panel) and fused coronal (right panel) images are shown.

the standard of care for ED (29). Etoposide/cisplatin was initially evaluated in patients who had recurrent disease after or failed to respond to CAV, with RRs of 55% (42). It was later evaluated as a first-line treatment in patients unable to tolerate CAV, demonstrating a median OS of 39 weeks in ED, with less toxicity (43). In a phase III trial, the equivalent efficacy of EP and CAV was confirmed by randomizing 437 patients to receive four cycles of EP, six cycles of CAV, or alternation of these two regimens for 18 weeks (CAV/EP, three cycles each) (44). The RRs (61%, 51%, 59%, respectively) and median OS (8.6, 8.3, and 8.1 months, respectively) were equivalent across the arms. Myelosuppression was the dose-limiting toxicity, and four cycles of EP were better tolerated. Similar results were seen in a Japanese trial (30). Four cycles of EP became the standard of care for patients with ED (29), although it is common in practice to continue for six cycles in the face of continuing regression after four and good tolerance.

Increased Length of Induction and Maintenance Chemotherapy

A meta-analysis of 14 randomized clinical trials, including 2,550 patients with SCLC, revealed a modest reduction in both 1- and 2-year mortality with prolonged treatment, referred to as maintenance or consolidation chemotherapy (45). Maintenance chemotherapy improved 1- and 2-year survival by 9% (from 30% to 39%, $P < .001$) and 4% (from 10% to 14%,

$P < .001$), respectively. The trials in this analysis predominantly studied alkylator- or anthracycline-based regimens as induction, with one exception that studied EP with or without TRT and maintenance CAV, and failed to show a benefit for maintenance. Further, the two most positive trials studied consolidative EP following anthracycline-based chemotherapy with or without chest RT for LD patients only. The positive effect of consolidative EP in LD patients treated with anthracycline-based induction heavily contributed to the results of the meta-analysis.

Maintenance therapy with etoposide or topotecan following induction with EP has also been evaluated in ED (46, 47). Both of these trials demonstrated a small benefit in PFS (<2 months) without improvement in OS. Thus, when EP is used as induction, maintenance therapy is not recommended.

Substitutions and Additions to Induction Therapy

Adjustments to the EP regimen have been investigated. Carboplatin is frequently used in combination with etoposide in ED because of similar efficacy to cisplatin and less toxicity. A meta-analysis of four randomized trials comparing carboplatin to cisplatin demonstrated no differences in terms of OS, PFS, and RRs (median 9.6 vs 9.4 months, 5.5 vs 5.3 months, and 67% vs 66%, respectively) (39).

Multiple-drug combinations, including variations of EP, and three- and four-drug regimens have shown

higher RRs and improvement in survival without a consistent meaningful clinical benefit over EP. Based on activity of irinotecan in recurrent disease, it was combined with cisplatin in frontline therapy. Four large randomized trials have compared irinotecan/cisplatin (IP) versus EP. The multicenter phase III JCOG 9511 trial compared IP to EP in treatment-naïve patients with ED⁽⁴⁸⁾. Although the projected accrual was set for 230 patients, the study was terminated early, after accrual of 154 patients, given the clear survival advantage in the IP over the EP group (median OS 12.8 vs 9.4 months, respectively; $P = .0021$). However, subsequent studies have failed to confirm the results in non-Asian populations. Two North American trials^(49, 50) and one European trial⁽⁵¹⁾ have not shown a significant survival benefit with IP over EP. In the Southwest Oncology Group (SWOG) S0124 trial, over 600 patients with ED received either IP or EP⁽⁵⁰⁾. No significant differences were found in median PFS, OS, or overall response rates (ORRs) between the regimens (5.8 vs 5.2 months, 9.9 vs 9.1 months, and 60% vs 57%, respectively). Similarly, topotecan, given in combination with cisplatin, has failed to demonstrate a clinical advantage over EP as initial therapy for patients with ED⁽⁵²⁾.

The addition of ifosfamide to EP led to a modest survival improvement in one study (9.0 vs 7.3 months; $P = .045$); however, given the greater toxicities and minimally improved outcomes, this regimen is not commonly used⁽⁵³⁾.

In a phase III trial by the French Federation of Cancer Institutes, EP was compared to EP plus cyclophosphamide and 4'-epidoxorubicin (PCDE) in ED⁽⁵⁴⁾. The four-drug regimen led to only a minimal survival improvement at the cost of increased toxicity.

Alternating or Sequential Combinations

Despite initial chemosensitivity, almost all patients will eventually relapse, due to either intrinsic multi-drug resistance or development of resistance during therapy. Goldie and Coldman hypothesized that non-cross-resistant regimens could be rapidly alternated or administered sequentially to eliminate these resistant clones⁽⁵⁵⁾. Several trials have evaluated alternating regimens, including EP alternating with CAV⁽³⁰⁾ and cyclophosphamide, doxorubicin and etoposide alternating with vincristine, carboplatin, ifosfamide, mesna⁽⁵⁶⁾, with no significant benefit in patients with ED.

Rapid sequencing of several active agents over a short period has also been evaluated. The most studied regimen comprised weekly treatments of CODE (cisplatin, vincristine, doxorubicin, etoposide). Although early studies indicated that CODE conferred a possible survival advantage to patients with ED, subsequent phase III trials did not confirm superiority to alternating traditionally scheduled CAV/EP^(57, 58).

Altering Dose Intensity and Density

Preclinical studies of chemotherapy in SCLC have shown a dose-response relationship, leading to the evaluation of higher-dose chemotherapy in the clinical setting. A meta-analysis of 60 trials showed that increasing the dose intensity of CAV and EP did not improve survival of patients with ED⁽⁵⁹⁾. Two randomized trials comparing high-dose to standard-dose EP doublets failed to demonstrate a survival advantage^(60, 61).

Dose-dense chemotherapy, with integration of marrow growth factors to reduce the time interval between cycles of chemotherapy, has also been studied. Several trials evaluated this approach, with conflicting results. In a randomized study, patients with LD and ED were assigned to ifosfamide, etoposide, carboplatin, and vincristine given every 3 (intensified) or 4 (standard) weeks⁽⁶²⁾. Patients in the dose-intense arm had a longer median survival (443 vs 351 days, respectively) and an improved 2-year survival rate (33% vs 18%, respectively; $P = .0014$). However, delivery of this regimen every 3 weeks was highly feasible and did not represent dose-dense therapy. Over 400 SCLC patients were randomized to doxorubicin, cyclophosphamide, and etoposide every 2 or 3 weeks⁽⁶³⁾, and only a small survival advantage was seen in the dose-dense arm (10.9 vs 11.5 months; $P = .04$). The British Medical Research Council multicenter randomized trial investigated a four-drug regimen—ifosfamide, carboplatin, etoposide, and vincristine (ICE-V)—every 4 weeks for six cycles over standard chemotherapy (according to center preference) in patients with SCLC⁽⁶⁴⁾. Prolonged OS was noted in the ICE-V group (HR 0.74, $P = .0049$), median OS was 15.6 versus 11.6 months, and 2-year survival rates were 20% versus 11%, in the ICE-V versus control groups, respectively, at the cost of increased toxicity. It is important to note that the 85% of patients enrolled had LD, and 82% of patients in the control arm were treated with non-platin-based regimens. Therefore, these results most likely reflect, again, the survival impact of platin exposure in patients with LD and do not support the ICE-V regimen.

Two randomized trials compared ICE every 4 weeks with ICE every 2 weeks with autologous stem cell support. One small trial of 83 patients stopped at interim analysis showed an OS improvement with the high-dose regimen (30.3 vs 18.5 months); however, a larger randomized phase III trial did not demonstrate a survival improvement in the high-versus standard-dose arm (14.4 vs 13.9 months, respectively)^(65, 66).

Thoracic Radiation Therapy

Prospective trials have evaluated the role of consolidative TRT in patients with ED who initially respond to systemic chemotherapy. In a single-center study, 206 patients received three cycles of EP⁽⁶⁷⁾, and complete

responders at distant sites and those with intrathoracic PR or CR ($n = 109$) were randomized to thoracic AHRT (54 Gy, 36 fractions over 18 days) combined with CE or four additional cycles of EP. Patients with brain metastases, stable disease, progressive disease, or only PR outside the thorax were not randomized. The addition of TRT to chemotherapy improved median OS (17 vs 11 months, 5-year survival rate 9% vs 4%, respectively; $P = .041$). There was a trend to reduced local recurrence in the radiation arm, but no difference in metastasis-free survival. Acute high-grade toxicity was higher in the chemotherapy arm.

In the phase III multicenter European CREST trial, patients with ED were initially treated with four to six cycles of platinum-based chemotherapy. Patients with any response were then randomized to TRT (30 Gy in 10 fractions) plus PCI ($n = 247$) or to PCI alone ($n = 248$)⁽⁶⁸⁾. The study did not meet the primary end point of 1-year survival improvement (33% with thoracic RT vs 28% without; $P = .07$). However, 2-year survival and PFS rates were significantly longer for those receiving TRT after prolonged follow-up (2-year OS, 13% vs 3%, $P = 0.004$; PFS, 24% vs 7%, respectively, at 6 months). The most common grade 3 toxicities in the TRT group compared with the control group were fatigue (4.5% vs 3.2%) and dyspnea (1.2% vs 1.6%). Patients most likely to benefit were those with residual disease in the thorax.

The RTOG 0937 phase II study (NCT 01055197) comparing PCI alone versus PCI with consolidative

RT to residual loco-regional and metastatic disease in patients with ED who responded to platinum-based chemotherapy was closed early due to excess grade 5 toxicity in the experimental arm.

Currently, it is our practice to consider consolidative TRT in selected patients with ED with excellent control of extrathoracic disease, residual disease in the thorax, and retained PS following chemotherapy. Thoracic RT should be limited to palliative dosing and conventional fractionation, and concurrent chemotherapy should not be given.

Figure 17-5 demonstrates metabolic response on PET in a patient with ED and extensive bone metastases after four cycles of CE. Figure 17-6 shows the treatment algorithm for the management of extensive-stage SCLC.

Recurrent Disease

Despite initial response to chemoradiation, approximately 11% of patients with LD and only 1% to 2% of those with ED are alive at 5 years, with the vast majority succumbing to recurrent SCLC⁽¹⁾. Historically, recurrent disease is less responsive and survival is limited, with median survival ranging from 2 to 6 months following relapse. The response to initial treatment and the time to relapse following induction chemotherapy are both important determinants of response to second-line chemotherapy. Patients with objective response to initial treatment and PFS at least

FIGURE 17-5 Response of extensive-stage SCLC following treatment with platin/etoposide at PET-CT imaging. Baseline (left) and restaging coronal PET (right) images are shown.

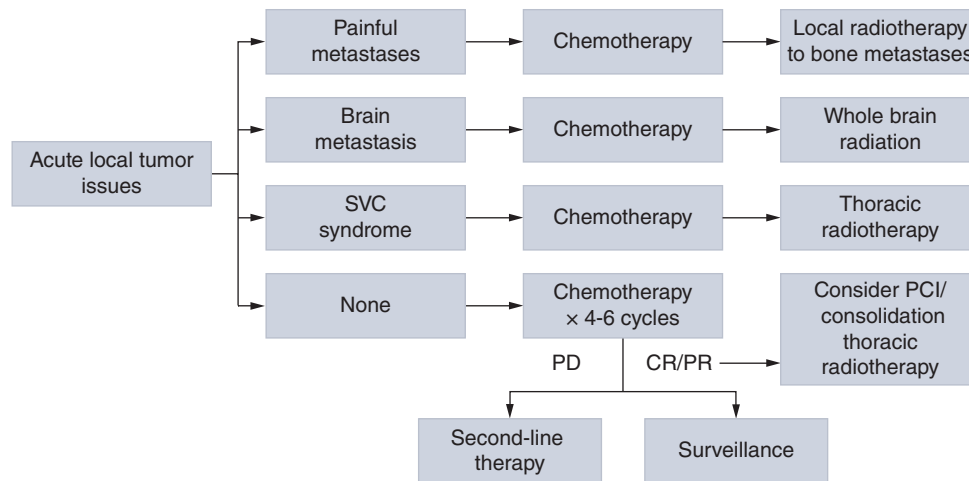

FIGURE 17-6 Treatment algorithm for management of extensive-stage SCLC.

60 to 90 days following completion of induction chemotherapy are more likely to respond to additional chemotherapy and are considered to have “sensitive” disease. Those who do not achieve disease regression with initial chemotherapy or with shorter duration of response after chemotherapy is discontinued are considered refractory ⁽⁶⁹⁾.

Reintroduction of the chemotherapy regimen used for induction has been a therapeutic strategy for relapse in patients with prolonged PFS after first-line therapy. The first evidence to support this was suggested in a series of six patients who had achieved a greater than 2-year remission following induction chemotherapy ⁽⁷⁰⁾. Five of these patients received some or all of the agents of their induction regimen, with four responses, lasting up to 18 months. Other studies also suggested responses when first-line therapy was reintroduced at relapse if patients had either a CR or a response longer than 34 weeks following induction ^(71, 72). In the modern era, when many patients receive just four courses of induction chemotherapy, re-treatment with EP could be considered if initial response was dramatic and maintained PFS for 3 months or more.

Topotecan and irinotecan have been studied in recurrent disease. Topotecan is the only drug for which there are several randomized trials in this setting and is the only agent approved by the Food and Drug Administration (FDA) for recurrent SCLC. Oral topotecan was found to have similar efficacy to intravenous topotecan, with less toxicity and ease of administration ⁽⁷³⁾. A phase III trial showed that intravenous topotecan had similar efficacy to the CAV regimen in patients with sensitive relapse, with an RR of 24% versus 18%, with a similar median TTP (13 vs 12 weeks) and OS (25 vs 24.7 weeks) for topotecan versus CAV, respectively ⁽⁶⁹⁾. The topotecan group had better symptom control, with less-severe neutropenia. The improvement in

symptom control led to its FDA approval. In a phase III registration trial, oral topotecan was compared to BSC in patients who had relapsed 45 days or more after achieving a response to first-line therapy and were not candidates to receive intravenous topotecan ⁽⁷⁴⁾. Topotecan significantly improved OS (25.9 vs 13.9 weeks), including significant benefit in patients who relapsed 60 days or less after initial treatment, and was associated with a slower deterioration in quality of life compared to BSC. In a phase III trial, 304 patients with sensitive relapse were randomized to oral (2.3 mg/m² daily for 5 days) or intravenous (1.5 mg/m² daily for 5 days) topotecan every 3 weeks ⁽⁷⁵⁾. The RRs and the median and 1-year survival rates as well as the toxicity profiles were similar between the two arms (18% vs 22%, 33 vs 35 weeks, and 33% vs 29%, respectively). Topotecan is typically administered on days 1 to 5 of a 3-week cycle. Irinotecan has not been directly compared to topotecan, and phase III trials have not been performed; phase II studies suggested similar efficacy compared to topotecan in the recurrent setting ⁽⁷⁵⁾.

Amrubicin is a novel anthracycline that showed promising activity in single-arm and randomized phase II trials for patients with recurrent SCLC in Japan ⁽⁷⁶⁾. A phase III trial in North America and Europe randomized 637 patients with refractory or sensitive SCLC to amrubicin or topotecan ⁽⁷⁷⁾. Median OS and PFS were 7.5 versus 7.8 months (HR 0.88; *P* = .17) and 4.1 versus 3.5 months (HR 0.8; *P* = .018) with amrubicin and topotecan, respectively. Thus, amrubicin is approved for use only in Japan.

Temozolomide is a well-tolerated oral alkylating agent with an ORR of 16% in a small phase II study ⁽⁷⁸⁾. Currently, a phase II randomized trial (NCT 01638546) is evaluating the efficacy of temozolomide with or without veliparib in relapsed disease, as detailed in the experimental agents section.

BRAIN METASTASIS

The brain is a common site of metastatic spread in SCLC, with 10% of patients presenting with brain involvement at diagnosis and an additional 40% to 50% developing CNS metastasis during the course of disease.

Whole-Brain Radiation Therapy

Whole-brain radiation therapy (WBRT) rapidly resolves symptoms of brain involvement from SCLC. Radiotherapy with 30 Gy in 10 daily fractions has been shown equally effective as altered fractionation to a higher dose (54 Gy in 34 fractions) in the phase III trial RTOG 9104 (⁷⁹), which evaluated these WBRT regimens in 429 patients with unresected brain metastases, including 39 patients with SCLC. Median OS was 4.5 months in both arms; 1-year survival was also similar, at 19% with accelerated fractionation and 16% on the control arm.

Reirradiation of the CNS may be considered (20 Gy in 10 fractions) for symptom palliation in recurrent intracranial disease (⁸⁰). Stereotactic radiosurgery (SRS) represents a therapeutic option for progressive brain metastases following WBRT. The technique uses external irradiation beams that deliver a single, high dose of radiation to a small volume of tissue with minimal invasion of and injury to healthy tissue. Stereotactic radiosurgery for brain metastases following WBRT from SCLC (fewer than four sites) is safe and achieves 1-year local control of 60% to 90%, especially in lesions less than 2 cm (⁸¹); however, regional CNS recurrence risk approaches 60%.

Chemotherapy

In general, RRs to chemotherapy in brain metastases mirror those in extracranial disease sites, with higher rates in therapy-naïve patients. In a meta-analysis, a 36% RR in the CNS was revealed in the results of five trials where 135 patients with brain metastases were treated, following initial therapy, with single-agent etoposide or carboplatin. Pooled data from another five studies conducted in 64 patients with brain metastases at diagnosis treated with various combination regimens showed a RR of 66% (⁸²).

In summary, for treatment-naïve patients who present with CNS involvement and are asymptomatic or minimally symptomatic, chemotherapy should be given initially, and if brain disease is controlled, WBRT may be given after completion of four cycles of chemotherapy. Brain irradiation should ultimately be administered given that it is associated with higher CR of brain metastases compared to chemotherapy alone. Symptomatic CNS involvement or progression

of brain metastases during chemotherapy is an indication for WBRT. The approach of combining WBRT and induction chemotherapy must be considered in situations where brain disease is bulky and symptomatic and there is also significant extracranial disease requiring urgent treatment. Myelosuppression is increased with concurrent modalities, and this should be expectantly managed. For those patients who develop CNS involvement following initial chemotherapy, WBRT is indicated, and chemotherapy may have a palliative role in those who progress after receiving WBRT. Occasionally, previously irradiated patients with SCLC are candidates for SRS; however, the rate of brain failure is high.

PROPHYLACTIC CRANIAL IRRADIATION

Despite only 10% of patients with SCLC presenting with CNS involvement at diagnosis, there is a significant rate of occult brain disease in patients who lack neurologic symptoms; thus, staging of the brain is indicated in all patients. Approximately 15% to 20% of patients with LD SCLC who initially respond to therapy will develop brain metastases as the sole site of relapse, suggesting that brain radiation early in the treatment course might be curative in this group (⁸³). The risk of developing brain disease in patients alive at 2 years after diagnosis who did not receive PCI is between 50% and 80% (⁸³). Prophylactic cranial irradiation has been investigated as a means to control brain metastatic disease following chemotherapy before it becomes clinically evident, in an effort to prevent morbidity and mortality. Numerous clinical trials have established the effectiveness of PCI in decreasing the incidence of intracranial disease in patients who have responded to initial treatment for LD and ED, although its impact on survival has been variable.

Prophylactic Cranial Irradiation in Limited Disease

The PCI Overview Collaborative Group meta-analysis evaluated seven randomized trials comparing PCI (treatment group) versus no PCI (control group) in 987 patients with SCLC who achieved CR to initial therapy. Approximately 85% of the patients enrolled in both groups had LD. The PCI provided a 5.4% improvement in 3-year survival (15.3% vs 20.7% in control vs treatment group, respectively), increased disease-free survival ($P < .001$), and decreased the risk of developing brain disease (33% vs 59%, HR 0.46; $P < .001$) (⁸³). A second meta-analysis evaluated 1,547 patients from 12 randomized studies, 5 of which required CR status for randomization (⁸⁴). The results

of the second analysis confirmed the reduced rate of brain metastasis for all patients, but improvement in OS only for patients in CR (HR 0.82, 95% confidence interval: 0.71-0.96). Based on these data, PCI became standard of care for patients with LD and disease control following chemoradiation.

Two large randomized trials have investigated the effect of RT doses above 25 Gy. A multinational phase III trial randomized 720 patients with LD and CR following induction therapy to receive PCI at 25 Gy in 10 fractions or 36 Gy (18 fractions of 2 Gy each or 24 fractions of 1.5 Gy twice daily) ⁽⁸⁵⁾. No significant differences were noted in the 2-year incidence rates of brain metastasis, and an increased mortality was noted with higher PCI doses (2-year survival rate 37% vs 42%, HR 1.20). The phase II randomized RTOG 0212 study similarly showed no differences in the incidence of brain metastasis or OS benefit in patients with LD and CR following initial chemoradiation comparing PCI with 25 Gy to 36 Gy ⁽⁸⁶⁾.

Prophylactic Cranial Irradiation in Extensive Disease

A phase III European Organization for Research and Treatment of Cancer (EORTC) study randomized patients with ED with response to initial chemotherapy to either PCI (choice of three schedules) or observation ⁽⁸⁷⁾. Baseline imaging of the brain was required only for symptomatic patients. Overall, 286 patients were randomized. Patients in the PCI group had a lower risk of brain metastases (15% vs 40%, HR 0.27; $P < .001$) and a longer median OS from time of randomization versus the observation group (6.7 vs 5.4 months, respectively). It is notable that more patients in the PCI group received second-line chemotherapy (68% vs 45%), possibly accounting for the OS improvement. Fatigue was significantly worse on the PCI arm in the first 24 weeks. Global health status and cognitive functioning were assessed only up to 9 months from randomization and were a mean of 8 points less (scale of 0-100) at 6 weeks and 3 months on the PCI arm ⁽⁸⁸⁾. These results are difficult to interpret given the lack of brain imaging at baseline and heterogeneity in both chemotherapy and PCI schedules. Further, the 1.3-month OS improvement could be attributed to an imbalance in subsequent chemotherapy use, which is known to influence survival.

Most recently, a Japanese trial evaluated the efficacy of PCI versus observation in 224 patients with SCLC who had response to induction chemotherapy with either etoposide or irinotecan and cisplatin ⁽⁸⁹⁾. Prior to randomization, brain MRI was performed to rule out occult metastases, and patients on both arms were followed postrandomization with serial brain imaging. Prophylactic cranial irradiation was given as 25 Gy in 10 fractions. The accrual was stopped early for futility

when analysis after 111 deaths revealed a trend toward shorter median survival with PCI (10.1 vs 15.1 months, HR 1.38; $P = .091$). As expected, decreased incidence of brain metastases with PCI at 1 year (32% vs 58%; $P < .001$) was observed, and fewer patients treated with PCI required RT for symptomatic brain involvement (31% vs 80%).

In summary, PCI clearly decreased the incidence of symptomatic brain disease in SCLC, but the impact on OS in patients with ED was variable. It is reasonable to discuss PCI in patients with ED who have a CR or very good PR to initial treatment and good PS. The lack of definite survival benefit and the potential for at least short-term toxicity should be discussed. It should be used with caution in the elderly and in patients with significant ischemic cerebrovascular disease due to a concern for increased acute and late brain toxicity. It is important to separate PCI from chemotherapy and to use radiation regimens that are safe in regard to late neurotoxic effects (eg, 25 Gy in 10 daily fractions).

THE ELDERLY AND INFIRM

Approximately 25% of patients with SCLC are over the age of 70 years. These patients have often been excluded from clinical trials because of concerns for greater toxicity due to lowered organ reserves, especially myelosuppression and frequently lowered functional status due to comorbidities. However, retrospective studies have shown that elderly patients with retained PS have improved outcomes with more aggressive treatment ⁽⁹⁰⁾. In a Canadian analysis, elderly patients 70 years of age or older who received four or more cycles of CAV or EP had a median survival of 10.7 months; those patients who received three or fewer cycles had a median survival of 3.9 months, and untreated patients survived a median time of 1.1 months ⁽⁹¹⁾. Multivariate analysis showed that neither increasing age nor comorbidities was an adverse prognostic factor. This review reported that PS, stage, and treatment were the most important prognostic features. Additional studies have confirmed these conclusions, whereas only one retrospective Australian review reported that the complications from therapy adversely affected outcome in the elderly ⁽⁹²⁾. In a recent retrospective cohort study examining the impact of chemotherapy on survival among patients 65 years and older with SCLC selected from the SEER database ⁽⁹³⁾, 67% of the patients received chemotherapy, mainly EP or CE, which provided a 6.5-month improvement in median survival ($P < .001$), even in patients more than 80 years of age.

With regard to radiation tolerance in the case of LD, elderly patients have been reported to have increased toxicity. Analysis of the patients older than 70 years of

age in the INT trial 0096 (EP with conventional TRT vs AHRT) showed that they experienced a higher rate of treatment-related death (>70 years vs ≤70 years: 10% vs 1%, respectively)⁽⁹⁴⁾. However, the 5-year OS rate for elderly patients was 16%, similar to that in the control arm overall. Altered fractionation did not appear to benefit the elderly subgroup.

In summary, patients with good PS and no significant organ dysfunction should receive full-dose chemotherapy and RT. Their higher risk of treatment-related death implies a need for close monitoring and intense supportive care. Patients with severe comorbidities, a worse PS prior to diagnosis, or the very elderly may require a change in strategy from standard of care. A meta-analysis of randomized trials evaluating patients with “poor-risk” SCLC (generally ED) has shown a benefit of combination chemotherapy over single-agent oral etoposide⁽⁹⁵⁾. These trials reported that intravenous combination regimens palliated symptoms better and improved median PFS and OS. Therefore, in patients with a poor PS, initial treatment should be combination chemotherapy. Etoposide/cisplatin is recommended over cyclophosphamide- or doxorubicin-based regimens in the elderly population because it is less myelosuppressive⁽⁹⁰⁾. Several studies have evaluated the CE regimen in the elderly population^(96,97). With the exception of the trial reported by Samantas et al, which used low doses of both agents, studies using CE have shown good RRs and tolerance in elderly patients.

In conclusion, carboplatin (area under the curve 5) and etoposide (100 mg/m² for 3 days) can be recommended for most patients with SCLC considered “high risk” on the basis of age, comorbidities, or reduced functional status. The time of highest risk for treatment-related mortality is in the first cycle. Prophylactic use of pegfilgrastim is recommended in this group when chemotherapy is given alone. The use of marrow growth factors is contraindicated during concurrent chemoradiation; thus, modest dose reduction and conventional fractionation should be considered. Continued research in this area, especially in the very elderly, is needed.

TARGETED AGENTS

There are no approved targeted agents for SCLC despite a plethora of trials over the past 15 years. Angiogenesis inhibitors, tyrosine kinase and other signal transduction inhibitors, as well as BH3 mimetics targeting apoptosis, have not demonstrated substantial promise in early-phase trials, and none has been validated in phase III studies⁽⁹⁸⁻¹⁰¹⁾. However, early experience with the Aurora A kinase inhibitor alisertib and inhibitors of PARP showed promise.

Aurora A Kinase Inhibitors

Data in SCLC cell lines and xenografts indicate that expression of MYC is correlated with sensitivity to Aurora A kinase inhibition⁽¹⁰²⁾. In a phase II study of alisertib (50 mg by mouth twice a day for 14 days, every 21 days) in solid tumors, a partial RR of 15% was observed in 47 patients with relapsed SCLC⁽¹⁰³⁾. A randomized phase II trial testing paclitaxel plus either alisertib or placebo in the second-line setting is ongoing (NCT 02038647). There is no molecular selection in this trial.

Poly(ADP-Ribose) Polymerase Inhibitors

Proteomic profiling of a large panel of SCLC cells showed high expression of PARP1 and other repair proteins. Several PARP inhibitors have shown single activity in in vitro and in vivo models of SCLC⁽¹⁰⁴⁾. BMN-673 is the most potent PARP1/2 inhibitor, inducing synthetic lethality in tumors deficient in homologous recombination. In a phase I trial of BMN-673, 2 of 11 patients with recurrent SCLC had PR⁽¹⁰⁵⁾. Veliparib, another PARP inhibitor, is being studied in randomized phase II trials with EP in newly diagnosed ED patients and with temozolomide in the second-/third-line setting (NCT 01642251 and NCT 01638546).

IMMUNOTHERAPY

Tumor Vaccines

The immunologic and clinical effects of a cancer vaccine consisting of dendritic cells transduced with the full-length, wild-type *p53* gene delivered via an adenoviral vector were tested in a single-arm phase study of 29 patients with ED. Most patients had disease progression to vaccination; however, retrospectively, high ORRs to chemotherapy administered post vaccination were observed (62%). This study supported the clinical use of *p53* vaccination as a chemotherapy sensitizer⁽¹⁰⁶⁾. However, this strategy has not been tested prospectively.

Small cell lung cancer expresses numerous gangliosides, including fucosyl monosialotetrahexosylganglioside (GM1), polysialic acid, Disialotetrahexosylganglioside (GM2), GD2, and GD3, not expressed on most normal tissues. The antiidiotypic antibody (BEC-2), which mimics GD3, failed to improve survival in a phase III trial⁽¹⁰⁷⁾.

Immune Checkpoint Inhibition

Experience to date with the immune checkpoint inhibitors targeting programmed death receptor 1 (PD-1) or its ligand (PD-L1) in NSCLC suggests efficacy may be directly correlated with degree of tobacco exposure and thus mutation burden and neopeptide expression.

Given the strong association with tobacco, SCLC is a relevant tumor for testing. Clinical trials with the PD-1 antibody pembrolizumab planned or ongoing include maintenance following induction chemotherapy (NCT 02359019), combined with irinotecan in recurrent disease (NCT 02331251), and combined with chemoradiation for LD (NCT 02402920).

Ipilimumab, a monoclonal antibody directed against CTLA-4 (cytotoxic T lymphocyte-associated antigen 4), has been given in sequential combination with carboplatin/paclitaxel in a randomized phase II of 130 untreated patients with SCLC. There was improved PFS (HR 0.64; $P = .03$), but not OS (median 12.5 vs 9.1 months for the sequential combination vs chemotherapy alone; $P = .13$)⁽¹⁰⁸⁾. A phase III trial of EP with or without ipilimumab has completed accrual and results are awaited (NCT 01450761).

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes are a complex spectrum of symptoms secondary to hormones secreted from tumor cells not related to their tissue or organ of origin or to immune-mediated tissue destruction through the production of autoantibodies against tumor cells. Small cell lung cancer is one of the most common cancer types associated with such phenomena. Ectopic hormone production has been associated with ED and a poorer outcome, whereas the antibody-mediated PNSs are associated with more favorable outcomes^(7,10). It is critical to recognize the manifestations of PNSs as this may lead to the diagnosis of an underlying, previously unsuspected, malignancy and be useful in monitoring the course of the underlying disease.

Endocrine Paraneoplastic Syndromes

Hyponatremia of malignancy occurs in 15% of patients with SCLC. This disorder is caused by ectopic production of antidiuretic hormone (ADH) from tumor cells, resulting in the SIADH⁽¹⁰⁹⁾. Fluid restriction, saline infusion with furosemide diuresis, hypertonic saline, and demeclocycline are options for acute management depending on the severity of symptoms. Chemotherapy should be started urgently.

The incidence of ectopic Cushing syndrome in SCLC is approximately 5%. Patients with SCLC with such a syndrome commonly present with signs and symptoms of rapid-onset hypercortisolism, including weight loss (83%), hypokalemia (87%), abnormal glucose tolerance (73%), and edema (58%) compared with the classic Cushingoid features of moon facies, central obesity, or hirsutism, which are more commonly seen in patients with carcinoid tumors⁽¹⁰⁹⁾. This may be due to the slower growth rate of carcinoids, which

causes a gradual, rather than acute, increase in ACTH levels. Patients with SCLC with Cushing syndrome have higher hydroxycorticosteroid (17-OHCS) and ACTH plasma levels than those seen in the Cushing disease of pituitary origin. These patients are immunosuppressed and at high risk for opportunistic infections from hypercortisolism; therefore, cortisol-suppressing agents, such as metyrapone or ketoconazole, are recommended prior to initiating myelosuppressive antineoplastic therapy. Radiotherapy can also be used in these cases to palliate and temporize until hypercortisolism has been controlled. Endocrine syndromes parallel cancer control, subsiding with cytoreduction of tumor and recurring with progression.

Neurologic Paraneoplastic Syndromes

Neurologic PNS disorders occur as the result of onconeural antibodies recognizing tumor and neuronal cell antigens; thus, they are autoimmune in mechanism. Lambert-Eaton myasthenic syndrome (LEMS), seen in 1% to 3% of patients with SCLC, is caused by autoantibodies directed against P/Q-type voltage-gated calcium channels (VGCCs) on the tumor cells and at presynaptic nerve terminals. These antibodies impair acetylcholine release from the presynaptic motor terminal at the neuromuscular junction and cause transient cranial nerve palsies, upright presyncopal symptoms, proximal muscle weakness with lower extremity predominance, and depressed tendon reflexes⁽¹⁰⁾. The electromyographic findings of decreased baseline muscle action potential that increases with repeated stimulations are characteristic and allow for clear-cut diagnosis. Lambert-Eaton myasthenic syndrome represents a favorable prognostic factor presumably based on antitumor immunity⁽¹⁰⁾. Unfortunately, these patients frequently experience progressive neurologic decline despite tumor control with treatment due to the fact that by the time neurologic symptoms and deficits emerge, permanent neuronal damage has occurred.

Additional paraneoplastic CNS disorders are associated with inflammation and neuronal loss. The most common syndromes in this group are paraneoplastic cerebellar degeneration, limbic encephalitis, opsoclonus-myoclonus, and diffuse encephalitis with multifocal neurologic symptoms⁽¹⁰⁹⁾. It remains unclear whether these syndromes or the presence of antibodies can serve as predictive markers of tumor response or progression.

THE SPECTRUM OF NEUROENDOCRINE CARCINOMAS

Neuroendocrine carcinomas are a wide spectrum of diseases, including low-grade typical carcinoid (TC), intermediate-grade atypical carcinoid (AT), and high-grade

neuroendocrine carcinomas (small cell carcinoma and LCNEC) ⁽¹¹⁰⁾. Carcinoid tumors are more often found in the gastrointestinal system than in the lungs. Behavior of these tumors is often dependent on grade of differentiation. The histopathological features of these tumors are identical regardless of their anatomic location; thus, the determination of a primary site often requires careful clinical evaluation.

Many of the same IHC markers are used to define NETs, regardless of primary site. Some IHC stains appear to be expressed in tumors in certain locations. For example, TTF-1 is commonly positive in thoracic tumors, while CDX2 is more commonly expressed in gastrointestinal tumors. On limited biopsies, definitive tumor grading may be challenging, especially in tumors of low and intermediate grade.

Pulmonary NETs comprise approximately 20% of all invasive lung malignancies. After SCLC, LCNEC accounts for 3% of resected lung cancers in surgical series, and TCs account for 1% to 2% of lung cancers. Atypical carcinoid is the rarest lung NET, as it comprises approximately 10% of all lung carcinoids, accounting for 0.1% to 0.2% of invasive lung cancers. Large cell neuroendocrine carcinoma is classified as an NSCLC but has similar biology, behavior, and natural history to SCLC ⁽¹¹⁾. **Table 17-2** shows the grading criteria and the histopathological features for pulmonary NETs ⁽¹¹⁾. The different types of NETs possess diverse epidemiological, clinical, pathological, and molecular features ⁽¹¹²⁾.

Surgical resection is recommended for localized pulmonary NETs if pulmonary reserve is adequate.

For surgically unfit patients or for exceptional low-grade cases, transbronchoscopic resection may be considered. Approximately 5% to 20% of bronchial TCs and 30% to 70% of ATs metastasize to lymph nodes; thus, a complete mediastinal lymph node sampling or dissection at the time of surgery is recommended. The 5-year survival rates of surgically resected pulmonary TCs and ATs range between 87% and 100% and 30% and 95%, respectively ⁽¹¹³⁾. Patients with TCs are unlikely to benefit from adjuvant systemic therapy, even if lymph node involvement is present. The ATs have higher recurrence rates; therefore, despite the lack of consensus, adjuvant EP with or without RT for patients with stage II or III may be considered ⁽¹¹²⁾.

Due to the rarity of LCNEC, most of the data regarding treatment are retrospective in nature. In general, there is a worse prognosis for patients with resected LCNEC compared to those with stage-matched other NSCLC. Treatment recommendations for this entity are extrapolated from treatment paradigms for SCLC. For resected stage I and II LCNEC, four cycles of adjuvant EP are recommended. For locally advanced disease (stage III), concurrent chemoradiation/chemotherapy is recommended (one or two cycles of EP concurrent with RT followed by additional chemotherapy to complete a total of four courses). For stage IV disease, four to six cycles of EP and palliative RT, if clinically indicated, are recommended. Prophylactic cranial irradiation cannot be routinely recommended due to limited data on the incidence of brain metastases in patients with LCNEC ⁽¹¹⁰⁾.

Table 17-2 Grading Criteria and Histologic Features of Pulmonary Neuroendocrine Tumors

Grade	Histology	Conventional Nomenclature
Low grade (well-differentiated)	<ul style="list-style-type: none"> • < 3 mitotic figures × 10 hpf • Absent or only focal punctate necrosis • Absent or mild nuclear atypia 	Carcinoid
Intermediate grade (moderately-differentiated)	<ul style="list-style-type: none"> • 3-10 mitotic figures × 10 hpf • Comedonecrosis present • Moderate nuclear atypia 	Atypical carcinoid
High grade, poorly differentiated (small cell carcinoma)	<ul style="list-style-type: none"> • > 10 mitotic figures × 10 hpf • Necrosis present • Prominent nuclear atypia with or without positive NE markers 	Small cell carcinoma
High grade, poorly differentiated (large cell neuroendocrine carcinoma)	<ul style="list-style-type: none"> • > 10 mitotic figures × 10 hpf • Necrosis present • Prominent nuclear atypia with positive NE morphologic features and positive or negative NE markers 	Large cell neuroendocrine carcinoma

hpf, high-power field; NE, neuroendocrine.

Data from Moran CA, Suster S, Coppola D, et al: Neuroendocrine carcinomas of the lung: a critical analysis, *Am J Clin Pathol* 2009 Feb;131(2):206-221.

SUMMARY

Small cell lung cancer is a very aggressive malignancy affecting 30,000 or more individuals annually in the United States. Most patients present with widespread disease at diagnosis, and despite the initial high sensitivity to chemotherapy and RT, resistance emerges rapidly. Extensive research over the last few decades has not significantly impacted the therapeutic paradigm of SCLC. The standard of care for both LD and ED is etoposide/platin chemotherapy for a minimum of four courses. Early integration of concurrent TRT is indicated for LD. Prophylactic cranial irradiation can be offered to patients who have excellent disease control following initial therapy. Major advances in treatment will require greater understanding of the drivers of the pan-resistant phenotype that characterizes recurrent disease and development of therapy to which these cells will be vulnerable. Recent discoveries from bench research and early-phase clinical investigation fuel the hope that outcomes for patients with SCLC can be improved in the next decade.

Non–Small Cell Lung Cancer

Diogo Bugano Diniz Gomes

Kathryn A. Gold

Don L. Gibbons

Commentary: George A. Eapen

INTRODUCTION

Lung cancer is the third most commonly diagnosed cancer, after breast and prostate cancers, but it is the most common cause of cancer-related death ⁽¹⁾. Every year, 1.5 million patients die of lung cancer worldwide ⁽¹⁾. About 70% of patients will be diagnosed with advanced stages that are not amenable to curative therapies. Only 15% of all patients diagnosed with lung cancer are alive 5 years after diagnosis.

Lung cancer is broadly divided into small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC). Approximately 85% of lung cancer is NSCLC. This chapter briefly describes the epidemiology, etiology, histology, prevention, and molecular biology of NSCLC. The major focus will be clinical presentation, diagnosis, staging, and treatment based on current clinical knowledge, with an emphasis on our approach at the University of Texas MD Anderson Cancer Center (MDACC).

EPIDEMIOLOGY

Lung cancer is rarely diagnosed in people younger than 35 years old. Incidence and death rates rise exponentially until age 75, when a plateau is reached. Non–small cell lung cancer accounts for the greatest number of deaths from cancer in both men and women over age 60.

The geographic, social, and temporal trends of the incidence of NSCLC are closely related to tobacco consumption. In developed Western countries, the

incidence of NSCLC has been declining; however, it has been increasing in Asia, Eastern Europe, and developing countries ⁽¹⁾.

Worldwide, NSCLC is more common in men, and this difference has been attributed to higher tobacco consumption. In some regions, like Eastern Europe and South America, there was an uptake of smoking by women in the 1980s, and these areas are currently experiencing a rise in NSCLC cases in women. In the United States, the incidence has been declining for both men and women as tobacco use declines; the male-to-female ratio from 2007 to 2011 was 1.4:1 ⁽²⁾.

There is some evidence that African Americans might be more susceptible to the carcinogenic effects of tobacco smoke ⁽³⁾; however, smoking behaviors might also account for socioeconomic and racial differences in lung cancer incidence.

ETIOLOGY

Smoking

The causal relationship between tobacco smoke and lung cancer was established in the 1950s in case-control and cohort studies. This led to the 1964 report of the US Surgeon General, concluding that smoking can cause lung cancer. Currently, it is estimated that 85% to 90% of lung cancers are due to smoking. Nonsmokers who are exposed to secondhand smoke are also at an increased risk. There is a dose-response relationship between smoking and lung cancer risk, and smoking cessation leads to a significant risk reduction (Table 18-1) ⁽⁴⁾.

Table 18-1 Approximate 10-Year Risk of Developing Lung Cancer^a

Age (years)	Duration of Smoking					
	25 Years		40 Years		50 Years	
	Quit (%)	Still Smoking (%)	Quit (%)	Still Smoking (%)	Quit (%)	Still Smoking (%)
One-pack-per-day smokers						
55	<1	1	3	5	NA	NA
65	<1	2	4	7	7	10
75	1	2	5	8	8	11
Two-packs-per-day smokers						
55	<1	2	4	7	NA	NA
65	1	3	6	9	10	14
75	2	3	7	10	11	15

NA, not available.
^aThis table assumes that people who have quit smoking will continue to abstain for the next 10 years and those who are still smoking will keep smoking the same amount for the next 10 years.
Adapted, with permission, from Bach PB, Kattan MW, Thornquist MD, et al. Variations in lung cancer risk among smokers. *Cancer*. 2003;95(1):470-478.

Tobacco smoke is a complex mixture of chemicals that includes multiple carcinogens, most importantly the *N*-nitrosamines (nicotine-derived nitrosamino ketone [NNK] and *N'*-nitrosonornicotine [NNN]) and polycyclic aromatic hydrocarbons [benzo(a)pyrene and dimethylbenz(a)anthracene]. They are activated through hydroxylation by the P450 enzyme system and exert their action through the formation of DNA adducts.

Smokeless tobacco is frequently advocated as a safer alternative. There has not been a clear association between smokeless tobacco and lung cancer; however, it increases the risk of head and neck, pancreatic, and gastric cancer. E-cigarettes deliver water vapor with scents and different amounts of nicotine containing lower amounts of nitrosamines. However, they still contain high levels of propylene glycol and glycerin, and their long-term effects on health are unknown. Their use should not be recommended to nonsmokers, and use as part of a smoking cessation approach needs further study.

Approximately 10% to 15% of cases of NSCLC occur in never smokers, corresponding to approximately 20,000 deaths annually. In addition to secondhand smoke exposure, several other agents have also been linked to the development of lung cancer (Table 18-2).

Asbestos

Asbestos exists in many natural forms. The silicate fiber has been implicated in carcinogenesis, is chemically inert, and can remain in a person's lungs for a lifetime. Epidemiologic studies have confirmed the association between asbestos exposure and certain lung diseases, such as pulmonary fibrosis,

mesothelioma, and lung cancer ⁽⁵⁾. Most exposure occurs in the workplace. When smoking is combined with asbestos exposure, the relative risk of lung cancer is strikingly increased ⁽⁵⁾.

Radon

Radon is a naturally occurring decay product of uranium. It is a colorless, odorless, chemically inert gas that can penetrate the earth's crust and accumulates in buildings. It emits heavy ionizing alpha particles, which may damage DNA. It was shown that many households in Europe, Canada, and the United States have some degree of radon radiation that may increase NSCLC risk among smokers and nonsmokers ⁽⁶⁾.

Diet

The majority of studies that have examined vegetable consumption in relation to lung cancer have shown a

Table 18-2 Relative Risk Of Developing Lung Cancer

Risk Factor	Relative Risk	Reference
Cigarette smoking in males	17.4	8
Cigarette smoking in females	10.8	8
Passive smoking	1.5	4
Asbestos	1.2-2.6	9, 18
Asbestos and smoking	28.8	19
Mining	3-8	4, 21
Radon (residential)	1.1-2	4

protective effect (reviewed in Alberg and Samet [7]), but there are inherent biases in these population studies. There is also epidemiologic evidence that dietary intake of certain vitamins decreases lung cancer risk; however, trials of vitamin supplementation for cancer prevention have ultimately been unsuccessful (see later “Chemoprevention” section).

Other Factors

Environmental or industrial exposure to arsenic, chromium, chloromethyl ether, vinyl chloride, and polycyclic aromatic hydrocarbons increases lung cancer risk (reviewed by Field and Withers [8]). Preexisting lung disease such as tuberculosis, silicosis, pulmonary fibrosis, and chronic obstructive pulmonary disease are also associated with an increased lung cancer incidence even when correcting for the degree of cigarette consumption. This suggests that common pathways to these conditions, such as chronic inflammation, may drive the tumorigenic process.

Genetic Predisposition

Family history of lung cancer is associated with a two- to three-fold increase in lung cancer risk, even after correction for smoking, and this risk seems to be inherited in a Mendelian co-dominant fashion (9).

Many studies describe weak but consistent associations between some polymorphisms and lung cancer risk. The cytochrome P450 (CYP) family is responsible for the metabolism of tobacco smoke, and the polymorphism CYP1A1 Ile⁴⁶²Val is associated with a higher risk in Asians (odds ratio [OR], 1.61) (10). The glutathione S-transferase (GST) enzyme prevents oxidative damage, and the polymorphism GSTM1 increases risk in Asians (OR, 1.17) (11). Finally, individuals with impaired DNA repair capacity are at higher risk for developing lung cancer, even if they are nonsmokers, and the polymorphism Lys⁷⁵¹Gln in the DNA-repairing enzyme ERCC2 was associated with lung cancer (OR, 1.15) (12).

Large genome-wide association studies (GWAS) (13) have identified three loci strongly associated with lung cancer risk in different populations: 15q25, 5p15, and 6p21. The 15q25 susceptibility region encodes three cholinergic nicotine receptor genes (*CHRNA3*, *CHRNA5*, *CHRNA4*), and alterations in those regions have been associated with a higher risk for nicotine dependence and higher smoking burden. In nonsmokers, they have also been associated with impaired healing of the respiratory mucosa, suggesting a higher sensitivity to toxin-induced airway damage. The 5p15 region encodes the *TERT* gene, responsible for telomerase function, which is frequently altered in many cancers.

PREVENTION OF LUNG CANCER

Smoking Cessation and Prevention

The most effective method of preventing lung cancer is reducing tobacco exposure, either through encouraging smoking cessation or preventing young people from starting to smoke. In the United States, campaigns to reduce smoking rates have been successful. The estimated percentage of Americans who actively smoke decreased from 42.4% in 1965 to 25% in 1990 and to 18.1% in 2012. However, former smokers retain an increased risk of lung cancer, and there are still a considerable number of smokers, highlighting the need for better education and prevention strategies, especially those targeted to youths.

Early Detection and Screening

Previous studies examined the role of chest x-ray, with or without cytologic analysis of sputum, to screen for lung cancer, and none showed a clear benefit. Most of them were confounded by lead time, length time, and overdiagnosis biases.

Spiral computed tomography (CT)—also called helical CT or low-dose CT—is much more sensitive to detect early NSCLC than chest x-ray. In 2011, the results of the National Lung Screening Trial (NLST) were published (14). In this trial, 53,454 current or former smokers age 55 to 74 years old with at least a 30-pack-year smoking history and no symptoms that could be related to lung cancer were randomized to undergo yearly chest x-rays or low-dose CT for 3 years. After a median follow-up of 6.5 years, the low-dose CT group had a 20% reduction in the rate of lung cancer–specific mortality, from 309 to 247 per 100,000 person-years, as well as a 6.7% reduction in overall mortality. In the CT group, 39% of patients had suspicious lung nodules (vs 16% in the control arm), and the majority of these (96%) were considered false-positive results. Sensitivity and specificity of low-dose CT were 93.8% and 73.4%, respectively, compared to 73.5% and 91.3% for chest radiography. Cost-effectiveness analysis showed a median cost of \$43,000 per quality-adjusted life-year gained for current smokers assigned to the low-dose CT group. Based on these results, the US Preventive Services Task Force currently recommends lung cancer screening with yearly low-dose CT for current or past smokers, age 55 to 80, with a smoking history of at least 30 pack-years. Screening should be discontinued once a person has not smoked for 15 years. Another trial is currently being conducted in Belgium and the Netherlands (the NELSON study) looking at the 10-year impact of lung cancer screening using low-dose CT scan.

Table 18-3 Large Randomized Lung Cancer Chemoprevention Trials

Study	Intervention	Population	Size	End Point	Outcome
ATBC ⁽¹⁵⁾	β-Carotene; α-tocopherol	Male smokers	29,133	Lung cancer incidence	Harmful
CARET ⁽¹⁶⁾	β-Carotene; retinol	Current and former smokers	18,314	Lung cancer incidence	Harmful
Intergroup Lung Trial ⁽¹⁷⁾	Isotretinoin	Resected NSCLC	1,166	Second malignancies	Harmful
Euroscan ⁽¹⁸⁾	Retinol, N-acetylcysteine	Resected NSCLC and head and neck cancer	2,592	Second malignancies	Negative
ECOG 5597 ⁽¹⁹⁾	Selenium	Resected NSCLC	1,772	Second malignancies	Negative
Physicians' Health Study II ⁽²⁰⁾	Vitamin C and vitamin E	Healthy male physicians	14,641	Cancer incidence	Negative
NORVIT and WENBIT ⁽²¹⁾	Vitamin B ₁₂ and folic acid	Patients with ischemic heart disease	6,845	Cancer incidence	Harmful

NSCLC, non-small cell lung cancer.

Despite recent developments, low-dose CT screening still has significant limitations, including high false-positive ratios and the development of interval lung cancers, which can be aggressive. Positron emission tomography (PET)-CT scan, epigenetic markers, and cell-free tumor DNA are additional approaches under investigation, which are only recommended in the setting of a clinical trial.

Chemoprevention

Cigarette smoking has an effect of field cancerization, with the accumulation of genetic mutations and other premalignant changes throughout the lungs and the aerodigestive tract. Patients treated and cured of early-stage lung cancer have a high risk of developing second primary tumors. Therefore, a series of chemoprevention trials has focused on smokers and survivors of lung and head and neck cancers.

Multiple studies evaluated supplementation with vitamins and oligo-elements, but none showed a benefit to supplementation, and several studies showed risk, with increased lung cancer incidence and mortality (Table 18-3) ^(15–21).

Given the potential connection between inflammation and tumorigenesis, phase II studies have used anti-inflammatory agents, such as celecoxib, and prostaglandin analogues, such as iloprost. These agents have been able to reduce proliferation and dysplasia of oral and bronchial epithelium in smokers and former smokers, but their benefit in cancer prevention remains to be proven. There are currently no proven agents for the chemoprevention of lung cancer.

HISTOLOGY AND MOLECULAR PATHOLOGY

Most lung tumors arise from epithelial cells and are called bronchogenic carcinomas. Neuroendocrine tumors also arise in the lung and can appear as SCLC, carcinoids, or large cell neuroendocrine carcinomas. Bronchogenic carcinomas include NSCLCs, a category comprising three major types: adenocarcinoma, squamous cell carcinoma (SCC), and large cell carcinoma.

The most current histologic classification of NSCLC was proposed by the International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society in 2011 ⁽²²⁾ and uses immunohistochemistry to identify subgroups with different molecular profiles and clinical behaviors (Tables 18-4 and 18-5). Adenocarcinomas usually stain positive for cytokeratin 7, thyroid transcription factor 1 (TTF-1), and surfactant apoprotein A and are negative for cytokeratin 20. Metastatic adenocarcinomas from other sites except the thyroid stain negative for TTF-1. All carcinoids and most SCLCs stain positive for chromogranin and synaptophysin, whereas NSCLC is usually negative for these two markers. Mesothelioma is distinguished from adenocarcinoma by the presence of calretinin and cytokeratin 5/6 and the absence of carcinoembryonic antigen (CEA), B72.3, Ber-EP4, and MOC-31.

Adenocarcinoma

Adenocarcinoma is the most common subtype of NSCLC in the United States, representing 40% of

NOS, not otherwise specified; NSCLC, non–small cell lung cancer. Adapted with permission from Travis WD, Brambilla E, Noguchi M, et al. International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society international multidisciplinary classification of lung adenocarcinoma, *J Thorac Oncol* 2011 Feb;6(2):244-285.

cases in men and 50% in women. It is predominant in nonsmokers, and its incidence has been rising. These tumors are classically peripheral and, on histologic examination, demonstrate gland formation, papillary structures, or mucin production (Fig. 18-1).

Non–small cell lung cancer is one of the cancer types with the highest mutation burden, with an average of 360 exonic mutations per sample⁽²³⁾. However, the patterns of mutations are different for adenocarcinomas and SCCs.

About 75% of lung adenocarcinomas have alterations in driver genes that activate intracellular pathways leading to proliferation, cell survival, and oxidative stress response⁽²⁴⁾ (Fig. 18-2). Up to 79% of those alterations are in the RTK/RAS/RAF pathway, including mutations in the ErbB family member *EGFR* (ErbB1).

The prevalence of *EGFR* mutations ranges from 5% to 10% in smokers to 40% to 50% in nonsmokers in the Western population⁽²⁵⁾. The alterations are usually in the tyrosine kinase domain of the gene within exons 18 to 24, most specifically in the intracellular adenosine triphosphate (ATP)-binding domain (Table 18-6)⁽²⁵⁻²⁷⁾.

Frequencies of *EGFR*, *KRAS*, *ALK*, *ROS1*, and other driver genetic alterations commonly found in lung adenocarcinoma samples are listed in Table 18-7^(24, 25, 28-32). This is a rapidly changing landscape that is defining the many molecular subsets of this heterogeneous disease.

Squamous Cell Carcinoma

Squamous cell carcinoma is now the second most frequent histology, accounting for 30% of NSCLC in men and 20% in women. This tumor arises most frequently in the proximal bronchi and has the strongest association with smoking. Pathologically, it is characterized by visible keratinization, with prominent desmosomes and intercellular bridges (Fig. 18-3).

Squamous cell carcinomas frequently have amplifications in chromosome 3q, which contains genes involved in squamous differentiation (*SOX2* and *TP53*) and cell proliferation (*PI3K*). About 81% to 90% of patients with SCCs have *TP53* mutations, and 47% have alterations in the PI3K/AKT/mTOR pathway, whereas only 26% of SCCs have activations of the RTK/RAS/RAF pathway⁽²³⁾. The prevalence of *EGFR* mutations is 1% to 3%, 6% of patients have *EGFR* amplifications, and 1% to 6% have *KRAS* mutations⁽²³⁾ (Fig. 18-4).

Large Cell Carcinoma

The least common subtype of NSCLC, large cell carcinoma, accounts for approximately 8% of all NSCLCs (Fig. 18-5). Refinements in histopathologic techniques have led to the diagnosis of adenocarcinoma or SCC in cases previously diagnosed as undifferentiated large cell carcinoma.

CLINICAL PRESENTATION

Non–small cell lung cancer is often asymptomatic at diagnosis and may be found incidentally on imaging

Table 18-5 Adenocarcinoma Histologic Subtypes and Molecular and Radiologic Associations

Predominant Histologic Subtype	Molecular Features	Computed Tomography Scan Appearance	Relative Risk of Recurrence After Resection
Lepidic	TTF-1 positive: 100% EGFR amplification: 20%-50% EGFR mutation (nonsmokers): 10%-30% KRAS mutations (smokers): 10% BRAF mutations: 5%	Ground glass or solid nodule	1.0
Papillary	TTF-1 positive: 90%-100% EGFR amplification: 20%-60% EGFR mutation: 10%-30% KRAS mutations: 3% BRAF mutations: 5% ERBB2 mutations: 3% P53 mutations: 30%	Solid nodule	2.7 (95% CI, 1.1-6.8)
Acinar	TTF-1 positive or negative EGFR amplification: 10% EGFR mutation (non-smokers): <10% KRAS mutation (smokers): 20% P53 mutation: 40% EML4/ALK translocation: >5%	Solid nodule	2.3 (95% CI, 0.9-5.7)

performed for other reasons. If symptoms are present, they are often related to the specific locations of tumor masses and the occurrence of paraneoplastic syndromes. The symptoms of centrally located lesions include cough, hemoptysis, wheezing, stridor, dyspnea, and postobstructive pneumonia. Peripheral lesions can cause pain due to pleural or chest wall invasion, cough, or restrictive dyspnea.

The involvement of thoracic and cervical structures can also lead to classical clinical presentations:

- Pancoast syndrome: Shoulder pain radiating to the arm in an ulnar distribution caused by invasion of

the eighth cervical and first thoracic nerves in the superior sulcus.

- Horner syndrome: Enophthalmos, ptosis, miosis, and ipsilateral dyhidrosis caused by involvement of the paravertebral sympathetic nerves.
- Hoarseness: Involvement of the left recurrent laryngeal nerve as it passes through the aortopulmonary window.
- Elevation of the hemidiaphragm: Involvement of phrenic nerve at the mediastinum.
- Superior vena cava syndrome: Swelling of the face and arm and superficial venous engorgement caused by compression of the superior vena cava.

FIGURE 18-1 Adenocarcinoma. Photomicrograph of adenocarcinoma of the lung stained with hematoxylin and eosin. (Used with permission from Cesar Moran, MD.)

The production of hormones or hormone-like substances can lead to paraneoplastic syndromes:

- **Cancer cachexia:** The most common paraneoplastic syndrome, characterized by weight loss, impaired immune function, and weakness that are not completely explained by poor oral intake. The exact mechanism for development of cachexia is unknown, but tumor-elaborated cytokines have been implicated.

- **Hypercalcemia:** The second most common paraneoplastic syndrome in NSCLC, hypercalcemia is caused by ectopic production of a parathyroid hormone-related protein (PTHrP) or bone metastases. It is more common in the squamous cell subtype.
- **Hypertrophic pulmonary osteoarthropathy:** Arthropathy and clubbing of the fingers and toes with evidence of periostitis of the long bones (Fig. 18-6). Its etiology is unknown, and it is more common in adenocarcinomas and large cell carcinoma.

Non–small cell lung cancer is frequently metastatic, and symptoms secondary to metastases are common. The most common sites for metastases are intrathoracic nodes, pleura, contralateral lung, liver, adrenal glands, bone, and brain.

DIAGNOSIS

Solitary Pulmonary Nodule

A solitary pulmonary nodule is a single asymptomatic mass that is surrounded by lung tissue, is well circumscribed, measures less than 3 cm, and does not show evidence of mediastinal or hilar adenopathy. The differential diagnosis includes primary cancer, metastatic cancer, infection, benign tumors (eg, hamartomas), vascular abnormalities, and inflammation (eg, granulomatous disease). The American College of Chest Physicians has issued guidelines on the evaluation of

FIGURE 18-2 Somatic alterations in the RTK/RAS/RAF pathway in lung adenocarcinoma. (Adapted with permission from Collisson EA, Campbell JD, Brooks AN, et al. Comprehensive molecular profiling of lung adenocarcinoma, *Nature* 2014 Jul 31;511(7511):543-550.)

Table 18-6 Most Common *EGFR* Mutations in Lung Adenocarcinomas

Mutation	Prevalence in Treatment-Naïve <i>EGFR</i> -Mutant Tumors	Sensitivity to Erlotinib/Gefitinib
Exon 19 deletion (del19)	45%-50% ⁽²⁵⁾	Sensitive
Exon 21 Leu858Arg insertion (L858R)	40%-45% ⁽²⁵⁾	Sensitive
Exon 20 insertions	5% ⁽²⁶⁾	Resistant
Exon 12 and 18 insertions	2%-3% ⁽²⁶⁾	Unknown
Exon 20 T790M	1%-5% ⁽²⁷⁾	Resistant

solitary lung nodules, based on their size (\leq or >8 mm), the clinical probability of malignancy, and the patient's surgical risk ⁽³³⁾ (Table 18-8 and Fig. 18-7).

The management of small nodules (<8 mm) is less clear. Lesions that are too small to be biopsied (<5 mm) should be followed with CT scans in 6 months (any risk factors for lung cancer) or 12 months (no risk factors for lung cancer). For lesions 5 to 8 mm, some recommend close follow-up with CT scans in 3, 6, and 12 months, and others recommend nonsurgical biopsies ⁽³³⁾.

Pulmonary Mass

Lesions that are large (>3 cm), multiple, or with enlarged hilar, mediastinal, and/or supraclavicular lymph nodes should undergo complete lung cancer staging and a nonsurgical biopsy. Fiberoptic bronchoscopy is appropriate for central lesions and is able to establish the diagnosis in 97% of cases. For peripheral lesions, the diagnostic yield of bronchoscopy is only 55%, and percutaneous transthoracic biopsies can be considered. Because of the tissue requirements for immunohistochemistry and molecular marker testing of lung cancers, at MDACC, we usually perform an image-guided core-needle biopsy. Mediastinoscopy or endobronchial ultrasound (EBUS) can be used to obtain biopsy samples from mediastinal nodes.

Staging

Once the histologic diagnosis of NSCLC has been established, the extent of disease must be determined (Fig. 18-8).

The stage of disease will dictate therapy. All patients must undergo a complete history and physical examination, chest x-ray, CT scan of the chest and upper abdomen (to include the adrenal glands), a complete blood count, and blood chemistry tests that include electrolyte and liver enzyme studies.

Table 18-7 Common Driver Genes Altered in Lung Adenocarcinoma

Name	Alteration	Main Effects	Incidence
<i>KRAS</i> mutations	Multiple, usually in codons 12 and 13; most common G12D (nonsmokers) and G12C (smokers)	Activation of RAS/RAF/MEK/ERK pathway	30%-35% (mostly in smokers) ⁽²⁵⁾
<i>EGFR</i> mutations	Several alterations in the ATP-binding domain of the receptor	Activation of RAS/RAF/MEK and PI3K/AKT/mTOR pathways	10%-15% (40%-50% in nonsmokers) ⁽²⁸⁾
<i>BRAF</i> mutations	About 50% are the V600E mutation also described in other cancers	Activation of RAS/RAF/MEK/ERK pathway	7%-10% ⁽²⁴⁾
<i>MET</i> mutations	Exon 14 skipping; can occur with or without <i>MET</i> amplification	Activation of MET	7% ⁽²⁴⁾
<i>PIK3CA</i>	Many activating mutations	AKT, TSC, and mTOR	7% ⁽²⁴⁾
<i>EML4/ALK</i> and other <i>ALK</i> translocations	Inversion within chromosome 2p	Constitutively activates the anaplastic lymphoma kinase (<i>ALK</i>) gene leading to downstream activation of RAS and PI3K	1%-4% ^(29, 30)
<i>ROS1</i> fusions	Multiple rearrangements of the <i>ROS1</i> gene with different genes	Related to the <i>ALK</i> protein, also activates RAS and PI3K	1%-2% ⁽²⁹⁾
<i>RET</i> fusions	Multiple rearrangements of the <i>RET</i> gene with different genes	Activation of the <i>RET</i> proto-oncogene and RAS pathway	1% ⁽³¹⁾
<i>ERBB2</i> (<i>HER2</i>) mutations	Various mutations; in about 50% of cases co-occurrence with <i>HER2</i> amplification	Activation of RAS/RAF/MEK and PI3K/AKT/mTOR pathways	2%-4% ⁽³²⁾

FIGURE 18-3 Squamous cell carcinoma. Photomicrograph of squamous cell carcinoma of the lung stained with hematoxylin and eosin. (Used with permission from Cesar Moran, MD.)

All patients with stage II to IV disease should have evaluation of the brain, with magnetic resonance imaging (MRI) if possible. Central nervous system (CNS) imaging may be considered for patients

with stage I disease. For stage I to III NSCLC, ^{18}F -fluorodeoxyglucose (FDG)-PET should be performed to evaluate mediastinal nodes and for distant metastases. Because the involvement of mediastinal lymph nodes will influence surgical decisions (see section “Treatment”), the presence of FDG-avid mediastinal lymph nodes in a PET-CT scan should be confirmed with either mediastinoscopy or EBUS (see “Commentary”). Routine use of mediastinoscopy or EBUS in patients with a normal-appearing mediastinum on PET-CT scans is controversial.

After the completion of staging evaluation, the disease is assigned a TNM stage (Figs. 18-9 to 18-17; Tables 18-10 and 18-11). The TNM staging for NSCLC was revised and updated in 2009 in the seventh edition of the American Joint Committee on Cancer/International Union Against Cancer staging system (³⁴).

Clinical staging has inherent inaccuracies and therefore typically underestimates the true extent of disease. In patients who undergo surgical tumor resection, surgical/pathologic staging should be done to predict recurrence and to evaluate the need for adjuvant therapy. Patients’ 5-year survival rates by tumor stage are shown in Table 18-11.

TREATMENT

Stages I and II Disease

Surgery

Surgery is standard treatment for stages I and II NSCLC (Figs. 18-18 and 18-19).

The extent of lung resection will be dictated by the size and location of the tumor. The entire tumor must be removed, with margins negative for cancer. Wedge resection and segmentectomy are associated with higher rates of local recurrence than lobectomy and pneumonectomy and are not considered standard of care, although they may be an option for patients who cannot tolerate a larger surgery due to poor pulmonary function⁽³⁵⁾. All patients should also undergo complete ipsilateral mediastinal lymph node dissection or systematic mediastinal sampling for accurate staging⁽³⁶⁾.

Any patient who is being considered for surgery must undergo pulmonary function tests to assess the ability to withstand pulmonary resection. Split-lung function studies can further help to predict lung function after the planned resection. There is no single accepted value, criterion, or cutoff for pulmonary resection. Published criteria that have been shown to predict high risk for lung resection include estimated posttreatment forced vital capacity <2 L, forced expiratory volume in 1 second <1 L, and diffusing capacity of the lungs for carbon dioxide <40% to 60%⁽³⁷⁾.

Radiation Therapy

For patients with early-stage lung cancer who cannot undergo surgery because of poor pulmonary reserve

FIGURE 18-6 Hypertrophic pulmonary osteoarthropathy (HPO). This 62-year-old man with non-small cell lung cancer reported a 1-month history of finger clubbing and arthritic lower extremity pain. The plain radiographs of the lower extremities show periosteal reaction in both femora as well as in bilateral tibias/fibulas that is consistent with HPO.

Commentary: Mediastinal Lymph Node Sampling Using Endobronchial Ultrasound and Transbronchial Needle Aspiration

Accurate mediastinal lymph node staging is a critical aspect of non–small cell lung cancer (NSCLC) management. Non-invasive staging typically relies on a combination of computed tomography (CT) and ^{18}F -fluorodeoxyglucose (FDG)–positron emission tomography (PET) data to detect mediastinal metastases. Lymph nodes are considered abnormal by CT criteria if the short-axis diameter is >10 mm; however, both false negatives and false positives are possible. Fluorodeoxyglucose-FDG-PET scanning has been a welcome addition to the staging armamentarium and increases diagnostic accuracy. However, limitations of non-invasive staging modalities remain, and current guidelines recommend tissue sampling by invasive means to improve diagnostic accuracy among patients whose subsequent therapy is contingent on mediastinal involvement.

Multiple modalities are available for sampling mediastinal and hilar lymph nodes. These range from minimally invasive approaches such as endobronchial ultrasound–guided transbronchial needle aspiration (EBUS-TBNA), endoscopic ultrasound guided–fine-needle aspiration (EUS-FNA), and CT-guided needle aspiration to surgical approaches such as mediastinoscopy and thoracotomy.

Endobronchial ultrasound–guided transbronchial needle aspiration EBUS-TBNA is a technology that utilizes an integrated ultrasonic bronchoscope to obtain real-time image–guided transbronchial needle aspiration biopsy of lymph nodes in proximity to the central airways and. EBUS-TBNA is currently our preferred method for assessing mediastinal lymph node involvement. It is a minimally invasive procedure that is typically performed on an outpatient basis and often utilizes only moderate sedation. Biopsies can be taken

at all lymph node stations adjacent to a major airway, and as such, EBUS-TBNA can sample more lymph nodes in a single procedure than any other invasive mediastinal tissue sampling technique. Furthermore, rather than merely confirming malignancy in an enlarged or FDG-avid lymph node, true lymph node mapping can be carried out using this technology. It can be safely performed in most patients, including those that who have undergone prior surgical or radiation therapy to the thorax. The risk profile is minimal and similar to the risks of standard bronchoscopy. Numerous studies have documented the safety and diagnostic accuracy of EBUS-TBNA in staging lung cancer. Samples obtained have also been shown to be adequate for molecular testing. Importantly, EBUS-TBNA has shown significant utility even in patients with radiologically normal mediastinum.

AlthoughWhile cervical mediastinoscopy was traditionally considered the reference standard for invasive mediastinal lymph node sampling, it is difficult to repeat, is more invasive, and has higher associated morbidity and mortality than EBUS-TBNA, and increasing evidence suggests diagnostic equivalence. Current American College of Clinical Pharmacy ACCP guidelines recommend a needle biopsy technique such as EBUS-TBNA as the initial invasive mediastinal staging technique of choice for lung cancer with the caveat that negative biopsies may need surgical confirmation. In summary, EBUS-TBNA provides a safe, minimally invasive, and highly accurate method of mediastinal lymph node sampling and has rapidly become part of our standard practice in the mediastinal staging of NSCLC.

George A. Eapen

or medical comorbidities, stereotactic radiosurgery is a feasible option with local control rates of 90% and cancer-specific survival of 88% at 3 years⁽³⁸⁾.

There is controversy regarding whether stereotactic radiosurgery should be considered in patients who are candidates for surgery and who have small primary tumors and no lymph node involvement. Retrospective series suggest that outcomes with radiation may be similar to those of surgery⁽³⁸⁾. Surgery, however, remains the standard of care for patients who can tolerate it.

Adjuvant Chemotherapy

Even after complete resection, rates of recurrence of NSCLC are high, prompting the study of adjuvant

chemotherapy in this disease. The potential benefit of adjuvant chemotherapy is the eradication of micro-metastatic disease before it becomes clinically evident, thus potentially increasing cure rates. For patients with completely resected stage II or III NSCLC, multiple meta-analyses demonstrate that adjuvant platinum-based chemotherapy is associated with an absolute benefit in 5-year survival of about 5%⁽³⁹⁾ and should be offered to all patients with good performance status (Table 18-12)^(40–44). For patients with no lymph node involvement and a primary tumor smaller than 4 cm, adjuvant chemotherapy is not recommended. For node-negative tumors larger than 4 cm, the Cancer and Leukemia Group B 9633 trial suggested a benefit of adjuvant platinum-based chemotherapy, and it should be considered⁽⁴⁰⁾ (see Table 18-12).

Table 18-8 Clinical Probability of Malignancy of Solitary Lung Nodules

	Low Probability (<5%)	Intermediate Probability (6-65%)	High Probability (>65%)
Patient	Young, low smoking burden, no previous history of cancer	Mixture of low- and high-probability features	Older, heavy smoker, previous cancer
Nodule (CT scan)	Small, regular margins, non-upper lobe location, enhancement <15 HU in the contrast phase	Mixture of low- and high-probability features	Large, irregular/spiculated, upper lobe location; enhancement >15 HU in the contrast phase
FDG-PET results	Low or moderate clinical probability with low PET probability	Weak or moderate PET activity	Intense hypermetabolic nodule
Nonsurgical biopsy results (bronchoscopy or transthoracic biopsy)	Specific benign diagnostic	Nondiagnostic	Suspicious for malignancy
Behavior on CT surveillance	Progressive decrease in size or resolution; no growth over ≥ 2 years (solid nodules) or over ≥ 3 years (semi-solid nodules)	NA	Clear evidence of growth

CT, computed tomography; FDG-PET, ^{18}F -fluorodeoxyglucose–positron emission tomography; NA, not applicable.

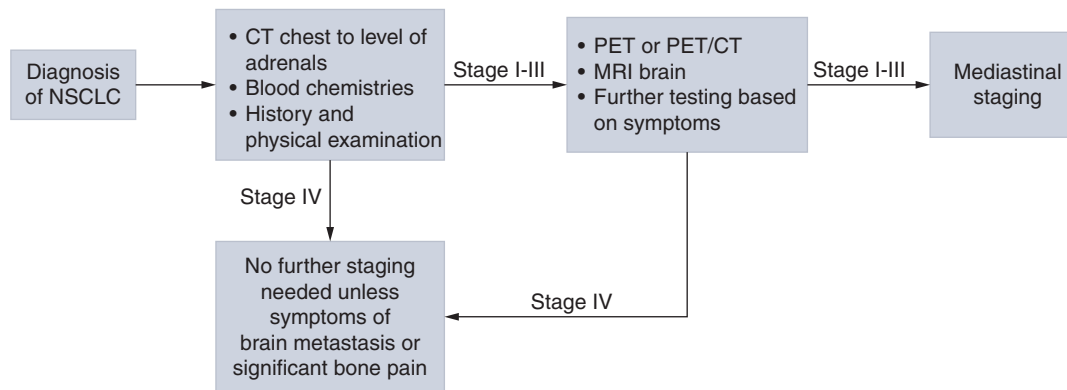

FIGURE 18-8 Staging algorithm for non–small cell lung cancer (NSCLC). CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography. See text for details.

Cisplatin-vinorelbine is the most studied regimen for adjuvant chemotherapy; in practice, other cisplatin-based doublets are frequently used. Acceptable second agents include pemetrexed (for nonsquamous NSCLC), docetaxel, etoposide, and gemcitabine. Cisplatin is preferred over carboplatin, but if cisplatin is not feasible, carboplatin/paclitaxel is an appropriate alternative⁽⁴⁰⁾.

There is no evidence that targeted agents such as bevacizumab, erlotinib, and crizotinib are effective in the adjuvant setting, although the National Cancer Institute ALCHEMIST trial will assess the benefit for specific molecular subsets of patients.

Neoadjuvant chemotherapy offers several real and theoretical advantages over postoperative therapy: better patient compliance, improved tumor resectability, earlier treatment of micrometastatic disease, and earlier assessment of clinical and pathologic response. There has been one randomized trial and one meta-analysis⁽⁴⁵⁾ that suggest the equivalence of the neoadjuvant and

FIGURE 18-9 Stage I non–small cell lung cancer. [Visual Art: ©2015 The University of Texas MD Anderson Cancer Center.]

FIGURE 18-10 Stage I non–small cell lung cancer. This T2N0M0 NSCLC was an incidental finding when the patient presented with an unrelated medical illness. The computed tomography of the chest revealed a 3.8- by 3.1-cm right-upper-lobe mass with no hilar or mediastinal adenopathy. Pathologic staging after a right upper lobectomy and mediastinal lymph node dissection confirmed the clinical stage.

FIGURE 18-11 Stage II non-small cell lung cancer. [Visual Art: ©2015 The University of Texas MD Anderson Cancer Center.]

FIGURE 18-12 Stage II non-small cell lung cancer. This patient presented with symptoms of pneumonia and was found to have a right hilar mass impinging on the right-lower-lobe bronchus and a right-lower-lobe infiltrate by computed tomography scan. Positron emission tomography scan showed increased uptake in the hilar mass and physiologic uptake. Staging evaluation showed no distant metastatic disease. He underwent a right middle and lower lobectomy with a mediastinal lymph node dissection. This revealed a 3.1-cm primary squamous cell carcinoma with two positive hilar nodes and no involved mediastinal nodes (T2N1M0).

FIGURE 18-13 Classification of regional lymph nodes. [Visual Art: ©2015 The University of Texas MD Anderson Cancer Center.]

adjuvant approaches. Adjuvant treatment is the standard of care, but neoadjuvant chemotherapy could be considered in special situations, such as for stage III disease when response to chemotherapy may help to determine whether a patient should undergo surgery or chemoradiation.

Adjuvant radiation or chemoradiation for resected stage I and II NSCLC has been shown to be detrimental and should not be recommended⁽⁴⁶⁾.

Stage III Disease

Patients with stage III disease have better outcomes with multimodality rather than single-modality therapy, and their care should be managed by a multidisciplinary team. For patients with stage IIIB disease, chemoradiation represents the standard of care. Chemoradiation is often used for patients with stage IIIA disease as well, but surgery with adjuvant treatment can be considered for carefully selected patients.

In a randomized trial of chemoradiation alone versus chemoradiation followed by resection, the patients

who benefited from the surgical approach were those with stage IIIA disease who had limited involvement of mediastinal lymph nodes and who underwent lobectomy (as opposed to pneumectomy)⁽⁴⁷⁾. Neoadjuvant chemoradiation followed by surgery has been compared to neoadjuvant chemotherapy followed by surgery and adjuvant radiation⁽⁴⁸⁾ and was associated with more toxicity with no survival benefit. At MDACC, we consider surgical treatment in patients with stage IIIA disease with good performance status and without multistation mediastinal adenopathy. These patients are typically treated with neoadjuvant chemotherapy followed by consideration of surgery. Adjuvant radiation therapy is typically given if there is evidence of mediastinal node involvement based on assessment of surgical pathology (Fig. 18-20).

Patients with stage IIIA disease and extensive mediastinal involvement or IIIB disease should be treated with concurrent chemoradiation. When compared with sequential radiotherapy and chemotherapy, this approach is associated with higher survival rates (23.8% vs 18.1% at 3 years; hazard ratio [HR], 0.84;

FIGURE 18-14 Stage III non-small cell lung cancer. [Visual Art: ©2015 The University of Texas MD Anderson Cancer Center.]

FIGURE 18-15 Stage IIIB non-small cell lung cancer (NSCLC). This patient presented with chest pain, and the chest x-ray (left) showed an approximately 4.0- by 3.0-cm mass in the left upper lobe and an additional mass in the right mediastinum. Initial computed tomography (CT) revealed a 4.5-cm mass in the left upper lobe and a 5-cm mass in the paratracheal region. Biopsy confirmed NSCLC. Staging evaluation showed no distant metastatic disease (T2N3M0). The patient was treated with concurrent chemotherapy and radiotherapy. The posttreatment CT (right) showed significant therapeutic response.

FIGURE 18-16 Stage IV non–small cell lung cancer. [Visual Art: ©2015 The University of Texas MD Anderson Cancer Center.]

$P = .004$) but increased toxicity (acute esophageal toxicity, 18% vs 4%; relative risk [RR], 4.9; $P = .001$)⁽⁴⁹⁾.

Standard radiotherapy for stage III NSCLC consists of radiation given once daily for 6 weeks (30 fractions) to a total dose of 60 Gy. All attempts to increase efficacy through hyperfractionation, acceleration, or increased radiation dose have failed⁽⁵⁰⁾. In the recent Radiation Therapy Oncology Group 0617 trial, patients receiving high-dose radiation (74 Gy) had higher rates of locoregional failure (44% vs 35.3%; $P = .04$) and worse median survival (19.5 vs 28.7 months; $P = .0007$) than those receiving standard-dose radiation (60 Gy)⁽⁵¹⁾. Proton therapy is a newer technique that is able to deliver a higher dose to the tumor while delivering lower doses to normal surrounding tissue; it is currently being compared to standard radiation in a randomized phase III trial (NCT00915005).

Multiple concurrent chemotherapy regimens have been tested against radiation alone with proven benefit⁽⁵²⁾; however, these regimens have not been directly compared to each other, and multiple regimens are considered acceptable (Table 18-13). At MDACC, many physicians favor carboplatin and paclitaxel because retrospective data suggest that this regimen is less toxic than cisplatin and etoposide⁽⁵³⁾.

The use of consolidation docetaxel after concurrent chemoradiation with cisplatin and etoposide was detrimental in the phase III Hoosier Oncology Group LUN 01-24 trial⁽⁵⁴⁾. However, most studies with carboplatin/cisplatin and pemetrexed or carboplatin and paclitaxel included consolidation chemotherapy after radiation. It is reasonable to consider consolidation chemotherapy for patients who received those regimens and have a good performance status at the end of concurrent therapy.

There are no definitive data on adjuvant anti-EGFR tyrosine kinase inhibitors (TKIs) in stage III NSCLC patients with activating *EGFR* mutations. In a population not selected for *EGFR* mutations, adjuvant gefitinib was detrimental⁽⁵⁵⁾. There is no proven benefit for any targeted therapies in combination with chemoradiation for locally advanced lung cancer, although this is an active area of investigation.

Tumors in the lung apex invading apical structures, termed Pancoast tumors (Fig. 18-21), are challenging. Tumors that are N0 to N1 should undergo preoperative concurrent chemoradiation followed by resection. For these patients, 5-year disease-free survival rates are 40% to 50%⁽⁵⁶⁾. Patients with N2 to N3 disease should be treated with concurrent chemoradiation alone.

Stage IV Disease

Stage IV NSCLC remains an incurable disease, and management should include adequate palliation of symptoms. Patients with symptomatic brain or spinal cord metastases, hemoptysis, postobstructive pneumonia, or painful bone metastases should receive radiotherapy before any consideration for systemic therapy. Early referral to specialized palliative care services has also been shown to improve overall survival⁽⁵⁷⁾.

Decisions about systemic therapy demand the classification into SCC versus nonsquamous carcinoma and the testing of adenocarcinoma cases for actionable alterations (eg, *EGFR* mutations, *ALK* and *ROS1* rearrangements). The most recent guidelines⁽⁵⁸⁾ recommend that all adenocarcinomas, mixed adenocarcinomas, and NSCLCs not otherwise specified should undergo evaluation for *EGFR* mutations using polymerase chain reaction–based tests and testing for *ALK* and *ROS1* translocations using fluorescent in situ hybridization. Often, in practice, more complete molecular profiling is being performed, which also includes testing for less common alterations such as *BRAF* and *HER2* mutations and *RET* fusions. Pure SCC with no immunohistochemistry markers of adenocarcinoma should not undergo molecular testing. Because of the importance of molecular testing, attempts should be made to obtain core biopsies rather than fine-needle aspirations to ensure sufficient tissue for profiling.

FIGURE 18-17 Stage IV non-small cell lung cancer (NSCLC). Upon evaluation for back pain, this patient was found to have a pleural effusion (A, B), and biopsy revealed NSCLC. Positron emission tomography/computed tomography (C) revealed a 5.4- by 3.6-cm hypermetabolic mass in the right middle lobe, many small satellite fluorodeoxyglucose (FDG)-avid right lung nodules, and extensive FDG-avid pleural-based masses on the right (T4N0M1). No disease was found outside the chest.

Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors for EGFR Mutant Lung Adenocarcinoma

Epidermal growth factor receptor (EGFR) TKIs should be considered first-line therapy in patients with metastatic lung adenocarcinoma with *EGFR* exon 19 deletion or L858R mutation. Exon 20 mutations (including T790M), which are found in 5% of cases at diagnosis, have an intrinsic resistance to EGFR-TKIs⁽²⁷⁾ and should be treated with standard chemotherapy.

The EGFR-TKIs erlotinib, afatinib, and gefitinib have been tested against standard chemotherapy as first-line agents in patients with NSCLC with *EGFR*-activating mutations and showed improvement in response rates (70% vs 33%, $P < .001$), progression-free survival (PFS) (9.5 to 13.1 months vs 4.1 to 6.3 months, $P < .0001$), and quality of life^(59–61). No benefit in overall survival (OS) has been detected because most trials allowed for

cross-over after progression (Table 18-14)^(59–65). Gefitinib is not available in the United States, so either erlotinib or afatinib can be used in the frontline setting. There are no head-to-head data comparing erlotinib to afatinib, and afatinib has higher reported rates of toxicity. There is some evidence that combining EGFR-TKIs with the anti-vascular endothelial growth factor (VEGF) monoclonal antibody bevacizumab improves response rates and PFS⁽⁶⁶⁾, but benefits in OS have not been confirmed.

Acquired Resistance to Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors

Patients with activating *EGFR* mutations who progress on EGFR-TKIs and those with unknown mutation status who have a prolonged response to EGFR TKIs (>6 months) and then progress are classified as having acquired resistance to EGFR-TKIs. For these patients,

Table 18-9 Definitions for T, N, and M Descriptors

Descriptors	Definitions	Subgroups ^a
T	Primary tumor	
T0	No primary tumor	
T1	Tumor ≤3 cm, ^b surrounded by lung or visceral pleura, not more proximal than the lobar bronchus	
T1a	Tumor ≤2 cm ^b	T1a
T1b	Tumor >2 but ≤3 cm ^b	T1b
T2	Tumor >3 but ≤7 cm ^b or tumor with any of the following ^c : Invades visceral pleura, involves main bronchus ≥2 cm distal to the carina, atelectasis/obstructive pneumonia extending to hilum but not involving the entire lung	
T2a	Tumor >3 but ≤5 cm ^b	T2a
T2b	Tumor >5 but ≤7 cm ^b	T2b
T3	Tumor >7 cm; or directly invading chest wall, diaphragm, phrenic nerve, mediastinal pleura, or parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina ^d ; or atelectasis/obstructive pneumonitis of entire lung; or separate tumor nodules in the same lobe	T3 _{>7} T3 _{inv} T3 _{center} T3 _{center} T3 _{satell}
T4	Tumor of any size with invasion of heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; or separate tumor nodules in a different ipsilateral lobe	T4 _{inv} T4 _{ipsi nod}
N	Regional lymph nodes	
N0	No regional node metastasis	
N1	Metastasis in ipsilateral peribronchial and/or perihilar lymph nodes and intrapulmonary nodes, including involvement by direct extension	
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph nodes	
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph nodes	
M	Distant metastasis	
M0	No distant metastasis	
M1a	Separate tumor nodules in a contralateral lobe; or tumor with pleural nodules or malignant pleural dissemination ^e	M1a _{contr Nod} M1a _{p1 Dissem}
M1b	Distant metastasis	M1b
Special situations		
TX, NX, MX	T, N, or M status not able to be assessed	
Tis	Focus of in situ cancer	Tis
T1 ^d	Superficial spreading tumor of any size but confined to the wall of the trachea or mainstem bronchus	T1 _{ss}

^aThese subgroups labels are not defined in the International Association for the Study of Lung Cancer publications but are added here to facilitate a clear discussion.

^bIn the greatest dimension.

^cT2 tumors with these features are classified as T2a if ≤5 cm.

^dThe uncommon superficial spreading tumor in central airways is classified as T1.

^ePleural effusions are excluded that are cytologically negative, nonbloody, transudative, and clinically judged not to be due to cancer.

a postprogression biopsy is recommended to identify the mechanisms of resistance ^(67, 68) (Fig. 18-22).

In about half of cases, the mechanism of resistance is the development of an acquired exon 20 T790M mutation, which occurs at the binding site of the TKI to EGFR, displacing the TKI. The growth of those tumors still shows EGFR dependence, and multiple trials are currently evaluating the effects of third-generation TKIs (eg, AZD9291 and CO-1686) with specific affinity for *EGFR* with T790M mutation. Early data look promising, and these agents may receive regulatory approval in the near future. There are also phase I/II data on using the combination of afatinib with the anti-EGFR monoclonal antibody cetuximab in patients with acquired EGFR resistance (response rate, 29%; PFS, 4.7 months) ⁽⁶⁹⁾. Interestingly, efficacy was similar in patients with and without T790M mutations. Currently, however, there are no approved targeted agents for patients with resistance to first-line TKIs.

About 5% of patients experience small cell transformation. These patients should be treated similarly to

Table 18-11 Five-Year Survival for Non-Small Cell Lung Cancer by Pathologic and Clinical Stage

Table 18-12 Chemotherapy Regimens for Adjuvant Treatment of NSCLC

Trial	Regimen
IALT ⁽⁴¹⁾	Cisplatin 80-120 mg/m ² every 3 of 4 weeks, for 3-4 cycles, with:
	Vinorelbine 30 mg/m ² weekly; or
	Vinblastine 4 mg/m ² every week for 5 weeks, then every 2 weeks; or
	Etoposide 100 mg/m ² , days 1-3, with each cisplatin
ANITA ⁽⁴²⁾	Cisplatin 100 mg/m ² , day 1, every 4 weeks and vinorelbine 30 mg/m ² weekly for 4 cycles
NCIC-CTG JBR.10 ⁽⁴³⁾	Cisplatin 50 mg/m ² , days 1 and 8, every 4 weeks for 4 cycles; vinorelbine 25 mg/m ² every week for 16 cycles
TREAT ⁽⁴⁴⁾ (nonsquamous histology)	Cisplatin 75 mg/m ² and pemetrexed 500 mg/m ² every 3 weeks for 4 cycles
CALGB 9633 ⁽⁴⁰⁾	Carboplatin AUC 6 and paclitaxel 200 mg/m ² every 3 weeks for 4 cycles
Others	Cisplatin 75 mg/m ² and docetaxel 75 mg/m ² , day 1, every 3 weeks for 4 cycles Cisplatin 75-80 mg/m ² , day 1; vinorelbine 25-30 mg/m ² , days 1 and 8, every 3 weeks for 4 cycles Cisplatin 75 mg/m ² , day 1, and gemcitabine 1,250 mg/m ² , days 1 and 8, every 3 weeks for 4 cycles Carboplatin AUC 6 and pemetrexed 500 mg/m ² every 3 weeks for 4 cycles (nonsquamous histology)

AUC, area under the curve; NSCLC, non–small cell lung cancer.

benefit from pulsatile high-dose erlotinib (1,500 mg once a week), with response rates in the CNS of 67% and median time to CNS progression of 2.7 months ⁽⁷⁰⁾. This approach is also being further studied in clinical trials. Another option is treating the brain metastases with radiation and continuing with erlotinib ⁽⁷¹⁾.

Outside of clinical trials, patients with resistance to frontline TKIs should receive standard chemotherapy (see below). Postprogression continuation of EGFR-TKIs in combination with chemotherapy has recently been addressed with two clinical trials. The data demonstrate that despite increases in response rates

compared to chemotherapy alone, PFS and OS are not improved ⁽⁷²⁾.

ALK Inhibitors for Patients With Adenocarcinomas With ALK Translocations or ROS1 Fusions

Approximately 5% of patients with adenocarcinoma have tumors harboring an *ALK* fusion, and another 1% to 2% of patients have a *ROS1* fusion. For patients with an *ALK* translocation, treatment with crizotinib is associated with response rates greater than 60% and median

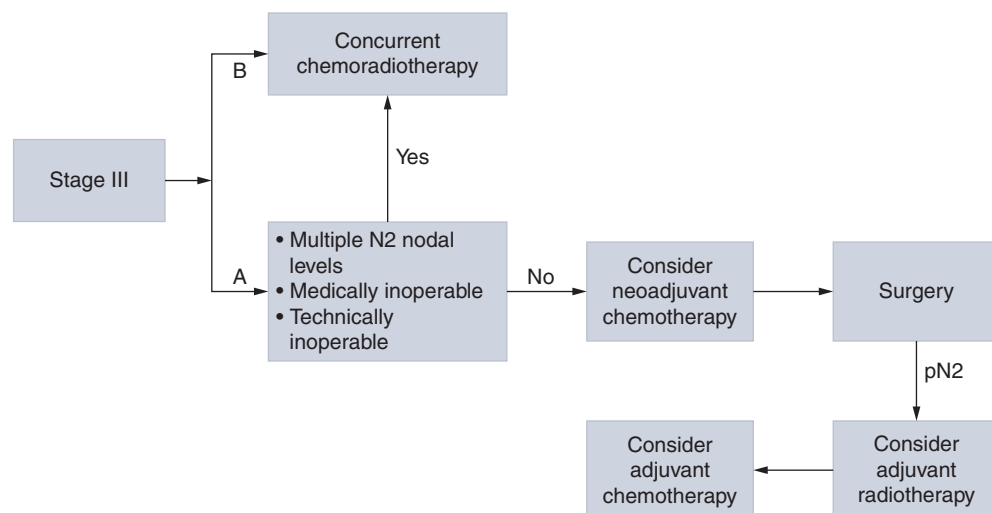

**FIGURE 18-20** Treatment algorithm for stage III non–small cell lung cancer. See text for details.

Table 18-13 Chemoradiation Regimens for Stage III NSCLC

Regimen	Histology	Doses	Adjuvant Treatment After the Completion of Chemoradiation
Cisplatin + etoposide	All NSCLC	Cisplatin 50 mg/m ² days 1, 8, 29, 36 Etoposide 50 mg/m ² days 1-5, 29-33	No
Cisplatin + vinblastine	All NSCLC	Cisplatin 100 mg/m ² days 1 and 29 Vinblastine 5 mg/m ² weekly × 5	No
Carboplatin + pemetrexed	Adenocarcinoma	Carboplatin AUC 5 day 1 every 21 days × 4 Pemetrexed 500 mg/m ² day 1 every 21 days × 4	Yes; continue carboplatin + pemetrexed to a total of 4 cycles
Cisplatin + pemetrexed	Adenocarcinoma	Cisplatin 75 mg/m ² day 1 every 21 days × 3 Pemetrexed 500 mg/m ² day 1 every 21 days × 3	Yes; continue cisplatin + pemetrexed to a total of 3 cycles
Carboplatin + paclitaxel	All NSCLC	Carboplatin AUC 2 weekly during radiation Paclitaxel 45-50 mg/m ² weekly during radiation	Yes; 2 cycles of carboplatin AUC 6 + paclitaxel 200 mg/m ² every 21 days after the completion of chemoradiation

AUC, area under the curve; NSCLC, non-small cell lung cancer.

FIGURE 18-21 A. Pancoast tumor. B. By magnetic resonance imaging, this non-small cell lung cancer tumor at the right lung apex invades the second right rib and extends apically into right apical fat, with a loss of the fat plane between the tumor and the T1 nerve. The T2 nerve is also involved by the mass.

PFS around 8 months⁽⁶²⁾. Crizotinib is similarly effective in patients with *ROS1* translocations, with response rates over 70% and median PFS over 19 months⁽⁶⁵⁾. Crizotinib is the standard first-line therapy in patients with advanced lung adenocarcinoma with *EML4-ALK* translocations or *ROS1* fusions (see Table 18-14).

The mechanisms of resistance to crizotinib therapy have been studied. About 46% of patients develop further alterations in the *ALK* gene (28% secondary *ALK* mutations, 18% *ALK* copy number gains), 8% develop *EGFR* mutations, and 18% develop *KRAS* mutations⁽⁷³⁾. The most common resistance mutations are L1196M and G1269A, which occur at the crizotinib binding site. Another proposed mechanism of resistance is the overexpression of insulin-like growth factor receptor 1 (IGF-1), which activates the same downstream pathways as *ALK*.

Regardless of the mechanism of resistance, patients with acquired resistance to crizotinib should receive second-line treatment with one of the second-generation *ALK* inhibitors. Ceritinib has shown promising results in a large phase I trial and is US Food and Drug Administration (FDA) approved for *ALK*-positive patients following progression on crizotinib⁽⁶³⁾. Other second-generation *ALK* inhibitors, including alectinib, AP26113, and X-396, are currently in clinical development (see Table 18-14).

Frontline Chemotherapy for Advanced Non-Small Cell Lung Cancer

Most patients with lung cancer do not have a tumor that is targetable with an approved therapy. For these patients, as well as for patients with *EGFR* mutation or *ALK* or *ROS1* fusions progressing on targeted

Table 18-14 Summary of Selected Trials of TKIs in Lung Adenocarcinoma

Drug	Pivotal Trial	Dose	Response Rate	Progression-Free Survival	Grade 3–4 Side Effects of TKIs
EGFR exon 19 del and L875R					
Gefitinib	IPASS ⁽⁶⁰⁾	Gefitinib 250 mg once daily	71%	9.5 months	Rash 3.1%; diarrhea 3.8%
		Carboplatin AUC 5 + paclitaxel 200 mg/m ² every 3 weeks	47%	6.3 months	
Erlotinib	EURTAC ⁽⁵⁹⁾	Erlotinib 150 mg once daily	58%	9.7 months	Rash 13%; diarrhea 5%
		Cisplatin 75 mg/m ² or carboplatin AUC 6 + docetaxel 75 mg/m ² every 3 weeks	15%	5.2 months	
Afatinib	LUX-Lung 3 ⁽⁶¹⁾	Afatinib 40 mg once daily	56%	11.1 months	Rash 14%; diarrhea 16%
		Cisplatin 75 mg/m ² + pemetrexed 500 mg/m ²	23%	6.9 months	
EML4-ALK translocation					
Crizotinib	PROFILE 1014 ⁽⁶²⁾	Crizotinib 250 mg twice daily	74%	10.9 months	Elevated AST/ALT 14%; neutropenia 11%; vision disorder 1%
		Cisplatin 75 mg/m ² or Carboplatin AUC 5-6 and pemetrexed 500 mg/m ² every 3 weeks	45%	7.0 months	
Ceritinib	Second-line after crizotinib failure ⁽⁶³⁾	Ceritinib 750 mg once daily	58%	6.9 months	Elevated AST/ALT 23%; elevated lipase 10%
Alectinib	Second-line after crizotinib failure ⁽⁶⁴⁾	Alectinib 300-900 mg twice daily	55%	Not reported	Edema 2%; neutropenia 4%; elevated liver enzymes 4%
ROS1 fusions					
Crizotinib	Second-line after platinum chemotherapy ⁽⁶⁵⁾	Crizotinib 250 mg twice daily	72%	19.2 months	Elevated AST/ALT 4%; hypophosphatemia 10%; neutropenia 10%

ALT, alanine aminotransferase; AST, aspartate aminotransferase; AUC, area under the curve; TKI, tyrosine kinase inhibitor.

therapies, cytotoxic chemotherapy represents the standard of care.

When compared to best supportive care, chemotherapy is associated with a modest improvement in median OS (1.5 months) and significant gains in symptom control⁽⁷⁴⁾. Multiple platinum-based doublets are equally effective with response rates around 18% to 35%, PFS of 3 to 6 months, and OS of 8 to 12 months^(75–79) (Table 18-15). Acceptable agents to combine with platinum include paclitaxel⁽⁷⁵⁾, docetaxel⁽⁷⁵⁾, pemetrexed^(76,77) (nonsquamous only), gemcitabine⁽⁷⁵⁾, and nab-paclitaxel⁽⁷⁸⁾. One trial showed that cisplatin-pemetrexed is superior to cisplatin-gemcitabine in patients with adenocarcinoma but inferior in patients with SCC^(76,77). Because this combination is relatively well tolerated and has a convenient once every 3 weeks dosing schedule, it is often used as first-line therapy in patients with adenocarcinoma.

In the past, trials suggested that cisplatin was associated with better response rates and PFS than carboplatin, but a meta-analysis focusing only on modern regimens (docetaxel, paclitaxel, vinorelbine, or gemcitabine combined with platinum)⁽⁸⁰⁾ showed that carboplatin and cisplatin lead to similar outcomes. The toxicity profile is different, and cisplatin has a higher risk for nausea, whereas carboplatin has higher rates of myelosuppression.

The addition of the VEGF monoclonal antibody bevacizumab to carboplatin/paclitaxel can be considered in patients with adenocarcinomas. The phase III Eastern Cooperative Oncology Group (ECOG) 4599 trial⁽⁷⁹⁾ randomized patients with nonsquamous NSCLC to carboplatin and paclitaxel with or without bevacizumab. The bevacizumab-containing arm had better response rates (35% vs 15%, $P < .001$), PFS (6.2 vs 4.5 months, $P < .001$), and OS (12.3 vs 10.3 months,

FIGURE 18-22 Most common acquired alterations in patients with *EGFR*-mutant tumors and acquired resistance to epidermal growth factor receptor tyrosine kinase inhibitors.

$P = .003$), although there were higher rates of adverse events, including a higher risk of severe bleeding (4.4% vs 0.7%, $P < .001$). Patients with squamous histology, hemoptysis, or uncontrolled hypertension and those older than 70 are at higher risk for bleeding with bevacizumab and are not candidates for this therapy.

Maintenance Chemotherapy

For patients who do not progress after four to six cycles of therapy with a platinum doublet, multiple trials have studied maintenance therapy—either continuation maintenance (continuing the same nonplatinum drug) or switch maintenance (initiating a non-cross-resistant nonplatinum drug) (Table 18-16) (81–87).

Patients receiving either pemetrexed or bevacizumab as part of their initial therapy should continue these drugs as long as tolerated or until progression (79, 85, 86). For patients who are treated with other frontline regimens, maintenance therapy is more controversial. Switch maintenance to either pemetrexed (for nonsquamous NSCLC) (82) or docetaxel (81) is associated with benefits in PFS, although effects on OS are unclear, particularly for patients who go on to receive second-line therapy. Maintenance pemetrexed in patients with SCC has

been shown to be associated with shorter PFS (82) than observation alone; based on these data and the other data described earlier, pemetrexed should not be used for patients with NSCLC with predominantly squamous histology.

Chemotherapy for Patients With Platinum-Refractory Disease

Patients with disease progression after platinum-based therapy who maintain good performance status are candidates for second-line therapy. The agents with proven efficacy in this setting are single-agent docetaxel, pemetrexed (in nonsquamous NSCLC only), and ramucirumab in combination with docetaxel (Table 18-17) (77, 88–95). Second-line pemetrexed is equivalent to docetaxel in nonsquamous histologies (response rate, 12.8% vs 9.9%; OS, 9 vs 9.2 months) but inferior in squamous NSCLC (response rate, 2.8% vs 8.1%; OS, 6.2 vs 7.4 months; $P = .018$).

Reexposure to platinum in second-line therapy increases response rates, but not PFS or OS, even in patients with long (>6 months) platinum-free intervals (91) and is not frequently used. The only combination therapy approved in the second-line setting is docetaxel with the anti-VEGF receptor 2 (anti-VEGFR2) monoclonal antibody ramucirumab (92). In the pivotal REVEL trial comparing docetaxel alone to docetaxel plus ramucirumab in patients with NSCLC of any histology, the combination arm had better PFS (4.5 vs 3 months, $P < .0001$) and OS (10.5 vs 9.1 months, $P = .023$) with no increased risk of severe bleeding. It is important to highlight that only 14% of patients enrolled in REVEL had received prior bevacizumab, making it difficult to draw conclusions about this group. Also, unlike the phase III bevacizumab trials that excluded patients with SCC, 25% of patients on this trial had squamous histology, and there was no increased risk of bleeding seen in this group.

For patients with wild-type *EGFR*, docetaxel and pemetrexed appear to be better second-line options than erlotinib (93, 95), although erlotinib remains an FDA-approved option for third-line therapy (94).

Treatment of Stage IV Non–Small Cell Lung Cancer in the Elderly

Treatment of advanced NSCLC in the elderly has been addressed in several prospective studies and retrospective analyses, and the International Society of Geriatric Oncology (SIOG) has issued clear guidelines (96). Basically, patients older than age 70 years should undergo

Table 18-15 Summary of First-Line Chemotherapy Trials in NSCLC

Pivotal Trial	Histology	Drug	Response Rate	PFS (months)	OS (months)	Trial Interpretation
ECOG 1594, 2002 ⁽⁷⁵⁾	All NSCLC	Cisplatin 75 mg/m ² D1 + paclitaxel 135 mg/m ² over 24 h D2 every 3 weeks	21%	3.4	7.8	No significant difference between the 4 drug regimens
		Cisplatin 100 mg/m ² D1 + gemcitabine 1,000 mg/m ² D1, D8 every 4 weeks	22%	4.2	8.1	
		Cisplatin 75 mg/m ² + docetaxel 75 mg/m ² every 3 weeks	17%	3.7	7.4	
		Carboplatin AUC 6 + paclitaxel 225 mg/m ² every 3 weeks	19%	3.1	8.1	
Socinski et al, 2012 ⁽⁷⁸⁾	All NSCLC	Carboplatin AUC 6 D1 + nab-paclitaxel 100 mg/m ² D1, 8, 15 every 3 weeks	33%	6.3	12.1	Similar efficacy; nab-paclitaxel associated with more neutropenia and less neuropathy
		Carboplatin AUC 6 + paclitaxel 200 mg/m ² every 3 weeks	25%	5.8	11.2	
ECOG 4599, 2006 ⁽⁷⁹⁾	Nonsquamous	Carboplatin AUC 6 + paclitaxel 200 mg/m ² + bevacizumab 15 mg/kg every 3 weeks × 6 then maintenance bevacizumab every 3 weeks	35%	6.2	12.3	Benefit of adding bevacizumab to the induction and maintenance phases; high risk of bleeding in squamous histology
		Carboplatin AUC 6 + paclitaxel 200 mg/m ² every 3 weeks × 6	15%	4.5	10.3	
Scagliotti et al, 2008 ^(76, 77)	Nonsquamous	Cisplatin 75 mg/m ² + pemetrexed 500 mg/m ² every 3 weeks	29%	5.5	12.6	Benefit of pemetrexed in nonsquamous histology
		Cisplatin 75 mg/m ² + gemcitabine 1,250 mg/m ² D1, D8 every 3 weeks	22%	5.0	10.9	
	Squamous	Cisplatin 75 mg/m ² + pemetrexed 500 mg/m ² every 3 weeks	23%	4.4	9.4	Benefit of gemcitabine in squamous NSCLC
		Cisplatin 75 mg/m ² + gemcitabine 1,250 mg/m ² D1, D8 every 3 weeks	31%	5.5	10.8

	Squamous	Pemetrexed 500 mg/m ² every 3 weeks	2.8%	2.3	6.2	Benefit of docetaxel over pemetrexed in squamous NSCLC
		Docetaxel 75 mg/m ² every 3 weeks	8.1%	2.7	7.4	
GOIRC 02-2006/NVALT-7, 2012 ⁽⁹¹⁾	All NSCLC	Carboplatin AUC 5 + pemetrexed 500 mg/m ² every 3 weeks	15%	3.6	8.7	No benefit of platinum doublets over nonplatinum single-agent second-line therapy
		Pemetrexed 500 mg/m ² every 3 weeks	9%	3.5	8.2	
REVEL, 2014 ⁽⁹²⁾	All NSCLC	Docetaxel 75 mg/m ² + ramucirumab 10 mg/kg every 3 weeks	23%	4.5	10.5	Benefit of ramucirumab when added to docetaxel in second line
		Docetaxel 75 mg/m ² every 3 weeks	14%	3.0	9.1	
TAILOR, 2013 ⁽⁹³⁾	EGFR wild-type NSCLC	Erlotinib 150 mg/day	3%	2.4	5.4	No benefit of second-line erlotinib in EGFR wild-type NSCLC
		Docetaxel 75 mg/m ² every 3 weeks	15%	2.9	8.2	
Third line						
BR-21, 2005 ⁽⁹⁴⁾	All NSCLC (EGFR status unknown)	Erlotinib 150 mg/day	8.9%	2.2	6.7	Third-line erlotinib can prolong survival in patients with NSCLC and unknown EGFR status
		Placebo	<1%	1.8	4.7	
DELTA, 2014 ⁽⁹⁵⁾	EGFR wild-type NSCLC	Erlotinib 150 mg/day	17%	1.3	9	Docetaxel is superior to erlotinib as second- or third-line therapy in patients with no activating EGFR mutations
		Docetaxel 60 mg/m ² every 3 weeks	17%	2.9	10.1	

AUC, area under the curve; D, day; NSCLC, non-small cell lung cancer; OS, overall survival; PFS, progression-free survival.

functional evaluation, and those with good functionality should receive standard therapy.

For lung adenocarcinomas with actionable mutations, TKIs should be recommended. For patients without actionable mutations, platinum-based doublets should be offered. In the IFCT-0501 trial⁽⁹⁷⁾, patients older than age 70 were randomized to carboplatin-paclitaxel or single-agent therapy with vinorelbine or gemcitabine. The combination arm had a significant improvement in OS (10.3 vs 6.2 months, $P < .0001$) and better pain control rates with a small increase in the rates of toxic death (4.4% vs 1.3%). Based on the subgroup analysis from ECOG 4599⁽⁹⁸⁾ and on other trials, bevacizumab should not be added to chemotherapy in elderly patients because of lack of benefit and increased risk of severe side effects.

Immunotherapy in Advanced Non–Small Cell Lung Cancer

Immunotherapy has recently achieved significant outcomes in the treatment of metastatic melanoma, leading to the approval of immune checkpoint inhibitors such as anti-PD-1/PD-L1 and anti-CTLA4 antibodies (see chapter on cancer immunotherapy). Lung cancers are among the malignancies with the highest mutation burden, averaging 360 exonic mutations per sample⁽²⁵⁾. Many of those mutations generate neoantigens potentially able to stimulate effector CD8⁺ T cells. It has also been shown that NSCLC with high tumor-infiltrating lymphocytes have better outcomes after resection and in the metastatic setting⁽⁹⁹⁾, suggesting lung cancers as good candidates for the investigational use of immunotherapies.

Previous trials focused on cancer vaccines in NSCLC, which were shown to induce tumor-specific immune responses but failed to improve survival⁽¹⁰⁰⁾. The development of immune checkpoint inhibitors has renewed the interest in immunotherapy approaches for NSCLC (Table 18-18)^(101–106).

The CTLA4 receptor on T cells interacts with the B7-1 and B7-2 proteins on antigen-presenting cells and downregulates the T-cell response to tumor-related antigens. There are two anti-CTLA4 antibodies currently approved for the treatment of melanoma: ipilimumab and tremelimumab. In a randomized phase II trial for NSCLC patients⁽¹⁰¹⁾, the addition of ipilimumab during cycles 3 to 6 of first-line chemotherapy with carboplatin and paclitaxel was associated with better response rates and a nonsignificant increase in OS. There are multiple trials under way to investigate how best to use these agents in patients with metastatic disease (eg, alone or in combination, timing in combinations, incorporation of molecular markers for selection), such as the randomized trial with

carboplatin/paclitaxel with or without ipilimumab for patients with squamous histology (NCT01285609).

PD-1 is another receptor expressed on T cells that, upon interaction with its ligand, PD-L1, suppresses immune cell activation. Expression of PD-L1 on antigen-presenting cells and on tumor cells is believed to be a key player in local tumor microenvironment-mediated immunosuppression. Approximately 35% to 50% of stage IV NSCLC patients have moderate to high staining of PD-1 or PD-L1 depending on the methodology for staining and scoring.

Two anti-PD-1 antibodies have been studied in phase I and II trials of NSCLC: nivolumab and pembrolizumab (see Table 18-18). In general, the response rates have been 15% to 25% both in the first- and second-line settings, and the OS has been around 8 to 10 months, with no difference between adenocarcinoma and SCC. However, some responders have prolonged disease control, sometimes for more than 12 months. No predictor of response has been validated yet, but it appears that tumors with higher expression of PD-L1⁽¹⁰⁵⁾ and those with PD-L1–positive tumor-infiltrating lymphocytes⁽¹⁰⁶⁾ have better outcomes when treated with anti-PD-1/PD-L1 agents. There are also data emerging from several groups on regulation of the dynamic PD-L1 expression of tumor cells, including the effect of epithelial-to-mesenchymal transition to drive CD8⁺ T-cell suppression through PD-L1 activation⁽¹⁰⁷⁾.

The use of anti-PD-1/anti-PD-L1 therapy currently remains investigational, but the pending results of phase II and III trials of pembrolizumab and nivolumab in metastatic NSCLC could substantially change the landscape of treatments options in the near future.

Other Therapies for Advanced Disease and Management of Oligometastatic Disease

Radiotherapy and surgery may be helpful in managing selected patients with stage IV NSCLC. Radiotherapy can be used to palliate pain or to manage hemoptysis and obstructive symptoms in large primary tumors.

In patients with solitary brain metastasis as their only site of metastatic disease, resection or stereotactic radiation of the brain lesion followed by definitive therapy to the primary tumor (resection or radiation) is associated with significant improvement in median OS (26 months vs 13 months in patients who do not undergo therapy to the primary tumor), and 5-year survival rates are 34% versus 0%⁽¹⁰⁸⁾.

In patients with solitary adrenal metastasis, adrenalectomy associated with definitive therapy to the primary tumor also has good outcomes, with a median OS of 26 months and 5-year survival rates of 30%,

Table 18-18 Summary of the Larger Trials of Immune Checkpoint Inhibitors in Stage IV NSCLC

Trial Sample size	Design and Treatment Line	Drug and Dose	Response Rate	Outcomes	Conclusion
Anti-CTLA4 antibodies					
Lynch et al, 2012 ⁽¹⁰¹⁾ (204 patients)	Phase II First line	Carboplatin + paclitaxel every 3 weeks × 6 cycles	18%	PFS 4.2 mo OS: 8.3 mo	Nonsignificant improvement in OS; suggests more benefit in squamous histology
		Ipilimumab 10 mg/kg every 3 weeks added to cycles 1-4	21%	PFS 4.1 mo OS: 9.7 mo	
		Ipilimumab 10 mg/kg every 3 weeks added to cycles 3-6	32%	PFS 5.1 mo OS: 12.2 mo	
Anti-PD-1 antibodies					
Topalian et al, 2012 ⁽¹⁰²⁾ (76 patients)	Phase I Second/third line	Nivolumab 1-10 mg/kg every 2 weeks	18%	26% progression free at 6 mo	First signal of activity of nivolumab
Antonia et al, 2014 ⁽¹⁰³⁾ (56 patients)	Phase II First line	Nivolumab 10 mg/kg every 2 weeks + paclitaxel/carboplatin (any histology)	47%	38% progression free at 6 mo 59% alive at 12 mo	Good tolerability of combination nivolumab + chemotherapy; signal of activity in first line
		Nivolumab 10 mg/kg every 2 weeks + pemetrexed/cisplatin (nonsquamous)	47%	71% progression free at 6 mo 87% alive at 12 mo	
		Nivolumab 10 mg/kg every 2 weeks + gemcitabine and cisplatin (squamous)	33%	36% progression free at 6 mo 59% alive at 12 mo	
CheckMate – 063, 2015 ⁽¹⁰⁴⁾ (117 patients)	Phase II Third-line	Nivolumab 3 mg/kg every 3 weeks (squamous cell only)	14.5%	OS 8.2 mo 41% alive at 12 mo	Confirms activity seen in previous trials
KEYNOTE-001 ⁽¹⁰⁵⁾ (282 patients, ongoing)	Phase II First line	Pembrolizumab 10 mg/kg every 2 weeks or every 3 weeks	26%	PFS 6.7 mo OS not reached 86% alive at 6 mo	Only patients with PD-L1 expression were included; no difference between every 2 weeks and every 3 weeks dose or squamous vs nonsquamous carcinoma
	Phase II Second line	Pembrolizumab 10 mg/kg every 2 weeks or every 3 weeks	20%	PFS 2.2 mo OS 8.2 mo 57% alive at 6 mo	
Anti-PD-L1 antibodies					
Herbst et al, 2014 ⁽¹⁰⁶⁾ (85 patients)	Phase I Second/third line	MDPL3280A 10, 15, or 20 mg/kg every 3 weeks	26%	PFS 3.75 mo	More benefit in cases with high expression of PD-L1 in TILs
				44% alive at 6 mo	

NSCLC, non-small cell lung cancer; OS, overall survival; PD-1, programmed cell death protein 1; PD-L1, programmed cell death ligand 1; PFS, progression-free survival; TILs, tumor-infiltrating lymphocytes.

which has been consistent in multiple studies ⁽¹⁰⁹⁾. Patients who develop isolated adrenal metastasis more than 6 months after the resection of the primary tumor are the ones with the most benefit.

Patients with oligometastatic disease (one to five lesions) should undergo extensive workup including PET-CT scan and brain MRI. They can then be classified into three subgroups ⁽¹¹⁰⁾:

- Low risk: Development of oligometastatic disease more than 2 months after resection of the primary tumor (5-year OS, 47.8%).
- Intermediate risk: Synchronous metastases (at presentation or within 2 months of the resection of the primary) and no lymph node involvement (N0) disease (5-year OS, 36.2%).
- High risk: Synchronous metastases and N1/N2 disease (5-year OS, 13.8%).

There is currently one randomized trial ongoing evaluating the effect of definitive treatment (surgery or radiation) for oligometastatic disease (NCT01725165). However, observational studies have shown that, in patients who received two cycles of systemic therapy and did not have progression, definitive therapy to oligometastasis was associated with improvements in OS (27 vs 13 months; HR, 0.37; 95% confidence interval [CI], 0.2-0.7; $P < .01$) ⁽¹¹¹⁾. There are also data suggesting that, for patients with oligometastatic disease receiving chemotherapy, radiation therapy to the primary tumor is associated with improved OS (HR, 0.65; 95% CI, 0.43-0.93; $P = .019$) ⁽¹¹²⁾.

FUTURE DIRECTIONS

The treatment for NSCLC, especially in the metastatic setting, has witnessed remarkably rapid change over the last 10 years. This change has been driven primarily by the recognition of the significant molecular heterogeneity of the disease and identification of targetable genetic changes defining the many subgroups. We expect that this trend will continue to facilitate the successful application of targeted agents, especially for the squamous cell histology where there are still no approved targeted agents. Examples of molecular alterations under investigation are *BRAF*, *MEK*, *MET*, *mTOR*, and *HER2*, as well as new approaches to target *KRAS* mutant disease. There is also continued research on new-generation TKIs able to overcome acquired resistance to erlotinib and crizotinib. Because the molecular profile of tumors is dynamic, with variability at each tumor site and varying over time at any one site, the need for repeat biopsies has become increasingly accepted and therapeutic options are more frequently based on the changing genetics of an individual patient's tumor. In the future, this personalized

evaluation of mutations in circulating tumor cells or circulating cell-free tumor DNA might be an important tool in the process.

For patients with early-stage disease, large centralized trials like ALCHEMIST have been developed to evaluate molecular testing and the application of targeted agents in the adjuvant setting. The hope is to achieve more cures and/or produce longer periods of disease-free recurrence in this group of patients who have undergone curative-intent therapy.

Certainly the future of oncology and lung cancer, in particular, will be substantially impacted by the incorporation of immunotherapies. However, it is difficult to predict how this landscape might emerge as the currently available agents and new agents are developed. The investigation of single-agent immune checkpoint molecule (PD-1 and CTLA4) inhibitors in the refractory metastatic setting is moving very rapidly, with the expectation that one or more of the PD-1/PD-L1 axis inhibitors will be approved soon. Research is also focusing on evaluating combination strategies and on moving their use to the frontline and adjuvant settings. As with all other therapies, one particularly challenging aspect of applying immunotherapies to the clinic is the determination of which biomarkers are useful to select patients more or less likely to respond and to monitor response. However, given the complexity of the immune system and our limited experience in developing drugs of this type, the technical and conceptual challenges of marker development may lag behind the efficacy trials. It is hard to understate the current excitement around the immunotherapy agents, and it will be intriguing to see how they finally find their proper role in the treatment of patients with NSCLC.

CONCLUSIONS

Non-small cell lung cancer remains one of the most devastating illnesses in the United States and worldwide in terms of incidence and overall mortality rates. Primary prevention by smoking cessation and secondary prevention with screening have managed to reduce the incidence of NSCLC and NSCLC-related deaths in some areas of the world, but the incidence of lung cancers not related to smoking is still rising. Surgery and chemoradiation offer a potential for long-term survival in patients with localized disease, but metastatic disease remains lethal. In recent years, the evolving understanding of the molecular pathology of NSCLC has produced effective targeted agents, with high response rates and low toxicity, but resistance is still an issue. The development of new targeted agents able to overcome resistance and the effective implementation of cancer immunotherapy have the potential to further improve outcomes for patients with NSCLC.

Head and Neck Cancer

Head and Neck Cancer

Jennifer L. McQuade
G. Brandon Gunn
William N. William Jr.
Merrill S. Kies

Head and neck cancers are a diverse group of diseases, each with distinct epidemiologic, anatomic, and pathologic features. The natural history and treatment considerations may vary widely. In this chapter, our focus is on the primary management of squamous cell carcinomas (SCCs) of the head and neck (HNSCC). In recent years, we have observed significant advances in diagnosis and treatment and recognition of the human papillomavirus (HPV) as a significant causative agent and prognostic factor for cancers of the oropharynx. Tumor imaging is increasingly precise. Primary therapy eradicates disease in a majority of patients with early-stage HNSCC, and the long-term management of these patients currently involves an emphasis on general medical care, avoiding known carcinogens such as alcohol and tobacco, and participation in chemoprevention strategies to reduce the risk of second primary tumors. Therapy for patients with locally advanced disease is multimodal, and success has been achieved in improving local tumor control, disease remission, organ preservation, and overall survival. The integration of chemotherapy and novel “targeting” systemic treatment approaches with surgery and/or radiotherapy is under study and discussed.

EPIDEMIOLOGY

In the United States, HNSCC is estimated to represent approximately 3% (46,000) of new cancer cases and 2% (9,000) of cancer deaths in 2015 (¹). However, the disease is more common in many developing

countries, with a worldwide annual incidence of more than 500,000 (²).

The risk of developing head and neck cancer increases with age; most patients are older than age 50. There has been a clearly demonstrated association with tobacco and alcohol use. Molecular studies provide evidence that carcinogens found in these substances have a causal role. The prevalence and spectrum of *p53* mutations are prominent in cancers of patients with a history of tobacco and alcohol use (³). Cancers of the oral cavity, larynx, and hypopharynx are uncommon in persons with no smoking history.

Human papillomavirus infection is now widely accepted as another etiologic factor for HNSCC. In the United States, more than 50% of cancers arising in the oropharynx, particularly in the palatine tonsils and tongue base, harbor oncogenic HPV (⁴). The incidence of oropharyngeal cancer in the United States is increasing, primarily due to HPV-associated cases in men (⁵). It appears that the HPV-positive oropharyngeal malignancy represents a distinct clinical and pathologic subgroup of HNSCC, with poorly differentiated basaloid histopathology (⁶) and marked tumor responsiveness to radiation and chemotherapy. Moreover, HNSCCs with transcriptionally active HPV-16 DNA are characterized by occasional chromosomal loss, whereas those lacking HPV DNA typically have gross deletions, involving chromosomal arms known to be abnormal in HNSCC (⁷). Thus, HPV-16 infection may be an early carcinogenic event. Patients with HPV DNA–positive tumors, particularly those associated with E6 and E7 proteins, have improved survival after chemoradiotherapy when

compared to patients with HPV-negative tumors (^{8,9}). A recent case-control study reported that HPV-16-positive HNSCCs were independently associated with several measures of sexual behavior and exposure to marijuana but not with cumulative measures of tobacco smoking, alcohol use, or poor oral hygiene (¹⁰). These findings indicate that HPV-16-positive HNSCC and HPV-16-negative HNSCC have different risk factor profiles. In addition to detection of oncogenic HPV DNA by in situ hybridization, tumor overexpression of p16 by immunohistochemistry serves as a surrogate for HPV association in oropharyngeal cancer with prognostic implications, particularly when coupled with patient smoking status (⁸). In addition, HNSCC patients with heavy tobacco and alcohol exposures are at high risk of developing multiple cancers, with “field cancerization” throughout the upper aerodigestive tract and bladder. The observation that treated head and neck cancer patients may have a high risk (estimated to be 3%-4% per year) of metachronous tumors has driven chemoprevention trials designed to reduce the risk of second primary tumors.

MOLECULAR PATHOGENESIS

The progression of HNSCC is thought to involve multiple stepwise alterations of molecular pathways in the squamous epithelium (¹¹). Aberrations in the p53 and Rb tumor suppressor pathways are the most common molecular events, resulting in uncontrolled cell proliferation. Approximately 50% to 80% of HPV-negative tumor samples harbor a p53 mutation (^{12,13}). The Rb pathway can be disrupted either through inactivation of the *CDKN2A* gene, which encodes p16, an inhibitor of cyclin-dependent kinase, or amplification of the *CCND1* gene encoding cyclin D1 (¹⁴⁻¹⁶).

The epidermal growth factor receptor (*EGFR*) is overexpressed in invasive HNSCC in a majority of sample tumors (¹⁷). Binding to *EGFR* by its natural ligands, mainly epidermal growth factor or transforming growth factor α (TGF- α), prompts a conformational change in the receptor through dimerization, which results in subsequent autoactivation of the tyrosine kinase from the intracellular domain of the receptor. This process activates an intracellular signaling pathway, leading to the inhibition of apoptosis, activation of cell proliferation and angiogenesis, and an increase in metastatic spread potential (¹⁸).

In 2011, Stransky et al performed whole exome sequencing on 74 HNSCC tumor specimens (¹⁹). Not surprisingly, the mutational landscape of the disease is quite complex, and smoking-related HNSCC specimens had a mutation rate approximately twice that of HPV-positive HNSCC. Mutations in genes previously implicated in HNSCC were detected at a high

rate, including *TP53*, *CDKN2A*, *PTEN*, *PIK3CA*, and *HRAS*, validating this approach. However, this unbiased approach also identified a high rate of mutations in numerous genes not previously linked to HNSCC. In approximately 30% of cases, mutations were identified in genes that regulate squamous differentiation, such as *NOTCH1*, *IRF6*, and *TP63*. Mutations in genes regulating apoptosis were also frequent events. These novel findings have provided the rationale for testing novel therapeutic targets such as NOTCH inhibitors.

There are numerous challenges to the development of molecularly targeted therapies in HNSCC, including frequent tumor suppressor loss and difficulty in identification of true driver mutations within a complex mutational landscape. However, an improved understanding of the molecular biology of this disease should facilitate discovery of new prognostic markers and therapeutic targets.

DIAGNOSIS AND STAGING

Optimal therapy and treatment outcomes depend on the precise identification of the primary tumor (Fig. 19-1) as well as the local, regional, and distant extent of disease.

Patients with early-stage disease may present with vague symptoms and minimal physical findings, which is why a high index of suspicion for early diagnosis is needed, especially for tobacco users. A majority of patients will present with signs and symptoms of locally advanced disease, which vary according to the subsite in the head and neck. Sinusitis, unilateral nasal airway obstruction, and epistaxis may be early signs of cancers of the nasal cavity or paranasal sinuses. Otitis media that is recurrent or is refractory to antibiotics is an indication for a complete ear, nose, and throat evaluation to rule out a nasopharyngeal neoplasm. Chronic otalgia, dysphagia, odynophagia, and throat soreness lasting weeks may be the presenting symptoms of oropharyngeal or hypopharyngeal cancer. However, many patients with HPV-associated oropharyngeal cancer present with an otherwise asymptomatic neck mass and may have limited or no smoking history. Persistent hoarseness demands visualization of the larynx. Supraglottic laryngeal neoplasms do not usually present early, and a neck mass may be the presenting sign. Careful examination of lymph nodes in the facial, cervical, and supraclavicular regions is important because the anatomic patterns of lymphatic drainage may reflect the specific subsite of a head and neck primary tumor (Fig. 19-2) (²⁰). Level 2/3 adenopathy, for example, suggests a primary cancer of the oral tongue or oropharynx, and posterior cervical adenopathy is frequently a result of regional spread of a nasopharyngeal tumor.

FIGURE 19-1 Head and neck anatomy.

FIGURE 19-2 A. Nodal drainage. B. Nodal levels in the head and neck. (Reproduced with permission from Hong WK, Bast RB Jr, Hait WN, et al: *Cancer Medicine*. 8th ed. Shelton, CT: BC Decker—People's Medical Publishing House-USA; 2010: 959-998.)

Physical examination should include careful inspection of the skin and oral/oropharyngeal mucosal surfaces; palpation of the tongue, floor of the mouth, and oropharynx; and systematic palpation of the neck. A complete examination also requires an indirect mirror examination of the oropharynx, hypopharynx, and larynx, complemented by fiberoptic endoscopy ⁽²¹⁾. Leukoplakia (white mucosal patches that cannot be removed by scraping) and higher risk erythroplakia (red or mixed red-white patches) are the most common premalignant lesions in the head and neck. Any suspicious surface in the oral mucosa should undergo biopsy.

Three-dimensional imaging with computed tomography (CT), magnetic resonance imaging (MRI), and/or ultrasonography is also needed to evaluate the extent of disease and to complete staging. Magnetic resonance imaging is the preferred local imaging modality for nasopharyngeal cancer. Because the lungs are the most common sites of distant metastases, a chest x-ray should be performed as well. Computed tomography scanning of the chest should be performed for symptomatic or high-risk patients. This would include patients with nasopharyngeal cancer or those with primary tumors of other sites presenting with N2b or greater nodal disease and low neck or supraclavicular metastases. Circulating tumor markers that would be reliable in early detection of HNSCC have not yet been identified.

Patients who present with a suspicious neck mass and no obvious primary mucosal lesion should undergo a systematic examination of the head and neck. Head and neck imaging may be helpful. If no obvious primary site is found, fine-needle aspiration of the mass may establish a diagnosis of cancer. Detection of HPV or Epstein-Barr virus DNA in a lymph node suggests a tumor of oropharyngeal or nasopharyngeal origin, respectively. If metastatic SCC is demonstrated, examination under anesthesia is often performed. Suspicious lesions are biopsied, and consideration is given to tonsillectomy and blind biopsies of the nasopharynx, base of the tongue, and hypopharynx, depending on the pattern of lymphadenopathy. Open biopsy of the neck mass may be performed if fine-needle aspiration biopsy and panendoscopy have failed to yield a diagnosis or in patients suspected of having an alternative process (eg, lymphoma). An experienced head and neck surgeon may be prepared to proceed with selective neck dissection if SCC of unknown head and neck primary origin is determined.

Staging criteria for head and neck cancers are based on the American Joint Committee on Cancer TNM staging system, which classifies tumors according to anatomic site and extent of disease ⁽²²⁾. Head and neck primary tumor (T) staging is complex, varying with the primary subsite in the head and neck region.

Classifications for lymph node (N) and distant metastases (M) are uniform for sites (Table 19-1) other than nasopharynx ^(22a).

NATURAL HISTORY AND IMPLICATIONS FOR THERAPY

Two-thirds of patients with HNSCC will present with stage III or IV disease. For patients with T1/2 disease (stage I/II), surgery or radiotherapy as a single modality is most often applicable and effective. Depending on the precise primary site and stage, a curative outcome will be achieved in 70% to 95% of cases. In patients with intermediate and locally advanced disease at diagnosis, combined treatment strategies have become the standard of care. Multimodal treatment plans are designed to balance competing goals of tumor eradication and organ preservation ^(11,23,24). Despite optimal local therapy, 30% to 50% of patients may develop local or regional recurrence, and nearly 20% to 30% are at risk for distant metastases depending on the primary site and staging.

Nasopharynx

Over 95% of endemic nasopharyngeal carcinomas (NPCs) are associated with EBV. Nasopharyngeal carcinoma tends to occur in younger persons and is not associated with tobacco use. Nasopharyngeal carcinoma is an aggressive neoplasm with cervical lymph node metastases present in 60% to 90% of patients at diagnosis. Because of unique anatomic, biologic, and clinical characteristics, therapy for NPC is distinctive. Radiotherapy is the mainstay of local treatment. The anatomy of the nasopharynx and tumor sensitivity to radiotherapy limit the role of surgery to obtaining the initial biopsy and, for selected patients, resection of residual lymphadenopathy after radiotherapy. Nasopharyngeal carcinomas are highly sensitive to chemoradiotherapy. Because of the proximity of the nasopharynx to normal critical structures of the central nervous system and given the propensity of NPC for skull base invasion, intensity-modulated radiation therapy (IMRT) is the usual radiation therapy technique for NPC, which improves tumor coverage, reduces xerostomia, and improves patient quality of life compared to traditional techniques ^(25,26). Locoregional tumor control following chemoradiotherapy approaches 90%.

For stages III and IV, concomitant chemotherapy and radiotherapy followed by adjuvant chemotherapy is the accepted standard of care based on the Head and Neck Intergroup NPC 0099 trial ⁽²⁷⁾. Compared to radiation alone, chemoradiation with cisplatin (100 mg/m² on days 1, 22, and 43), followed by adjuvant chemotherapy with cisplatin and 5-fluorouracil (5-FU) demonstrated significant improvement in 3-year survival

Table 19-1A TNM Staging for the Oral Cavity and Oropharynx

Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
Tis	Carcinoma in situ.
T1	Tumor ≤2 cm in greatest dimension.
T2	Tumor >2 cm but not >4 cm in greatest dimension.
T3	Tumor >4 cm in greatest dimension.
T4(lip)	Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face, ie, chin or nose.
T4a	Tumor invades structures adjacent to the oral cavity (eg, through cortical bone, into deep [extrinsic] muscle of tongue [genioglossus, hyoglossus, palatoglossus, and styloglossus], maxillary sinus, skin of face).
T4b	Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery.
Note: Superficial erosion alone of bone/tooth socket by gingival primary tumor is not sufficient to classify a tumor as T4.	
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional node metastases.
N1	Metastasis to a single ipsilateral lymph node ≤3 cm in greatest dimension.
N2	Metastasis to a single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension, or to multiple ipsilateral lymph nodes none >6 cm in greatest dimension, or to bilateral or contralateral lymph nodes none >6 cm in greatest dimension.
N2a	Metastasis to a single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension.
N2b	Metastasis to multiple ipsilateral lymph nodes >3 cm but not >6 cm in greatest dimension.
N2c	Metastases to bilateral or contralateral lymph nodes none >6 cm in greatest dimension.
N3	Metastasis in a lymph node >6 cm in greatest dimension.
Distant Metastasis (M)	
MX	Presence of distant metastasis cannot be assessed.
M0	No evidence of distant metastasis.
M1	Distant metastasis.

Table 19-1B Stage Grouping

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage IVA	T4a	N0	M0
	T4a	N1	M0
	T1	N2	M0
	T2	N2	M0
	T3	N2	M0
	T4a	N2	M0
Stage IVB	Any T	N3	M0
	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

(78% vs 47%). Chan et al⁽²⁸⁾ have also demonstrated the efficacy of concomitant radiation and weekly cisplatin 40 mg/m². Phase III studies investigating the value of induction chemotherapy are under way. The NRG-HN001 study is an ongoing phase II/III study investigating the value of measuring plasma EBV DNA as a marker of the efficacy of concomitant chemoradiotherapy. With undetectable DNA, patients are randomized to observation or adjuvant chemotherapy. Patients with detectable DNA after chemoradiotherapy receive additional treatment, testing an alternative regimen consisting of paclitaxel and gemcitabine versus cisplatin and 5-FU.

Oral Cavity

The majority of oral cavity neoplasms occur in the anterior two-thirds of the tongue (oral tongue) and the floor of the mouth. Surgical resection, often with post-operative radiotherapy, is the most common and effective local treatment approach^(11, 24). Depending on site

and tumor volume, early cancers should be resected but may be treated with radiotherapy. Local tumor control rates of patients with stage I and II tumors are 80% to 90% and 50% to 80%, respectively (²⁹). For deeply invasive T1/2 disease, we favor surgical resection and neck dissection with postoperative concomitant chemoradiotherapy for selected patients with narrow margins or nodal metastases, particularly if there is extracapsular spread. Perineural invasion is also a significant negative prognostic sign. Forty percent of patients present with clinically evident lymph nodes, and bilateral nodal involvement is not uncommon. Although primary surgical approaches are preferred at our center, interstitial radiotherapy (brachytherapy) has been used in combination with external-beam therapy for selected cases to achieve higher control rates than external radiation alone.

For patients with locally more advanced disease (Fig. 19-3 shows an example of a patient with a retromolar trigone primary tumor invading bone, T4), surgery followed by radiation therapy (or chemoradiotherapy) is the most widely accepted approach. At the University of Texas MD Anderson Cancer Center (MDACC), selective neck dissections are routinely performed for patients with stages II to IVa disease.

Oropharynx

The most common cancers of the oropharynx are of the base of tongue and tonsils, and an increasing percentage

of these are HPV associated, with an improved prognosis. In an unplanned, post hoc analysis of RTOG 0129, Ang et al classified oropharyngeal cancer patients treated with concurrent chemoradiotherapy in to three risk-of-death groups using recursive partition analysis. The “low-risk” group were those with p16 positive tumors and minimal smoking history (94% 3-year overall survival). Conversely, the “high-risk” group were those characterized mostly by p16 negative tumors and greater smoking intensity (42% 3-year overall survival) (⁶). Radiation therapy serves as the principal treatment modality for the majority of oropharyngeal malignancies and is used as a single modality for T1 and many T2 tumors. Local control is obtained in over 90% of patients (³⁰). Regional lymph nodes are treated in all cases, and unilateral neck radiation is considered for well-lateralized earlier-stage tonsillar primaries, which reduces greatly the radiation dose to the contralateral parotid gland and key swallowing structures. Given recent technical advances and the popularity of minimally invasive transoral approaches, surgical resection for oropharyngeal cancer is being performed more frequently at many centers, and this approach is currently under study (Eastern Cooperative Oncology Group [ECOG] 3311). However, adjuvant radiation or chemoradiation may also be required, depending on the surgical pathology findings.

Concomitant chemoradiotherapy using IMRT is the current standard of care for patients with locally advanced disease. Under study, protons have unique physical properties compared with x-rays or photons due to the

FIGURE 19-3 Retromolar trigone squamous cell carcinoma (SCC) with mandibular destruction.

FIGURE 19-4 Axial computed tomography of advanced squamous carcinoma of the pyriform sinus, T3N3NO.

Bragg peak, where most of the proton dose is delivered at a finite depth, thus reducing dose to certain nontarget structures. Investigators at MDACC are currently conducting a phase II/III randomized trial of concomitant chemotherapy with intensity-modulated proton therapy vs IMRT for stage III/IV oropharyngeal cancer. Objectives are to compare tumor control and long-term toxicity.

Hypopharynx

With 75% of lesions occurring in the pyriform sinus, carcinoma of the hypopharynx is relatively uncommon but virulent (Fig. 19-4). Small-volume disease may be treated with surgery or radiation, but later-stage disease requires multimodal therapy. At presentation, more than 75% of patients have advanced disease (T3 or T4). The overall 5-year survival rate is lower than 30%. For many patients, surgical treatment also requires removal of the larynx. The European Organization for Research and Treatment of Cancer (EORTC), in a phase III trial, demonstrated that laryngeal preservation with sequential chemoradiotherapy is a feasible alternative to radical surgery for many patients with locally advanced disease (31). In a more recent trial of patients with resectable advanced SCC of the larynx or hypopharynx, Lefebvre et al (32) compared sequential treatment with two cycles of cisplatin and 5-FU followed by radiotherapy with an arm of four cycles of cisplatin and 5-FU administered during weeks 1, 4, 7, and 10, alternating with radiotherapy. Survival with a functional larynx was similar in both arms, as was overall survival (median, 4.4 vs 5.1 years, respectively). Please see the “Organ Preservation” section for further discussion.

Larynx

Given the critical role of the larynx in communication, swallowing, respiration, and airway protection, organ preservation to maintain functional status and quality of life has been the focus of laryngeal cancer treatment since the 1970s. The most widely used treatment of T1 and T2 cancers of the larynx is radiotherapy, which has demonstrated control rates greater than 90% for

T1 disease and approximately 70% to 80% for T2 tumors (33). For carefully selected patients with intermediate-stage disease, sequential chemotherapy followed by radiation and surgical salvage, if needed, showed equivalent survival outcomes compared with surgery in the Veterans Affairs (VA) laryngeal study (34). Although the rate of local failure is higher with organ preservation approaches, salvage surgery is effective, and this approach allows 60% of patients to preserve organ function (35). Larynx cancer treatment strategies are discussed in detail in the “Organ Preservation” section.

Salivary Gland Cancers

Tumors of the salivary glands are uncommon, with approximately 5,000 cases per year in the United States. Histologies are diverse, and risk factors are poorly defined, although radiotherapy may be causative. The age range of patients affected is broad. Many salivary neoplasms are benign, often involving the parotid gland, accounting for approximately 80% of parotid tumors, 50% of tumors arising in submandibular glands, and 25% of tumors arising in minor salivary glands.

Table 19-2 lists primary salivary malignancies.

Primary treatment depends on tumor extent and histology. Notably, parotid lymphadenopathy may reflect metastatic involvement by squamous cancers of the scalp or melanomas, and this must be borne in mind when evaluating these patients. Following a complete head and neck evaluation, consideration may be given to CT imaging of chest and a bone scan because these are common metastatic sites.

Surgical resection is the fundamental primary treatment for most patients, and the approach will be influenced by the primary histology (36). Adenoid cystic carcinoma (ACC) tends to track along nerves and may involve structures of the skull base, an important consideration in surgical and radiation therapy planning. C-kit is overexpressed in ACC (37). Lymph node metastases are uncommon. Low-grade mucoepidermoid carcinomas tend to be localized and are most often treated by surgery alone. High-grade mucoepidermoid

Table 19-2 Selected Salivary Gland Cancers

Frequently Observed
Adenoid cystic carcinoma
Adenocarcinoma not otherwise specified
Mucoepidermoid carcinoma (well vs poorly differentiated)
Less Common

carcinomas carry a much higher risk of lymph node and distant metastases. Salivary ductal carcinomas may be high grade and share biomarker characteristics, such as estrogen or progesterone receptor and HER2/neu overexpression, with breast cancer.

As a generalization, large tumors or those with close surgical margins will require postoperative radiotherapy. Postoperative concomitant chemoradiation is now under study (Radiation Therapy Oncology Group [RTOG] 1008) in a randomized trial of high-risk patients and is a consideration for patients with good performance status with locally advanced resectable disease.

For the palliative treatment of patients with recurrent disease not amenable to further local treatment or those with distant metastases, treatment with systemic chemotherapy, most often with a platinum-based combination, is an option⁽³⁸⁾. Cisplatin, 5-FU, cyclophosphamide, and doxorubicin are active compounds. The taxanes also have activity, although not demonstrated in patients with ACC. Combinations may be more effective, with response rates ranging from 20% to 30%. Salivary ductal cancers are much more sensitive to chemotherapy than ACC.

Treatment goals in the setting of distant metastatic disease are palliative because there has not been an overall survival advantage with chemotherapy. See [Table 19-3](#) for a listing of tumor markers in salivary cancer that have prompted clinical trials. *EGFR*, *KIT*, *HER2*, and *AR* are prospective targets for systematic study. Fibroblast growth factor receptor (*FGFR*) expression⁽³⁹⁾ and *MYB-NFIB* fusion oncogene⁽⁴⁰⁾ have been identified in subsets of ACC. In a phase II trial, lapatinib, a dual inhibitor of *EGFR* and *erbB2* tyrosine kinase activity, showed biologic activity in ACC⁽⁴¹⁾.

Some patients with advanced salivary tumors will have a protracted and indolent clinical course. This has been frequently observed in patients with metastatic ACC involving lung, so it is important to assess the pace of the disease before committing a patient to systemic therapy.

COMBINED-MODALITY THERAPY

For patients with locally or regionally advanced SCC, much effort has been directed toward improvements in primary management with the addition of chemotherapy to surgery, radiotherapy, or both. Toward this end, three general strategies have been undertaken: (1) induction, also known as neoadjuvant therapy, with chemotherapy given before surgery or radiation; (2) concomitant chemoradiation, with chemotherapy given simultaneously with radiation to enhance its effect; and (3) adjuvant therapy, where chemotherapy is given after surgery or radiation in an effort to decrease microscopic metastatic disease burden.

Induction Chemotherapy

Induction chemotherapy has been investigated as an approach to improve outcomes in terms of overall survival and tumor control in patients with stage III/IV disease undergoing definitive local therapy. Theoretical advantages to this approach include reducing the risk of distant disease recurrence, enhancing organ preservation, improving response to definitive radiotherapy by reducing tumor bulk, and modification of subsequent local therapy to response.

This approach was first investigated in the 1970s after the cisplatin and 5-FU regimen proved to be highly active in metastatic disease. Trials over the next three decades investigated the role of chemotherapy added to local therapy in locally advanced disease. In the 2009 meta-analysis that established concomitant chemoradiation as a standard of care for nonsurgical management of stage III/IV SCC, direct comparisons of concomitant chemoradiation and induction chemotherapy indicated that although concomitant chemoradiation was superior to induction chemotherapy followed by radiation for local control and survival, induction chemotherapy was more effective at decreasing distant failure⁽⁴²⁾. This conclusion lent credence to contemporaneous trials investigating induction chemotherapy followed by chemoradiation.

Following demonstration of the activity of taxanes in head and neck cancer, a series of trials investigated the combination of three-drug regimens with a platinum, taxane, and 5-FU. In 2007, two multicenter phase III trials, the European TAX 323⁽⁴³⁾ and the North American TAX 324⁽⁴⁴⁾, demonstrated the superiority of induction TPF (docetaxel, cisplatin, 5-FU) over PF (cisplatin, 5-FU). In TAX 323, a total of 358 patients with untreated, unresectable, and locally advanced tumors were randomized to receive either docetaxel 75 mg/m², cisplatin 75 mg/m², and 5-FU 750 mg/m²/d for 5 days (TPF) or cisplatin 100 mg/m² and 5-FU 1,000 mg/m²/d for 5 days (PF), followed by radiotherapy alone. The primary end point, median progression-free survival, was 11.0 months in the TPF group and 8.2 months in the PF group (hazard ratio [HR], 0.72; $P = .007$), and median overall survival was 18.8 months versus 14.5 months. The TAX 324 trial also compared TPF to PF, but in that study, the doses in the TPF arm were docetaxel 75 mg/m², cisplatin 100 mg/m², and 5-FU 1,000 mg/m²/d for 4 days. Both induction regimens were followed by concomitant chemoradiotherapy with weekly carboplatin area under the curve (AUC) of 1.5. The median overall survival was 71 months in the TPF group and 30 months in the PF group ($P = .006$). Notably, there was better locoregional control in the TPF group than in the PF group ($P = .04$). Rates of neutropenia and febrile neutropenia were significantly higher in the TPF group in both studies.

These two phase III trials led to US Food and Drug Administration (FDA) approval of induction chemotherapy TPF for patients with locally advanced HNSCC in 2007. Despite the impressive results of TAX 324, the value of adding induction chemotherapy to chemoradiation remained an unanswered question given the lack of definitive randomized trials comparing this approach to upfront chemoradiation. A randomized phase II trial by Paccagnella et al of induction TPF followed by chemoradiation versus chemoradiation alone reported a higher radiologic clinical response and a trend toward improved progression-free survival and overall survival⁽⁴⁵⁾.

Two recent phase III trials, PARADIGM⁽⁴⁶⁾ and DeCIDE⁽⁴⁷⁾, were designed to test the hypothesis that induction chemotherapy followed by chemoradiation would confer a survival benefit over chemoradiation alone. These studies failed to meet their accrual targets and were therefore underpowered. The PARADIGM trial enrolled previously untreated patients with SCC of the oral cavity, oropharynx, hypopharynx, or larynx, patients with tumors deemed to be either unresectable or of low surgical curability on the basis of T stage (T3 or T4) and/or nodal status (N2 or N3), or patients who were candidates for organ preservation. The concomitant chemoradiation alone control group received cisplatin 100 mg/m² on days 1 and 22, and radiotherapy was given as an accelerated concomitant

boost over 6 weeks for a total of 72 Gy in 1.8-/1.5-Gy fractions. Induction TPF was given as per TAX 324, and subsequent chemoradiation was adapted to response. Partial and complete responders received weekly carboplatin at AUC 1.5 for 7 weeks and 70 Gy of radiotherapy over 7 weeks in 2-Gy fractions. Patients who responded poorly were treated with an intensified regimen of weekly docetaxel 20 mg/m² for 4 weeks and 6 weeks of radiation to 72 Gy. The trial was powered to detect an improvement in 3-year survival from 55% in the control group (based on historical controls) to 70% in the induction group. However, due to slow accrual, the trial closed with 145 patients enrolled, less than half of the planned enrollment. Overall 3-year survival was 73% (95% confidence interval [CI], 60%-82%) in the induction TPF followed by chemoradiation group versus 78% in the chemoradiation alone group⁽⁴⁶⁾.

The DeCIDE trial⁽⁴⁷⁾ randomized patients with N2/3 M0 disease to either two cycles of induction TPF followed by chemoradiation or chemoradiation alone. Chemoradiation was given as DFHX (docetaxel, 5-FU, and hydroxyurea) with concurrent twice-daily radiotherapy or IMRT. Radiation doses were adaptive, with 74 to 75 Gy given to gross disease, 54 Gy to high-risk microscopic disease, and 39 Gy to low-risk microscopic disease. This study was similarly powered to detect an improvement in 3-year survival from 50% in the control group to 65% in the induction group. However, this trial also failed to accrue well, enrolling 280 patients versus the planned 400 patients. There were no statistically significant differences in overall survival (HR, 0.91; 95% CI, 0.59-1.41) or relapse-free survival. In competing risk analysis, there was a statistically significant reduction in risk of distant relapse without locoregional recurrence in the induction arm ($P = .043$).

Given that both studies failed to show survival benefit, but were ultimately underpowered to do so, the role of induction chemotherapy remains controversial. Importantly, in both studies, the 3-year overall survival rate of 70% to 78% in the chemoradiation alone arm was significantly higher than the historical control of 50% to 55% used in the pretreatment power calculations. This improvement in survival is likely multifactorial—a result of improved supportive care, technical advances in radiotherapy, and a shift in the biology of the disease the incidence as smoking-induced cancers declines and HPV-associated HNSCCs increases. Although the PARADIGM trial did not test for HPV, in DeCIDE, the HPV-positive rate of the 31% of patients tested was over 80%, and HPV-associated disease is known to have higher survival rates.

The Gruppo di Studio Tumori della Testa e del Collo (GSTCC) trial presented by Ghi and colleagues at the 2014 American Society of Clinical Oncology (ASCO) annual meeting, but not yet published, is a 2 × 2 factorial design of induction TPF versus no induction followed

by chemoradiation with either cetuximab or PF in 415 patients. This trial showed a survival benefit of 53.7 months in the induction arm versus 30.3 months in the upfront chemoradiation arm (HR, 0.72; 95% CI, 0.55-0.96; $P = .025$) and additionally showed a reduction in distant metastases. The difference in outcomes observed in this trial versus the DeCIDE and PARADIGM trials is likely due to different patient populations and inclusion criteria.

Induction chemotherapy may also have value as a component of a sequential approach in which chemotherapy is followed by radiotherapy as a single modality in select locally advanced patients, thus sparing some of the toxicity of concomitant chemoradiation. In our center, a phase II trial with 47 patients investigated the efficacy of combining cetuximab with paclitaxel and carboplatin in a 6-week induction regimen followed by risk-based local therapy (radiation, concomitant chemoradiotherapy, or surgery) based on tumor stage and site at diagnosis. Inclusion criteria were stage IV M0 with nodal staging of N2b/c/N3. Of note, local therapy was determined at diagnosis and was not adapted to response. After induction chemotherapy, 9 patients (19%) achieved a clinically complete response, and 36 patients (77%) achieved a partial response. Local therapy consisted of concomitant chemoradiotherapy in 23 patients, radiotherapy alone in 23 patients, and surgery in 1 patient. The 3-year progression-free survival and overall survival rates were 87% and 91%, respectively (⁴⁸). A recent update to this trial reported a 5-year overall survival rate of 89% and very favorable long-term speech and swallow functions (⁴⁹). This strategy is undergoing further testing. At the ASCO 2014 annual meeting, Cmelak et al (⁵⁰) presented preliminary results of E2399. Patients with locally advanced HPV-positive disease responding to induction chemotherapy with paclitaxel, cisplatin, and cetuximab were effectively treated with a reduced-dose cetuximab-IMRT regimen, 54 Gy, if they achieved a clinical complete response to the induction chemotherapy. An early outcomes analysis showed 84% progression-free-survival and 95% overall survival at 2 years.

Concomitant Radiotherapy and Chemotherapy

In patients with locally advanced but M0 disease, the strategy of concomitant radiotherapy and chemotherapy has led to improved local and regional tumor control compared to radiotherapy alone (⁴²). Synergy between chemotherapy and radiation is based on several mechanisms, including (1) inhibition of DNA repair; (2) redistribution of cells to sensitive phases of the cell cycle; and (3) promoting oxygenation of anoxic tissues. The net effect is to improve cellular

cytotoxicity (⁵¹⁻⁵³). However, combined therapy also enhances acute mucocutaneous toxicity, which may prompt subsequent dose reductions and treatment interruptions in radiotherapy. Thus, in combining these two treatment modalities, it is essential that toxicity not preclude the delivery of therapy in an effective schedule to avoid compromise of efficacy.

In a landmark phase II trial in 1987, the RTOG administered cisplatin (100 mg/m²) every 3 weeks to 124 patients with locally advanced unresectable head and neck cancer (⁵⁴). Sixty percent of patients completed the combined treatment per protocol, and 69% of all patients achieved a complete response. A comparison to RTOG patients treated with radiotherapy alone suggested improvement in survival time for the combined treatment.

The use of concomitant combination chemotherapy and radiation has long been under intense study (⁵⁵). Meta-analysis (⁴²) of prospective clinical trials demonstrates an enhancement of local tumor control and improvement of survival with combined therapy over radiation treatment alone, and chemoradiation is the standard of care in locally advanced non-surgical disease.

Combining several drugs with radiation will enhance acute toxicity, which may be severe. Therefore, investigators have piloted trials designed with split-course radiation to allow for healthy tissue recovery. Most of these studies have been limited to patients with stage III or IV locally advanced SCC, with local control and improved survival time as the primary objectives. These regimens alternate chemotherapy and radiotherapy or use split-course radiotherapy to maximize tumor cell kill and minimize tissue toxicity. However, protracted radiation treatment times may result in decreased local control rates because of accelerated repopulation of cancer stem cells (^{56, 57}). The strategy of alternating non-cross-resistant agents may potentially eliminate not only tumor cell repopulation but also primary drug resistance.

Brizel et al (⁵⁸) compared a hyperfractionated radiotherapy arm to total dose of 75 Gy versus concomitant PF and hyperfractionated radiation to 70 Gy followed by two cycles of adjuvant chemotherapy. There was a statistically significant improvement in local disease control and a strong trend toward improved overall survival for the combined-modality arm. In this trial, neck dissection was recommended in patients with N2/3 disease. Clayman et al (⁵⁹) have reviewed the MDACC experience, examining the indication for neck dissection in this patient population. Their report suggests that neck dissections are required only when there is radiographic evidence of residual disease 6 to 8 weeks following the completion of definitive chemoradiation. Wendt et al (⁶⁰) reported a statistically significant 3-year survival advantage after the concomitant use of cisplatin, 5-FU, and leucovorin with

split-course radiotherapy versus radiotherapy given as a single therapeutic modality. Calais et al.⁽⁶¹⁾ compared a more standard once-daily fractionation radiation schedule with the same radiotherapy and concomitant carboplatin and 5-FU, demonstrating a statistically significant advantage in locoregional tumor control and overall survival at 3 years. Jeremic et al.⁽⁶²⁾ also investigated the value of adding cisplatin given daily to a hyperfractionated radiation therapy program versus the same radiation schedule given alone in patients with locally advanced HNSCC. In this report, locoregional and distant disease control and overall survival were improved at 5 years. Adelstein et al.⁽⁶³⁾ compared standard daily radiotherapy with two schedules of concomitant chemoradiotherapy in a large intergroup study. The addition of high-dose cisplatin to conventional single daily dose radiotherapy improved survival from 23% to 37% at 3 years. The clearest benefit in these studies was an improvement in locoregional control, which translated into a survival advantage. Acute toxicity was increased, especially mucositis and hematologic effects, but there was no obvious escalation of long-term sequelae. However, this may need further investigation. In aggregate, overall 3-year survival exceeded 50% in these experimental programs, underscoring the potential therapeutic efficacy of concomitant chemotherapy and radiation in patients with advanced head and neck cancers.

Cetuximab, a monoclonal antibody, is approved for use in combination with radiation in previously untreated patients. In a landmark study, patients with locoregionally advanced head and neck cancer were randomly assigned to receive either high-dose radiotherapy alone (213 patients) or high-dose radiotherapy plus weekly cetuximab (211 patients) at an initial dose of 400 mg/m² of body surface area, followed by 250 mg/m² weekly for the duration of radiotherapy⁽⁶⁴⁾. The primary end point, median duration of locoregional control, was 24.4 months among patients treated with cetuximab plus radiotherapy and 14.9 months among patients given radiotherapy alone (HR, 0.68; $P = .005$). The median duration of overall survival was 49.0 months among patients treated with combined therapy and 29.3 months among patients treated with radiotherapy alone (HR for death, 0.74; $P = .03$). However, the rates of distant metastases at 1 and 2 years were similar in both groups. With the exception of acneiform rash and infusion reactions, the incidence of grade 3 or greater toxic effects, including mucositis, did not differ significantly between the two groups.

Cetuximab plus radiotherapy is directly compared to chemoradiation for patients with HPV-associated oropharyngeal cancer in a phase III randomized trial (RTOG 1016), but results from this trial are not yet available. This trial represents the recent trend in investigational treatment strategies undertaken by clinical

Table 19-4 EGFR-Based Bioradiotherapy With Panitumumab

trial cooperative groups that have focused on treatment “de-intensification” for selected patients (namely those with HPV-associated oropharyngeal cancer), with the goals of maintaining or improving established cure rates but reducing treatment-related toxicity.

There has been a series of trials investigating the use of *EGFR* antibodies with chemoradiation. The phase III RTOG 0522 trial randomized 940 patients to high-dose cisplatin-based chemoradiotherapy with or without cetuximab⁽⁶⁵⁾. The combined biochemoradiotherapy failed to meet the primary end point of improving progression-free survival, with a 3-year rate of 61.2% versus 58.9% with cetuximab, and demonstrated a trend toward worse locoregional control. This trend was likely the result of significantly increased toxicities that led to radiation interruptions in 26.9% of patients. There was also a significant difference in treatment-related deaths (10 vs 3; $P = .05$). The CONCERT-1 and -2 trials have further explored bioradiotherapy with panitumumab (Table 19-4)^(66,67), showing no overall survival or local disease control advantage after matching chemoradiotherapy with the addition of the antibody.

The aggregate results of these trials indicate that improved disease-free and overall survival times have been obtained for patients with locally advanced HNSCC using concomitant chemotherapy and radiotherapy rather than radiotherapy as a single treatment modality. Combination chemotherapy with radiotherapy may increase response but causes increased toxicity. Well-designed clinical trials are still needed to determine optimal chemotherapy and radiotherapy schedules.

Adjuvant Chemoradiotherapy

Adjuvant chemotherapy is indicated in patients at high risk of recurrence after surgical resection, generally defined as having narrow or involved margins at the primary site, multiple nodal metastases, or extracapsular spread (Table 19-5)⁽⁶⁸⁻⁷⁰⁾.

Table 19-5 Postoperative Chemoradiation: Randomized Trials

Study	Eligibility	Experimental Arms	Outcome
Bachaud et al (⁶⁸), 1996	Nodal ECS	RT + weekly cisplatin (n = 39)	DFS ($P < .02$) and OS ($P < .01$) better
RTOG 9501 (⁶⁹), 2004	Multiple nodal metastases, ECS, or positive margins	RT + cisplatin days 1, 22, 43 (n = 228)	2-y LRC (82% vs 72%; $P = .01$) + PFS ($P = .04$) better
EORTC 22931 (⁷⁰), 2004	Stage III/IV	RT + cisplatin days 1, 22, 43 (n = 167)	PFS ($P = .04$) + OS ($P = .02$) better

DFS, disease-free survival; ECS, extracapsular spread; EORTC, European Organization for Research and Treatment; LRC, local and regional control; OS, overall survival; PFS, progression-free survival; RT, radiotherapy; RTOG, Radiation Therapy Oncology Group.

Two large phase III studies, RTOG 9501 (⁶⁹) and EORTC 22931 (⁷⁰), tested cisplatin-based concomitant chemoradiotherapy in the adjuvant setting. Although with some variations between the studies, patients with high-risk features (positive margin, extracapsular spread, lymphovascular invasion, perineural invasion, and multiple positive lymph nodes) were randomly assigned to receive either radiotherapy alone or radiotherapy plus cisplatin at 100 mg/m² every 3 weeks for three cycles. In RTOG 9501, concomitant chemoradiotherapy significantly reduced the risk of locoregional recurrence compared with radiotherapy alone (HR for local or regional recurrence, 0.61; $P = .01$). However, no survival benefit was observed. In addition, the incidence of grade 3 or greater adverse effects was 34% in the radiotherapy group and 77% in the combined-therapy group ($P < .001$). In EORTC 22931, both the progression-free survival (HR, 0.75; $P = .04$) and overall survival (HR, 0.70; $P = .02$) rates were significantly higher in the combined-therapy group than in the radiotherapy group. Severe acute adverse effects were more frequent after combined therapy (41%) than in the radiotherapy group (21%).

More recently, based on the benefit of cetuximab bioradiotherapy in the definitive setting and the additive benefit of cetuximab to chemotherapy in the metastatic setting (⁷¹), RTOG 0234 explored the incorporation of cetuximab into adjuvant chemoradiation (⁷²). This phase II trial compared two biochemoradiotherapy regimens to historical high-dose cisplatin-based chemoradiotherapy in RTOG 9501 with the intent to select a regimen for further testing against standard high-dose cisplatin-based chemoradiotherapy in a phase III trial. Both docetaxel (15 mg/m²)/radiation/cetuximab and weekly cisplatin (30 mg/m²)/radiation/cetuximab outperformed the historical control with 2-year overall survival rates of 79% and 69% and 2-year disease-free survival rates of 66% and 57%, respectively (HR, 0.69 for the docetaxel arm vs control, $P = .01$; and HR, 0.76 for the cisplatin arm vs control, $P = .05$). Grade 3 or 4 myelosuppression was observed in 28% of patients in the cisplatin arm and 14% of patients in the docetaxel arm, and mucositis was observed in

56% and 54% of patients, respectively. Although these results are promising, as has been noted previously, comparison with historical controls is problematic given the shifting epidemiology from smoking-related cancer to better prognosis HPV-related cancers, which has likely contributed to the improvements in survival rates of the control arms seen in the recent induction trials (^{46, 47}). RTOG 1216 is an ongoing phase II/III trial of surgery and postoperative radiation delivered with concurrent cisplatin versus docetaxel versus docetaxel and cetuximab for high-risk HNSCC.

Although adjuvant concomitant chemoradiotherapy has been demonstrated to be more effective than radiotherapy, there is significant associated toxicity. The two risk factors most associated with benefit from concomitant chemoradiotherapy are extracapsular extension and positive surgical margins (⁷³).

ORGAN PRESERVATION

Many HNSCCs are diagnosed at a late stage. Stages III and IV tumors often necessitate extensive or radical surgery, which may alter organ function. Problems with radical surgery include loss of speech, loss of swallowing function, or disfigurement without a concomitant improvement in survival time. Therefore, preservation of function became one of the major challenges. This approach was first explored in laryngeal cancer given the high morbidity associated with laryngectomy.

The landmark VA study published in 1991 randomized 332 patients with stage III or IV SCC of the larynx to receive either induction chemotherapy consisting of PF followed by radiotherapy or surgery and postoperative radiotherapy (³⁴). Patients who experienced no tumor response to chemotherapy or those who had locally persistent or recurrent cancer underwent salvage laryngectomy. Two-year survival for both treatment groups was 68%, and 41% of patients randomly assigned to the experimental arm were alive with a functional larynx at 2 years. Thus, the efficacy of chemotherapy followed by radiotherapy (with surgical salvage) was similar to that

of surgery followed by radiotherapy and established organ preservation as a realistic goal of nonsurgical treatment administered with curative intent. Patterns of failure differed, with patients in the chemotherapy arm more likely to have locoregional recurrence and distant recurrence more common in the surgical arm. Lefebvre et al.⁽³¹⁾ later reported that sequential chemotherapy and radiation could also be effective in selected patients with cancers of the hypopharynx.

The VA larynx study prompted further investigations of chemotherapy and radiotherapy for the treatment of larynx cancer using the sequential administration of induction chemotherapy, consisting of PF, followed by radiotherapy versus concomitant cisplatin-radiotherapy versus radiotherapy administered as a single treatment modality in RTOG 91-11⁽⁷⁴⁾. For all groups, totaling 547 patients, surgical salvage was reserved for patients with persistent or locally recurrent disease. Both chemotherapy groups demonstrated improved laryngectomy-free survival (the composite primary end point) compared to radiotherapy alone. The results indicated a significant advantage for concomitant cisplatin treatment, with preservation of the larynx in 88% of patients treated in the concomitant arm. In the recently published 10-year update⁽⁷⁵⁾, locoregional control and larynx preservation were significantly improved with concomitant chemoradiotherapy compared with the induction arm RT (HR, 0.58; 95% CI, 0.37-0.89; $P = .005$), whereas the induction chemotherapy group showed a nonsignificant trend toward improved overall survival (HR, 1.25; 95% CI, 0.98-1.61; $P = .08$). This difference in survival was driven by non-cancer-related deaths, the cause of which remains unexplained.

Organ preservation has also been studied in hypopharyngeal cancer given that laryngectomy is often part of the surgical treatment of this disease. Similar to the VA study, the EORTC study compared induction chemotherapy with PF followed by radiation versus conventional surgery plus postoperative radiation. As in the VA study, survival between the two arms did not differ, and patients in the chemotherapy arm had a high rate of larynx preservation.

As with TAX 323 and TAX 324, TPF was also explored in locally advanced but resectable SCC of the larynx or hypopharynx⁽⁷⁶⁾. Compared to PF, TPF was shown to increase tumor responsiveness and lead to improved larynx preservation (70% vs 58% in the PF arm), with no compromise in overall survival. The efficacy of induction TPF versus concurrent chemoradiation has not been explored. The concurrent approach tends to be favored in the United States, whereas Europeans tend to prefer induction.

These trials indicate that for patients with intermediate-stage SCC of the larynx, a combined treatment program with the objectives of tumor eradication and

laryngeal preservation is appropriate. It is also important to recognize that patients with locally advanced, destructive primary laryngeal cancers were not included in the more recent multigroup trial. These patients may require total laryngectomy for optimal tumor control and preservation of function.

It should be noted, however, that nonsurgical treatment also carries risk of morbidity and functional impact. Radiation produces tissue changes that can result in immediate and long-term alterations in speech and swallowing. The adverse impact of radiation may equal or exceed that associated with surgery, depending on the treatment dose and volume, and the sequelae of treatment may manifest or increase in severity years after the completion of treatment. Fibrosis may reduce the range of motion of the tongue and jaw and diminish pharyngeal wall motion. Historically, 20% to 40% of patients receiving chemoradiotherapy for SCC of the oropharynx and hypopharynx may require long-term gastrostomy tube feedings. However, the long-term gastrostomy rate for patients with oropharynx cancer treated with modern radiation therapy approaches (eg, IMRT) is less than 10%⁽⁷⁷⁾. Radiation to the larynx often results in swallowing problems related to pharyngeal transport. To counteract the deleterious effects of radiation and chemoradiotherapy, there are rehabilitative options, which are best administered by a qualified speech pathologist.

RECURRENT OR METASTATIC DISEASE

Patients with tumor recurrence after primary treatment who are not candidates for surgical salvage may be offered palliative cytotoxic chemotherapy or investigational therapy. Methotrexate, cisplatin, carboplatin, bleomycin, 5-FU, and the taxanes are drugs with single-agent activity in the range of 15% to 25%. Previous studies have consistently demonstrated response rates of 30% to 40% for combination chemotherapy, usually cisplatin based, with a median survival of 6 to 9 months. There has been no clear demonstration of a survival advantage over single-agent treatment or even best supportive care. However, in the appropriate context with the goal of reducing symptoms, combination chemotherapy with PF or a platinum-taxane combination has become a frequently exercised practice in the care of patients with incurable HNSCC, and a fraction of patients treated with these combinations have extended survival.

Current investigations are under way in an attempt to develop effective targeted treatment approaches. Epidermal growth factor receptor is overexpressed in a majority of invasive HNSCCs. The small-molecule

inhibitors gefitinib (500 mg/d) and erlotinib (150 mg/d) downregulate the phosphorylation of tyrosine kinase residues in the cytoplasmic domain of *EGFR* and have demonstrated single-agent activity in 11% and 5% of patients, respectively, with advanced disease (^{78–80}). Cetuximab is a chimeric murine-human monoclonal antibody directed against the extracellular domain of *EGFR*. Burtneß et al (⁸¹) conducted a prospective randomized trial in patients with recurrent HNSCC and demonstrated responses in 26% of patients treated with cetuximab and cisplatin versus 10% of patients treated with cisplatin alone. However, the primary end point, progression-free survival, was not significantly different. Cetuximab was tested in a phase II trial as monotherapy in 103 patients with recurrent or metastatic HNSCC refractory to platinum-based therapy (⁸²). The response rate was 13%, disease control rate (complete response/partial response/stable disease) was 46%, and median time to progression was 70 days. There appeared to be no benefit in adding cisplatin to these patients. Afatinib is a small-molecule tyrosine kinase inhibitor that targets *EGFR* and HER2. This compound is under study in ECOG 1311 as an adjuvant systemic therapy after definitive chemoradiation and neck dissection for high-risk patients.

In a major phase III trial, cetuximab in combination with chemotherapy was investigated in patients with untreated recurrent or metastatic HNSCC (⁷¹). In this trial, 442 patients were randomized to receive either cisplatin or carboplatin plus 5-FU, with or without cetuximab. The cetuximab group had longer overall survival (10.1 vs 7.4 months) and median progression-free survival (5.6 vs 3.3 months). Thus, cetuximab plus PF chemotherapy improved overall survival when given as first-line treatment in patients with recurrent or metastatic HNSCC.

Further study of molecular biomarkers and selection of targeted therapies for trials both in definitive and palliative treatment settings is receiving much emphasis. Activation of the PI3k/Akt signaling pathway is under study in HNSCC, and phase I/II trials with PI3K inhibition are ongoing (⁸³). One of the more exciting agents currently under investigation is MK-3475, a PD-1 antibody that acts as an immune checkpoint inhibitor. This type of immunotherapy has been approved in melanoma and lung cancer and is being investigated in multiple tumor types with promising results. A phase Ib study presented by Seiwert et al (⁸⁴) at ASCO 2014 enrolled 61 patients with metastatic HNSCC, 36 HPV-negative patients and 23 HPV-positive patients. The response rate was 19.6%, and an additional eight patients experienced stable disease for over 6 months. Response was correlated with programmed death ligand 1 (PD-L1) expression. There was no difference in response between HPV-negative and HPV-positive disease. A phase III study is planned.

CHEMOPREVENTION

The decades-long history of clinical and translational study of retinoids in oral premalignant lesions, or intraepithelial neoplasia (IEN), has advanced our understanding of the biology of carcinogenesis and molecular-targeted drug development, even though definitive clinical testing has not shown that retinoids can prevent oral cancer (⁸⁵). One early trial in 1986 tested a high dose of the retinoid 13-*cis*-retinoic acid (13cRA) against placebo in 44 evaluable oral IEN patients for only 3 months (⁸⁶). The complete plus partial clinical response rate in the retinoid arm was 67% (vs 10% in the placebo arm) ($P = .0002$). Histopathologic responses also favored the 13cRA arm. Over half of the responders in the 13cRA arm, however, recurred or developed new lesions within 3 months of stopping the intervention. This high-dose, short-term trial led to another early trial in oral IEN patients, which was designed to reduce the toxicity of and prolong the response to 13cRA. A short-term (3-month) course of high-dose 13cRA (1.5 mg/kg/d) was followed by a 9-month maintenance course with low-dose 13cRA (0.5 mg/kg/d) or β -carotene (30 mg/d) in IEN patients who responded to or were stable after the induction phase (⁸⁷). The maintenance-phase progression rates were 8% in the 13cRA group and 55% in the β -carotene group ($P < .001$). Nonetheless, on long-term follow-up (median of 66 months), the incidence of in situ or invasive cancer was not different between the two arms (23% for low-dose 13cRA vs 27% for β -carotene) (⁸⁸).

To address the short-lived chemopreventive effects of 13cRA, Papadimitrakopoulou et al designed a follow-up study comparing an extended, 3-year treatment period with 13cRA at lower doses (0.5 mg/kg/d for 1 year followed by 0.25 mg/kg/d orally for 2 years; control arm) to β -carotene (50 mg/d) plus vitamin A (ie, retinyl palmitate 25,000 IU/d; experimental arm) in 162 patients with leukoplakia, using a noninferiority design (⁸⁹). During the study, β -carotene had to be dropped from the experimental arm due to emerging data demonstrating an increased risk of lung cancer incidence and mortality in other ongoing chemoprevention trials at that time. The study showed an inferior 3-month response rate in the vitamin A alone arm, lower tolerance to treatment with 13cRA, a lack of statistical significance in the test for noninferiority between the control and the experimental arm(s), and, more importantly, a similar oral cancer-free survival across all groups. This study, which is one of the longest term performed to date in patients with leukoplakia, demonstrated that 13cRA is still not well tolerated for long-term treatment, even at reduced doses and that less toxic regimens (ie, vitamin A alone) are ineffective. Furthermore, an impact on oral cancer incidence has yet to be demonstrated with any of these regimens. In

addition to trials involving oral IEN, retinoids have also been studied for prevention of second primary head and neck cancers. A randomized, placebo-controlled study of high-dose 13cRA (50–100 mg/m²/d for 12 months) in definitively resected head and neck cancer patients demonstrated a lack of effect of the retinoid on distant, nodal, or local recurrence rates, but there was a statistically significant decrease in the incidence of second primary tumors (4% vs 24%, $P = .005$) that persisted on long-term follow-up^(90,91). Unfortunately, a follow-up trial of a tolerable low dose of 13cRA (30 mg/d for 3 years) in 1,190 early-stage patients did not prevent second primary tumors⁽⁹²⁾. Randomized studies in this setting with the second-generation retinoid etretinate ($n = 316$ patients)⁽⁹³⁾, vitamin A and/or *N*-acetylcysteine ($n = 2,592$)⁽⁹⁴⁾, β -carotene ($n = 264$)⁽⁹⁵⁾, and α -tocopherol plus β -carotene ($n = 540$)⁽⁹⁶⁾ also did not demonstrate any clinical benefit in terms of prevention of second primary tumors.

Although the randomized retinoid trials failed to produce a chemoprevention strategy that could be considered standard of care, they were embedded with translational studies that helped to advance the overall understanding of the biology of intraepithelial carcinogenesis, molecular markers—for example, retinoic acid receptor (RAR) β , *p53*, *p16*, *EGFR*, and genetic instability—for developing drugs, monitoring interventions, and assessing cancer risk and pharmacogenomics.

In terms of cancer risk assessment, cyclin D1 genotype^(97,98) and loss of heterozygosity at certain chromosomal sites^(99,100) have emerged in multiple studies as prognostic factors that could be potentially useful in the clinic. Building on these data, investigators at MDACC led a clinical study evaluating the effects of erlotinib (150 mg/d for 1 year) on the incidence of invasive cancer in patients with oral premalignant lesions (with or without a prior history of oral cancer) selected for high risk based on loss of heterozygosity testing—the Erlotinib Prevention of Oral Cancer (EPOC) study^(101,102). This was the first large-scale study in oral IEN that used molecular risk assessment as part of the inclusion criteria, thus bringing the concept of precision medicine to the chemoprevention field. Loss of heterozygosity high-risk profiles were indeed associated with increased oral cancer incidence on long term follow-up and are now considered the most robust molecular markers of cancer risk in oral IEN. Erlotinib, however, did not improve oral cancer-free survival in this high-risk population.

As the role of HPV-16 in the pathogenesis of a subgroup of HNSCC becomes substantiated, preventive strategies targeting this infectious agent could be explored as well. Human papillomavirus vaccination is already being used to prevent cervical cancer. Human papillomavirus vaccine has been shown to reduce the prevalence of oral HPV infections, but its impact on

incidence of HNSCC is yet to be determined⁽¹⁰³⁾. One anticipates, though, that widespread HPV vaccination may contribute to reducing the burden of HPV-induced HNSCC in the coming decades.

SUMMARY

Head and neck SCC is a major international health problem. General public health strategies such as reducing tobacco usage and increasing awareness of associated risks are of primary importance.

The demonstration of HPV as a causative agent for oropharyngeal cancers is of great importance because this will carry implications for prevention and also will influence decision making in treatment planning as well as the conduct of clinical trials.

The optimal care and treatment of head and neck cancer patients are multidisciplinary. Surgical resection and/or radiotherapy are powerful local modalities and the care of treatment for most patients. Emerging data support the administration of chemotherapy as a component of combined-modality treatments, especially in patients with advanced HNSCC. For patients with locally recurrent or metastatic disease, combination chemotherapy may produce response rates of 30% to 40%. However, responses tend to be brief, lasting a median of 3 to 6 months, and are associated with only a modest prolongation of survival. Thus, chemotherapy for these patients is palliative. An exception to this is for patients with NPC, with higher response rates and a small proportion of long-term disease-free survivors. For patients with metastatic HNSCC of any primary site, the addition of cetuximab to platinum–5-FU appears to improve tumor responses and overall survival. Targeted agents are currently under investigation. Prognostic and predictive markers are needed to improve selection of patients who are most likely to benefit from palliative treatment. Enrolling in investigational studies is strongly supported.

In the newly diagnosed patient with locally advanced disease, high response rates have been observed with induction chemotherapy. The addition of a taxane to the more traditional PF platform has increased overall activity, but the use of induction treatment for most patients remains an investigational endeavor. The potential for augmentation of local control with a substantial response to chemotherapy followed by definitive surgery or radiation is also under investigation. Three large multicenter randomized trials have been successfully conducted in larynx cancer with preservation of function in subsets of patients.

Chemotherapy administered concomitantly with radiotherapy has improved local control and survival in a sequence of studies and is recognized as the standard of care for nonsurgical therapy of patients with

locally advanced squamous cancers of the pharynx and larynx. The increase in toxicity associated with these regimens should be carefully considered in selecting patients for combined treatment.

Patients with earlier-stage disease (ie, stage I or II) generally should receive therapy with either surgery or radiotherapy or both. Patients with locally advanced M0 (stage III/IVA/B) disease may be considered for non-surgical therapy, most often with chemotherapy and radiation, or entered into a combined chemoradiation treatment protocol. Patients with “resectable” disease can be further divided by site. Patients with primary oral cavity tumors are best served with surgery followed by radiotherapy (or chemoradiotherapy if there are high-risk pathologic features), whereas those with oropharyngeal, hypopharyngeal, or laryngeal tumors are often treated with radiation, with or without chemotherapy, depending on precise site and stage.

Basic and translational chemoprevention research in head and neck carcinogenesis is advancing our understanding of the molecular characteristics of carcinogenesis and cancer risk. We have studied *EGFR* inhibition in a prospective, controlled trial in high-risk patients. This project illustrates the convergence of prevention and therapy, whereby a molecularly targeted agent known to have efficacy in the setting of invasive cancer is brought into the premalignant space.

The management of head and neck cancer is a multidisciplinary activity. The identification of effective chemotherapeutic agents and their integration into the initial therapy of head and neck cancer have the potential to improve survival time and preserve organ function. Moreover, studies are under way to reduce treatment intensity and thereby long-term toxicity. Through well-designed and executed clinical trials, coupled with basic research of the biology of upper aerodigestive tract tumors, further advances in the management and prevention of these cancers can be achieved.

GASTRIC CANCER

Epidemiologic Characteristics

The incidence of gastric cancer varies widely worldwide. The highest incidence (>20 per 100,000 in men) is seen in Japan, China, Eastern Europe, and South America, while the lowest incidence (<10 per 100,000 in men) is seen in Northern America, parts of Africa, and Northern Europe (¹). In the United States, 24,590 new cases of gastric cancer are estimated in 2015, with 10,720 deaths (²). Gastric cancers occur at a median age of 69 years for men and 73 years for women (³). African Americans, Hispanic Americans, and Native Americans are 1.5 to 2.5 times more likely to develop gastric cancer than whites (³). In the United States, there are changing epidemiologic patterns regarding the anatomic location of esophagogastric cancers, with a trend of decreased occurrence of distal or noncardia gastric cancers (⁴). The reason for the decline is not known but may be related to change in dietary habits and food preservation. However, an increase in the incidence of gastric cardia cancers has been observed, from 2.4 cases per 100,000 individuals (1977-1981) to 2.9 cases per 100,000 individuals (2001-2006) in the white population (⁴). Similarly, the Surveillance, Epidemiology, and End Results (SEER) cancer registry program in the United States shows an approximate 2.5-fold increase in the incidence of gastroesophageal junction (GEJ) adenocarcinomas from 1973 to 1992, from 1.22 cases per 100,000 individuals (1973-1978) to 2.00 cases per 100,000 individuals (1985-1990), with rates stabilizing in the last two decades, with an incidence of 1.94 cases per 100,000 individuals (2003-2008) (^{3,5}).

Population studies suggest that proximal cancers have a different pathogenesis than distal cancers (⁶). Potential causes of distal gastric cancers include *Helicobacter pylori* infection or E-cadherin expression loss, whereas proximal gastric cancers may behave similarly to distal esophageal and GEJ cancers, which progress from Barrett metaplasia to dysplasia to invasive adenocarcinoma. Only 26% of newly diagnosed gastric cancers are localized. The 5-year overall survival (OS) rate is 28.3%, which has not changed significantly over the past 30 to 40 years (¹). Surgery is still the only chance for cure, and survival can be improved with multimodality therapy. The 5-year OS rate of patients with advanced disease remains dismal at less than 5%. Thus, despite decreasing incidence, gastric cancer remains a public health concern in the United States because of its high fatality rate.

Etiologic Characteristics and Risk Factors

The most frequent type of gastric cancer is adenocarcinoma, which consists of two main histologic variants: intestinal and diffuse. Intestinal-type gastric adenocarcinoma likely begins with an *H pylori* infection that leads to multistep progression (chronic active nonatrophic gastritis, multifocal atrophic gastritis, intestinal metaplasia, dysplasia, and invasive adenocarcinoma) (⁷). More than 40% to 50% of distal gastric adenocarcinomas are associated with *H pylori* infection (⁸). Other environmental risk factors and inflammatory cytokines may influence and contribute to this multistep progression.

Population studies have identified certain environmental risk factors associated with gastric cancer. Low consumption of fruits and vegetables, high intake of N-nitroso compounds in salted and preserved foods, and occupational exposure in coal mining and nickel, rubber and timber processing are commonly described risk factors. Long-standing chronic superficial gastritis caused by a high-salt diet and conditions such as pernicious anemia eventually leads to chronic atrophic gastritis and intestinal metaplasia (⁷). Additional notable risk factors include meat consumption (⁸), smoking (⁹), gastric surgery (¹⁰), and reproductive hormones (¹¹).

Overall, the pathogenesis of intestinal-type gastric adenocarcinomas involves a series of events. This sequence of events—increased cell proliferation due to the promotional effects of hypergastrinemia or bile reflux, increased luminal levels of mutagens (eg, N-nitroso compounds and free radicals), and decreased luminal levels of protective factors (eg, vitamin C)—provides an ideal milieu for carcinogenesis in susceptible hosts (⁷).

In contrast to intestinal-type gastric cancer, diffuse-type gastric adenocarcinoma results from defective intracellular adhesion molecules, which is the consequence of loss of E-cadherin protein expression, which is encoded by the cadherin 1 (*CDH1*) gene. This can occur through germline or somatic mutation, loss of heterozygosity, or epigenetic silencing of gene transcription through aberrant methylation of the *CDH1* promoter. A study by Zheng et al showed a positive rate of E-cadherin promoter methylation in dysplasia, early cancer, and advanced cancer (¹²). Furthermore, 30% of hereditary diffuse gastric cancer (HDGC) families show *CDH1* germline mutations, whereas the rest remain genetically unexplained (¹³). Currently, many families with HDGC have *CDH1* germline mutations. Inheritance is dominant. The lifetime cumulative risk for advanced gastric cancer has been estimated to be 40% to 67% in men and 60% to 83% in women (¹⁴). Women in affected families are also at high risk for developing lobular breast cancer, with a cumulative risk of 52% (¹⁴). A germline mutation in *TP53* is associated with familial gastric cancer (¹³), which includes Li-Fraumeni syndrome. Another familial cancer syndrome associated with gastric cancer is hereditary nonpolyposis colorectal cancer, resulting from defects of DNA mismatch repair genes (*hMLH1* and *hMSH2*, more frequent) (¹³) (Table 20-1).

Epstein-Barr virus (EBV)-associated gastric cancers have distinct clinicopathologic characteristics, including male predominance, preferential location in the gastric cardia or postsurgical gastric stump,

lymphocytic infiltration, and a more favorable prognosis (^{15, 16}).

Despite recent progress, the precise etiologic characteristics of gastric cancer and the relationship between the environment and host are unknown. Ongoing research promises to better elucidate the tumorigenesis of gastric cancer.

Prevention

Results from a number of population studies have demonstrated an increased likelihood of *H pylori* infection in patients with gastric cancer, particularly cancer of the distal stomach (^{17, 18}). However, gastric cancer does not occur in most patients infected with *H pylori*. Although the role of *H pylori* in gastric cancer pathogenesis is well defined, currently there is no definitive evidence showing that mass eradication could reduce the incidence of gastric cancer (¹⁹). A large Chinese study of 1,630 patients showed no benefit in the prevention of gastric cancer with the eradication of *H pylori* (²⁰). However, in a subgroup of patients with no precancerous lesions on presentation, no patient developed gastric cancer during a follow-up of 7.5 years after *H pylori* eradication treatment compared with six patients who received placebo ($P = .02$) (²⁰). In another large study, short-term treatment with amoxicillin and omeprazole statistically significantly reduced gastric cancer incidence by 39% during the period extending 14.7 years after *H pylori* treatment (²¹). A meta-analysis suggested that eradication could reduce the risk of gastric cancer; however, this meta-analysis was criticized for methodologic issues (²²). At present, the treatment of this infection should be confined to patients with peptic ulcer disease, patients with mucosa-associated lymphoid tissue lymphoma, and after endoscopic resection for esophagogastric cancer; a role for a broad prevention strategy has yet to be defined. Applicable to distal gastric cancer and *H pylori*, vaccination may be relevant as a preventive measure against development of *H pylori*.

Clinical Presentation

At presentation, most symptomatic patients will likely have advanced gastric cancer. Symptoms can be constitutional such as night sweats and unintentional weight loss, as well as vague, such as early satiety, abdominal pain, and nausea. Dysphagia is more common in patients with cancer originating in the gastric cardia or GEJ. Occult gastrointestinal (GI) bleeding is also common, whereas overt bleeding is observed in only 20% of cases.

Table 20-1 Summary of Selected Recurrent Cytogenetic Abnormalities and Frequent Molecular Changes Associated With Gastric Cancer

Conventional Cytogenetics	Simple Karyotypes	Complex Karyotypes
	+X, +8, +9, +19, del(7q), i(8q)	1, 3, 6, 7, 8, 11, 13, 17, 19
Molecular Cytogenetics	Gains	Loss
	3q, 7p, 7q, 8q, 13q, 17q, 20p, 20q	4q, 9p, 17p, 18q
Genes	Abnormalities	Clinical Association
<i>c-met</i>	Amplification	Tumor invasion, lymph node metastasis, poor prognosis
<i>K-sam</i>	Amplification	Advanced tumor stage/poor prognosis
<i>c-erbB2</i>	Amplification	Advanced tumor stage, lymph node and liver metastases, poor prognosis
<i>c-myc</i>	Amplification	Poor clinical course/predictor of aggressiveness
<i>TP53</i>	Loss of heterozygosity	Proliferative rate/lymph node metastasis/ shortened survival
	Mutation	
	Hypermethylation	
<i>BCL-2</i>	Loss of heterozygosity	Depth of invasion, lymph node metastasis and survival
<i>RUNX3</i>	Deletion	Metastasis
	Hypermethylation	
	Loss of expression	
<i>PTEN</i>	Loss of heterozygosity	Advanced tumor stage/metastasis
	Mutation	
<i>E-cadherin (CDH1)</i>	Loss of heterozygosity	Tumor metastatic ability and poor prognosis
	Mutation	
	Hypermethylation	
	Reduced expression	
<i>Cyclin E</i>	Amplification	Disease aggressiveness/lymph node metastasis
<i>p27</i>	Reduced expression	Advanced tumor stage/depth of invasion/lymph node metastasis
<i>p16</i>	Reduced expression	Tumor invasion/metastasis
DNA repair genes/ microsatellite instability	Mutation	Age/low prevalence of lymph node metastasis/ prolonged survival
	Hypermethylation	
	Reduced expression	
<i>Syndecan-1</i>	Reduce expression	Tumor differentiation
<i>β-catenin</i>	Amplification	Lymph node metastasis
<i>CD44s</i> and <i>CD44v6</i>	Amplification	Lymph node metastasis
<i>Sp1</i>	Amplification	Cancer angiogenic potential, poor prognosis

Pathologic and Molecular Characteristics

More than 95% of gastric cancers are adenocarcinoma. The remaining 5% include neuroendocrine tumor, lymphoma, squamous cell cancer, and sarcoma.

The Cancer Genome Atlas (TCGA) Research Network has classified gastric cancer into four subtypes based on the molecular characterization of 295 primary

adenocarcinomas in a way that can ultimately guide patient therapy ⁽²³⁾. They clearly converged on four major genomic subtypes of gastric cancer with distinct features and classes of molecular alterations:

- Tumors containing EBV, along with recurrent mutations in the *PIK3CA* gene pathway, extreme DNA hypermethylation, amplification of Janus

kinase 2 (*JAK2*), and extra copies of programmed death ligand 1 (*PD-L1*) and *PD-L2* genes, which are suppressors of immune response. This group made up about 10% of the cancers, with nearly 80% harboring a protein-changing alteration in *PIK3CA*.

- Tumors showing microsatellite instability, in which malfunctioning DNA repair mechanisms cause a high rate of mutations, including mutations of genes encoding targetable oncogenic signaling proteins. About 20% of tumors fell into this subtype.
- The largest category of tumors, making up about half of the cancer specimens, was termed *chromosomally unstable*. These contained a jumble of extra or missing pieces of genes and chromosomes (aneuploidy) and have a striking number of genomic amplifications of key receptor tyrosine kinases. This subtype of tumor is frequently found in the junction between the stomach and the esophagus, a type of gastric cancer that has been dramatically increasing in the United States.
- The fourth group was termed *genomically stable* because they lacked the molecular features of the other three types. These tumors, making up 20% of the specimens, were largely those of a specific class of gastric cancer enriched for the diffuse-type histologic variant, with approximately 30% of these tumors having genomic alterations in the Ras homolog gene family, member A (*RHOA*) signaling pathway. These tumors were characterized by the lack of high levels of aneuploidy and high metastatic potential.

This classification may serve as a valuable adjunct to histopathology and provides patient stratification as a guide to targeted agents.

Staging and Prognosis

Upper GI series with barium swallow and upper esophagogastroduodenoscopy (EGD) are mainstays for diagnosing gastric cancer and provide complementary diagnostic information. Esophagogastroduodenoscopy is more sensitive and specific to obtain tissue diagnosis. A single biopsy has 70% sensitivity for diagnosing gastric cancer; performing seven biopsies from the ulcer margin and base increases the sensitivity to >98% (²⁴). In contrast, barium swallow with upper GI series can identify both malignant gastric ulcers and infiltrating lesions, including some early gastric cancers. However, the false-negative rate with barium swallow can be as high as 50% (²⁵) and may be even higher for early gastric cancer, and sensitivity can be as low as 14% (²⁵).

Cancer staging is important because treatment is based on the pathology and the stage of disease at diagnosis, according to the TNM (tumor, node, metastasis) system of the American Joint Committee on Cancer (AJCC). Version 7 is the most current (²⁶) (Table 20-2). In this newest version, GEJ and proximal gastric cancers <5 cm from the GEJ are now included in the esophageal cancer staging system. The T classification has been modified to harmonize with the new esophageal T classification. T1 and T4 have been further subdivided. Positive peritoneal cytologic results are classified as M1. Because of its noninvasive nature, computed tomography (CT) has become the cornerstone of gastric cancer staging, although it is not sensitive at detecting the tumor invasion depth and local and regional lymph node involvement. Currently, CT is used in conjunction with endoscopic ultrasonography (EUS) of the primary site, which provides the most accurate data for depth of tumor invasion and locoregional lymph node involvement. Endoscopic ultrasonography has an accuracy of 77% (vs 40%-50% with CT) for staging depth and 69% for staging nodes (²⁷). Limitations of EUS include understaging nodal disease and its short field of vision (5-7 cm). The availability of EUS-guided biopsy of suspicious local and regional lymph nodes has circumvented its former limitation (Figs. 20-1 and 20-2). Laparoscopy is more invasive than CT or EUS, but it has the advantage of directly visualizing the liver surface, peritoneum, and local lymph nodes. It is sensitive at diagnosing liver metastases and peritoneal metastases in up to 23% of patients in whom no such involvement was seen on CT (²⁸). Diagnostic laparoscopy is usually performed when all noninvasive studies (CT and EUS) demonstrate localized or potentially resectable disease in patients with >T1b disease on EUS.

The effectiveness of fluorodeoxyglucose (FDG) positron emission tomography (PET) at diagnosing gastric cancer is uncertain because as many as 50% of primary tumors are FDG negative, particularly early gastric cancers (²⁹). Insufficient FDG uptake is mostly associated with diffuse-type gastric cancer with signet ring cells and mucinous content (³⁰). Currently, FDG-PET has no role in the primary detection of gastric cancer because of its low sensitivity. On the other hand, FDG-PET shows better results in the evaluation of lymph node metastases in gastric cancer compared with CT and could thus have a role in preoperative staging. For patients with FDG-positive disease, FDG-PET can be used to predict histologic response and survival outcomes (³¹), similar to results seen among patients with distal esophageal and GEJ adenocarcinoma (³²⁻³⁴). The addition of FDG-PET to CT increases diagnostic accuracy for recurrent gastric

Table 20-2 American Joint Cancer Committee TNM Staging System for Gastric Cancer

Primary Tumor (T)				
Tx	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
Tis	Carcinoma in situ: intraepithelial tumor with invasion of the lamina propria			
T1	Tumor invades muscularis propria or submucosa			
T1a	Tumor invades lamina propria, muscularis mucosae, or submucosa			
T1b	Tumor invades submucosa			
T2	Tumor invades muscularis propria			
T3	Tumor penetrates the subserosal connective tissue without invasion of visceral peritoneum or adjacent structures			
T4	Tumor invades serosa (visceral peritoneum) or adjacent structures			
T4a	Tumor invades serosa (visceral peritoneum)			
T4b	Tumor invades adjacent structures			
Regional Lymph Nodes (N)				
Nx	Regional lymph node(s) cannot be assessed

cancer because PET/CT is as sensitive and specific as contrast CT at detecting recurrent disease, except peritoneal seeding⁽³⁵⁾.

Among gastric cancer patients who had surgery, status of nodal involvement is perhaps the most powerful prognostic factor for them. Additionally, after curative resection, other factors affecting gastric cancer prognosis include tumor location, histologic grade, and lymphovascular invasion⁽²⁶⁾. Patients with proximal gastric cancer have poorer prognosis than those with distal gastric cancer,

at 28.5 versus 58.6 months ($P < .02$)⁽³⁶⁾. Although associations have been found between molecular genetic changes and pathologic features and biologic behavior and prognosis, the clinical significance of these genetic changes has not yet been established. In other words, these genetic parameters have been unable to translate into meaningful clinical diagnostic, predictive, or prognostic biomarkers. Therefore, the putative biomarker screening method for gastric cancer also remains elusive. However, with better appreciation of the complex interplay between

FIGURE 20-2 Gastric cancer: T2N1 lesion. **A.** Endoscopic view. **B.** Endoscopic ultrasound view. (Reproduced, with permission, from http://www.massgeneral.org/gastro/endo_homepage.htm.)

environment and host factors leading to gastric tumorigenesis, researchers hope to produce more effective screening methods for high-risk patients, better prognostic and predictive biomarkers, and superior therapeutic indices of cancer drugs. The recent comprehensive molecular characterization of gastric adenocarcinoma by the TCGA project is an approach toward this goal.

Treatment

Gastric cancer is treated according to the cancer stage at presentation. Reflecting the newest changes in the AJCC staging system, treatment for GEJ and proximal gastric adenocarcinoma <5 cm from the GEJ is discussed in the esophageal cancer section. Treatment for patients with locally advanced gastric cancer is dichotomized into resectable and unresectable disease. Surgery remains the best chance for long-term survival, but 5-year survival rates after surgery alone are 20% to 50%, and adjunctive therapy, such as chemotherapy or chemoradiotherapy, must be offered. Localized gastric cancer can be classified as clinical T1 disease or higher with or without involved regional lymph nodes. A minimum of 15 examined lymph nodes is recommended for adequate surgical staging⁽³⁷⁾. The adjunctive therapy used for the treatment of localized gastric cancer in addition to surgery depends on geographic location in the world. In North America and Europe, results from the Intergroup INT-0116⁽³⁸⁾ (the adjuvant chemoradiotherapy approach) and Medical

Research Council Adjuvant Infusional Chemotherapy (MAGIC)⁽³⁹⁾ (the perioperative chemotherapy approach) trials have established the standard of care in the early 2000s. In Asia, however, adjuvant chemotherapy following a D2 nodal dissection is considered the gold standard^(40, 41).

Unfortunately, the main therapeutic goal in patients with unresectable locally advanced disease remains symptom palliation. The treatment of unresectable locally advanced and metastatic gastric cancers is discussed in two separate subsections: Unresectable Locally Advanced Gastric, Gastroesophageal Junction, and Esophageal Cancers; and Advanced and Metastatic Gastric, Gastroesophageal Junction, and Esophageal Cancers.

Resectable Disease

Surgery

Surgical resection offers the best chance for long-term survival in patients with localized disease, particularly in combination with postoperative (adjuvant) chemoradiotherapy⁽³⁸⁾ or perioperative chemotherapy⁽³⁹⁾. Even with newer staging modalities, the major barrier to accurately identify patients with potentially resectable disease is the ability to accurately stage disease. In the United States, 67% of patients present with stage III or IV disease, and only 10% present with stage I disease⁽⁴²⁾.

By definition, curative resection (also referred to as R0 resection) involves removal of the primary cancer and regional lymph nodes with free margins. The goals of surgery are twofold: (1) local control and hopefully

eradication of gastric cancer and (2) attainment of accurate pathologic staging. Considerations for surgical management of gastric cancer are the (1) extent of luminal resection (total vs partial gastrectomy) and (2) extent of lymph node dissection. Total gastrectomy is mainly reserved for proximal gastric cancer and large midgastric tumors or linitis plastica (wherein a large region of the stomach is extensively infiltrated by cancer, resulting in a rigid, thickened fold), whereas partial gastrectomy may be used in distal gastric tumors. Two randomized control trials have demonstrated similar survival outcomes for total and partial gastrectomy for distal gastric cancer^(43, 44). Overall survival rates improved from 5% for R2 (surgical resection with gross residual disease) to 50% for R0⁽⁴⁵⁾.

Japanese surgeons routinely perform extended lymphadenectomy, whereas in the United States, 54% of primary gastrectomy patients undergo less than a D1 lymphadenectomy⁽³⁸⁾. A D1 lymphadenectomy refers to a limited dissection of the perigastric lymph nodes, whereas D2 refers to the removal of nodes along the hepatic, left gastric, celiac, and splenic arteries, as well as those in the splenic hilum. A D3 lymph node dissection includes lymph nodes located within the porta hepatis and periaortic regions.

Proponents of extended lymphadenectomy argue that only with extended dissection can accurate staging be guaranteed, which also implies accurate prediction of stage-specific survival. Furthermore, with extensive nodal dissection, locoregional relapse rates are lower. Using SEER Project data from 1973 to 2000, Schwarz and Smith⁴⁶ evaluated 1,377 patients with locally advanced gastric cancer (stages IIIA, IIIB, and IV, M0). The total lymph node (LN) count (or number of negative LNs examined; $P < .0001$) and number of positive LNs ($P < .0001$) were independent prognostic survival predictors. Furthermore, the stage-based survival prediction depended on the total LN number and number of negative LNs. In their earlier analysis of SEER data from 1973 to 1999, these same investigators demonstrated that for every 10 extra LNs dissected, survival improved by 7.6% (T1/2N0), 5.7% (T1/2N1), 11% (T3N0), or 7% (T3N1)⁽⁴⁷⁾. The results of this analysis demonstrated that for all T stages, extensive nodal dissection affects survival outcomes. Similarly, a 5-year survival benefit was reported for patients with D2 and D3 dissections compared with D1 lymphadenectomy (60% vs 54%, $P = .041$) in a Taiwanese study involving 221 patients with resectable gastric cancer⁽⁴⁸⁾.

Despite this evidence, prospective studies performed in non-Asian countries were unable to confirm these findings^(37, 49-51). The Medical Research Council (MRC) randomly assigned 400 patients with resectable gastric cancer to D1 or D2 nodal dissection. Postoperative morbidity and mortality rates were higher for D2 (46% and 13%) than for D1 (28% and 6%) dissection⁽⁵¹⁾.

Both the initial and long-term follow-up results in the Dutch Gastric Cancer Group (DGGC) study demonstrated a significant increase in morbidity and mortality, with no survival difference between D1 and D2 dissections^(37, 50). Although these large prospective studies performed in non-Asian countries could not confirm the initial findings, they went on to suggest that extended lymphadenectomy carries increased rates of morbidity and mortality, with a negligible change in survival.

Despite some disagreement about the benefits of D2 dissection, most experts agree that localized gastric cancer with clinical stage >T1b is best treated with multidisciplinary approaches and at high-volume centers, particularly by high-volume surgeons^(52, 53). There is great value of thorough LN dissection along with gastrectomy⁽⁵⁴⁾. We acknowledge that the literature lacks convincing results in favor of D2 dissection in randomized studies to date that have compared D1 versus D2 dissections; however, the pendulum is swinging in favor of a more thorough nodal dissection by experienced surgeons. A nodal dissection approaching D2 can have the following advantages: accurate nodal staging and removal of more uninvolved nodes that is associated with prolonged survival^(50, 51, 55). A 15-year update of the Dutch trial showed benefit in the D2 group in terms of the hazard ratio (HR) for gastric cancer-related death (0.74; 95% confidence interval [CI], 0.59-0.93; $P = .01$); however, only a few patients were at risk⁽⁵⁶⁾.

Perioperative Chemotherapy

This approach is based on the assumption that neoadjuvant systemic therapy can lead to tumor downstaging, leading to an improved R0 resection rate. This is particularly significant in Western patients in whom the tumors are usually bulky at diagnosis⁽⁵⁷⁾. The MAGIC trial has established level 1 evidence for this approach⁽³⁹⁾. It enrolled 503 patients with gastric, GEJ, and esophageal adenocarcinoma⁽³⁹⁾. These patients were randomized to receive three cycles of perioperative chemotherapy consisting of epirubicin, cisplatin, and infusional 5-fluorouracil (5-FU) (ECF) followed by surgery, followed by three more cycles of ECF, or undergo surgery followed by observation. In this trial, postoperative chemotherapy proved hard to deliver, with only 34% of patients receiving this treatment, and only 68% of patients underwent a curative resection. Despite this, both progression-free survival (PFS) and OS were improved in the group receiving ECF (HR for progression, 0.66; 95% CI, 0.53-0.81; $P < .001$; HR for death, 0.75; 95% CI, 0.60-0.93; $P = .009$). Five-year survival rates were 36.3% (95% CI, 29.5%-43.0%) among patients in the perioperative chemotherapy group and 23.0% (95% CI, 16.6%-29.4%) among those in the surgery group⁽³⁹⁾. Taken together, this suggests that

the majority of the benefit may in fact come from the preoperative portion of the chemotherapy.

A second, French study supports the findings of the MAGIC trial. The Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) and the Fédération Francophone de Cancérologie Digestive (FFCD) multicenter phase III trial was terminated prematurely for poor accrual and is therefore not adequately powered⁽⁵⁸⁾. Overall, 224 patients with resectable adenocarcinoma of the lower esophagus, GEJ, or stomach (only 25%) were randomly assigned to either perioperative chemotherapy (with cisplatin and 5-FU) and surgery followed by three to four cycles of cisplatin and 5-FU or surgery alone. Only approximately 50% of patients received any postoperative chemotherapy. Despite these issues, the chemotherapy and surgery group had a significantly higher OS (HR for death, 0.69; 95% CI, 0.50-0.95; $P = .02$) and disease-free survival (DFS; HR for recurrence or death, 0.65; 95% CI, 0.48-0.89; $P = .003$). Five-year survival rates were 38% (95% CI, 29%-47%) in the chemotherapy and surgery group compared to 24% (95% CI, 17%-33%) in the surgery group. These results are quite similar to those of the MAGIC trial and bring into question the usefulness of the addition of epirubicin to cisplatin and 5-FU.

In contrast, a study by the European Organization for Research and Treatment of Cancer (EORTC 40954) did not demonstrate a benefit from the addition of perioperative chemotherapy⁽⁵⁹⁾. This trial showed a significantly increased R0 resection rate but failed to demonstrate a survival benefit for the addition of chemotherapy; however, it was not sufficiently powered to demonstrate a difference, given its premature termination due to poor accrual. An ongoing Japanese Clinical Oncology Group (JCOG 0501) trial is attempting to answer the question of whether perioperative chemotherapy with cisplatin and S-1 (an oral fluoropyrimidine) adds anything to their standard of care, which is surgery followed by adjuvant S-1 chemotherapy. The results of this trial are awaited; however, they are unlikely to be generalizable to the North American population because of different tumor biology. Meanwhile, other researchers in the United Kingdom are evaluating the addition of targeted therapy to perioperative chemotherapy in the localized gastric cancer setting. The MAGIC B/ST03 trial will determine whether the addition of bevacizumab to perioperative epirubicin plus cisplatin and capecitabine improves survival⁽⁶⁰⁾. This trial is expected to enroll 1,100 patients.

Postoperative Chemoradiotherapy

The indication of adjuvant chemoradiotherapy comes from level 1 evidence of its benefit from the Intergroup INT-0116 trial that showed a significant improvement in OS in the group of patients treated with adjuvant chemoradiotherapy^(38, 61). In this trial, 559 patients with stage IB to IV disease were randomized

to chemoradiotherapy following surgery or surgery alone. The chemoradiotherapy group received chemotherapy consisting of one 5-day cycle of 5-FU and leucovorin (LV) starting on day 1, followed by chemoradiotherapy beginning 28 days after the start of the initial cycle of chemotherapy. Chemoradiotherapy consisted of 45 Gy of radiation at 1.8 Gy/d 5 days per week for 5 weeks, with 5-FU (400 mg/m²/d) and LV (20 mg/m²/d) on the first 4 and the last 3 days of radiotherapy. One month after the completion of radiotherapy, two 5-day cycles of 5-FU (425 mg/m²/d) plus LV (20 mg/m²/d) were given 1 month apart. The 3-year survival rates were 50% in the chemoradiotherapy group and 41% in the surgery-only group. The HR for death in the surgery-only group, as compared with the chemoradiotherapy group, was 1.35 (95% CI, 1.09-1.66; $P = .005$). The HR for relapse in the surgery-only group, as compared with the chemoradiotherapy group, was 1.52 (95% CI, 1.23-1.86; $P < .001$)⁽³⁸⁾. Recently updated results of this study continue to demonstrate a benefit in terms of both OS and recurrence-free survival (RFS)⁽⁶¹⁾. The major issue of this study was that the majority of patients did not receive an adequate LN dissection. Although a D1 resection was mandated per protocol, more than 50% of patients underwent a D0 resection, and only 10% of patients underwent a D2 nodal dissection. Therefore, it is questioned whether the survival difference occurred because of inadequate surgery rather than a true benefit of chemoradiotherapy.

Cancer and Leukemia Group B (CALGB) 80101, a US intergroup study, was designed to evaluate postoperative bolus 5-FU and LV with 5-FU plus concurrent radiation (an INT0116 trial treatment regimen) versus postoperative ECF (the MAGIC trial regimen) before and after 5-FU plus concurrent radiation in 546 patients with gastric or GEJ tumors after curative resection⁽⁶²⁾. In a preliminary report presented at the 2011 American Society of Clinical Oncology annual meeting, patients receiving ECF had lower rates of diarrhea, mucositis, and grade 4 or worse neutropenia. Overall survival, the primary end point, was not significantly better with ECF (3-year OS, 52% vs 50% for ECF and 5-FU/LV, respectively), regardless of the location of the primary tumor.

The Adjuvant Chemoradiation Therapy in Stomach Cancer (ARTIST) trial compared adjuvant chemoradiotherapy with adjuvant chemotherapy after an R0 resection with D2 dissection in 458 patients⁽⁶³⁾. The ARTIST trial was a negative study because its primary end point, 3-year DFS rate, was not statistically different between the two groups. In subgroup analyses, patients with node-positive disease in the adjuvant chemoradiotherapy group had a significantly improved 3-year DFS rate than those in the adjuvant chemotherapy group. Patients on the adjuvant chemoradiotherapy group were treated with two courses of

postoperative capecitabine plus cisplatin (XP) followed by concurrent chemoradiotherapy with capecitabine and two additional courses of XP, whereas those on the adjuvant chemotherapy group were treated with six courses of postoperative XP without radiotherapy. The improved DFS among patients with node-positive disease was later confirmed in the recently published update; however, there was no improved OS despite the prolonged follow-up interval⁽⁶⁴⁾. This improved DFS finding may suggest that compared to adjuvant chemotherapy, adjuvant chemoradiotherapy may be beneficial among node-positive resectable gastric cancer patients, a theory currently being tested in the ARTIST-2 trial. Different from INT0116, all patients in ARTIST-2 trial are required to have a D2 nodal dissection, and the chemotherapy administered to all patients consists of S-1 versus S-1 and oxaliplatin with or without radiotherapy. Hence, ARTIST-2 was designed to evaluate the benefit of chemoradiotherapy after a D2 nodal dissection.

The results of two trials, Chemoradiotherapy After Induction Chemotherapy in Cancer of the Stomach (CRITICS) and Trial of Preoperative Therapy for Gastric and Esophagogastric Junction Adenocarcinoma (TOPGEAR), are expected to determine the benefit and indication of chemoradiotherapy^(65, 66). In the Dutch CRITICS trial, all patients receive induction chemotherapy followed by surgery and are randomized to postoperative chemotherapy versus chemoradiotherapy. The TOPGEAR trial, which is under way in Australia, Europe, and Canada, directly compares preoperative chemotherapy alone (ECF) versus chemoradiotherapy (two cycles of ECF followed by concurrent fluoropyrimidine-based chemoradiotherapy) in patients with resectable adenocarcinoma of the stomach and GEJ; both groups will receive three further cycles of ECF postoperatively.

Postoperative Chemotherapy

The benefits of adjuvant chemotherapy after a D2 nodal dissection were initially demonstrated in Japan, and the chemotherapy used was S-1⁽⁴⁰⁾. The Adjuvant Chemotherapy Trial of S-1 for Gastric Cancer (ACTSGC) trial randomized 1,059 patients to 1 year of S-1 or observation. The updated analysis after 5 years of follow-up has demonstrated consistent results⁽⁶⁷⁾. The OS rate at 5 years was 71.7% in the S-1 group and 61.1% in the surgery-only group (HR, 0.669; 95% CI, 0.540-0.828). The RFS rate at 5 years was 65.4% in the S-1 group and 53.1% in the surgery-alone group (HR, 0.653; 95% CI, 0.537-0.793).

A second Asian study, the Capecitabine and Oxaliplatin Adjuvant Study in Stomach Cancer (CLASSIC) trial, randomized 1,035 patients who had undergone D2 gastrectomy to capecitabine plus oxaliplatin for 6 months or observation⁽⁴¹⁾. The study demonstrated a

benefit in patients treated with capecitabine and oxaliplatin for the primary end point of DFS (at 3 years; HR, 0.56; 95% CI, 0.44-0.72; $P < .0001$) at the prespecified interim analysis. After this analysis, the trial was stopped after a recommendation by the data monitoring committee. The mature OS data were recently published in *The Lancet Oncology*⁽⁶⁴⁾. By the clinical cutoff date, 103 patients (20%) had died in the adjuvant capecitabine and oxaliplatin group versus 141 patients (27%) in the observation group (stratified HR, 0.66; 95% CI, 0.51-0.85, $P = .0015$). Estimated 5-year OS was 78% (95% CI, 74%-82%) in the adjuvant capecitabine and oxaliplatin group versus 69% (95% CI, 64%-73%) in the observation group.

A phase III randomized clinical trial, the Stomach Cancer Adjuvant Multi-institutional Group Trial (SAMIT), of adjuvant paclitaxel followed by oral fluoropyrimidines for locally advanced gastric cancer brought into question the sequential administration of chemotherapy compared to 5-FU/LV⁽⁶⁸⁾. Although the 2×2 factorial design was not optimal to compare sequences, the study did not achieve its primary end point (3-year DFS: 57.2% vs 54%), showing no benefit with a sequential regimen compared to 5-FU/LV, which was consistent with previous studies (HR, 0.92; 95% CI, 0.80-1.07; $P = .273$).

All major phase III trials in localized gastric cancer and the most important ongoing studies in this setting are summarized in **Tables 20-3** and **20-4**. Given the variability in outcomes in many phase III trials, several meta-analyses have been undertaken (**Table 20-5**), all of which support a significant survival benefit for perioperative or adjuvant chemotherapy with somewhat better prognosis shown in Asian compared to Western populations⁽⁶⁹⁻⁷¹⁾, including one that was limited to trials from Western (non-Asian) countries⁽⁷²⁾. One of the most recent of these analyses evaluated data from 34 randomized trials comparing adjuvant systemic chemotherapy versus surgery alone, conducted in both Asian and Western populations⁽⁶⁹⁾. The risk of death in patients receiving adjuvant chemotherapy was reduced by 15% (HR for death, 0.85; 95% CI, 0.80-0.90).

Based on the previously mentioned trials and meta-analyses, postoperative chemoradiotherapy (United States), perioperative chemotherapy (Europe), and adjuvant chemotherapy after a D2 nodal dissection (Asia) can all be regarded as standards of care in the management of localized gastric cancer.

The University of Texas MD Anderson Cancer Center Approach to Resectable Gastric Cancer

All patients with newly diagnosed gastric cancer undergo a complete staging workup. Patients with resectable gastric cancer are evaluated by a multidisciplinary team that consists of surgeons, radiation oncologists, and medical

Table 20-3 Major Phase III Trials for Gastric Cancer in the Localized Setting

Trial	No. of Patients	Treatment Arms	HR for OS (P value)	Primary End Point Comparison in Months (survival rates in %)
Perioperative chemotherapy				
Cunningham et al (MAGIC) ⁽³⁹⁾	503	ECF → surgery → ECF vs surgery	0.75 (.009)	5-year OS: 36.3% vs 23%
Ychou et al (FNLCC/FFCP) ⁽⁵⁸⁾	224	CF → surgery → CF vs surgery	0.69 (.02)	5-year OS: 38% vs 24%
Schuhmacher et al (EORTC 40954) ⁽⁵⁹⁾	144	CFL → surgery vs surgery (only preoperative CT)	0.16	Underpowered to demonstrate a survival end point due to limited accrual (144/360 patients)
Postoperative chemoradiotherapy				
Macdonald et al ⁽³⁸⁾ (INT-0116)	556	Surgery → FL/CTRT (45 Gy + FL)/FL vs surgery	1.32 (.004)	OS: 36 vs 27
Fuchs et al ⁽⁶²⁾ (CALGB 80101)	546	Surgery → ECF/CTRT+FL/ECF vs surgery → FL/CTRT+FL/FL	1.03 (.80)	OS: 38 vs 37
Park et al ⁽⁶⁴⁾ (ARTIST)	458	Surgery → XP/XRT/XP vs surgery → XP	1.130 (.5272); N+ patients: HR for DFS, 0.70 (.04)	5-year OS: 75% vs 73%; N+ patients: 3-year DFS: 76% vs 72%
Postoperative chemotherapy				
Sakuramoto et al ⁽⁴⁰⁾ (ACTS- GC)	1,059	Surgery → S-1 vs surgery	0.68 (.003); HR at 5 years: 0.669	3-year OS: 80.1% vs 70.1%; 3-year RFS: 72.2% vs 59.6%
Bang et al ⁽⁴¹⁾ (CLASSIC)	1,035	Surgery → CapeOx vs surgery	0.56 (< .0001)	3-year DFS: 74% vs 59%
Tsuburaya et al ⁽⁶⁸⁾ (SAMIT), 2 × 2 factorial design	1,495	Surgery → UFT vs surgery → S-1 vs surgery → paclitaxel + UFT vs surgery → paclitaxel + S-1	HR for DFS 0.81 (.0048) for monotherapy (0.151 for noninferiority of UFT), 0.92 (.273) for monotherapy vs sequential	3-year DFS: 53% vs 58.2% (UFT vs S-1), 54% vs 57.2% (monotherapy vs sequential)

CapeOx, capecitabine and oxaliplatin; CF, cisplatin and 5-fluorouracil; CFL, cisplatin, 5-fluorouracil, and leucovorin; CT, chemotherapy; CTRT, chemoradiotherapy; DFS, disease-free survival; ECF, epirubicin, cisplatin, and 5-fluorouracil; FL, 5-fluorouracil and leucovorin; HR, hazard ratio; OS, overall survival; RFS, recurrence-free survival; UFT, tegafur and uracil; XP, capecitabine and cisplatin; XRT, capecitabine and radiotherapy.

oncologists. Treatment recommendations are made in multidisciplinary conferences. Both standard-of-care treatment options and clinical trials are discussed with our patients. Patients' treatment plans are individualized to optimize outcomes for each patient. For decades, the University of Texas MD Anderson Cancer Center (MDACC) has been developing the practice of multimodality management in a multidisciplinary setting for all patients, but it is especially useful for those with resectable disease. Arguments for front-loading therapy before surgery include poor tolerance and compliance to postoperative therapy, early initiation of therapy, early palliation of symptoms, and opportunity for cancer downstaging, enhanced surgical resectability, and higher rates of pathologic complete remission (pathCR).

Preoperative trimodality therapy consisting of induction chemotherapy followed by chemoradiotherapy and then surgical resection has been tested and evolved at MDACC over many years. Since the mid-1990s, it has been clinically recognized that preoperative trimodality therapy does not increase morbidity or mortality rates of subsequent surgery and can improve pathologic response. Ajani et al (⁷³) reported the results of several phase II studies that demonstrated the feasibility and effectiveness of a three-step strategy. Thirty-seven patients with locally advanced resectable gastric cancer were treated with trimodality therapy on a phase II clinical trial. Chemotherapy consisted of infusional 5-FU, cisplatin, and paclitaxel (FPT); 45 Gy of radiotherapy was administered concurrently with FPT. R0 and pathCR rates were 95% and 30%, respectively. Fourteen percent of patients had only microscopic residual disease. Patients who achieved pathCR or pathologic partial response after preoperative chemoradiotherapy had significantly longer median survival durations than those who did not (63.9 vs 12.6 months; $P = .03$).

As a result of the MDACC's single-institution success with preoperative trimodality therapy, the Radiation Therapy Oncology Group (RTOG) sponsored a multi-institution cooperative study, RTOG 9904. The primary end point was pathCR rate. Forty-nine patients with localized resectable gastric cancer from 20 institutions received 5-FU, LV, and cisplatin (FLP) as induction chemotherapy,

followed by concurrent chemoradiotherapy with 5-FU and weekly paclitaxel. The pathCR and R0 resection rates were 26% and 77%, respectively. At 1 year, more patients who had achieved pathCR (82%) were alive than those who did not (69%) (⁷⁴). A D2 dissection was performed in 50% of patients. The heterogeneity of different treating institutions minimized the selection bias typical of single-institution results. Outcomes in RTOG 9904 were no better or worse than those of more recent studies, particularly the pathCR and D2 lymphadenectomy rates. **Figure 20-3A** summarizes the MDACC's approach to localized gastroesophageal cancer.

ESOPHAGEAL AND GASTROESOPHAGEAL JUNCTION CANCERS

Esophageal cancer is estimated to be the eighth most common cause of cancer death among men in the United States and the fifth most common cause of cancer death worldwide (⁷⁵). In 2015, the estimated numbers of new cases and deaths from esophageal cancer in the United States are 16,980 and 15,590, respectively (²). Esophageal cancer is three to four times more common in men than in women (⁷⁶), with a mean age of 67 years (⁷⁷). Lifetime risk of developing esophageal cancer is 1 in 125 for men and 1 in 435 for women (⁷⁶). For classification purposes (AJCC staging version 7), primary tumors of the GEJ and proximal gastric cancer extending 5 cm into the stomach are included with esophageal cancers. The incidence of GEJ cancer has continued to increase over the last several decades. In recent years, this trend reached a new plateau, coinciding with the increased incidence of distal esophageal adenocarcinoma since the mid-1990s, a phenomenon confined to North America and other non-Asian countries. Overall, the prognosis of patients with esophageal/GEJ cancer remains poor. Histologic type makes a difference, because squamous cell cancer has a poorer prognosis than adenocarcinoma. Surgery is still the only chance for cure, and survival can be improved with multimodality therapy.

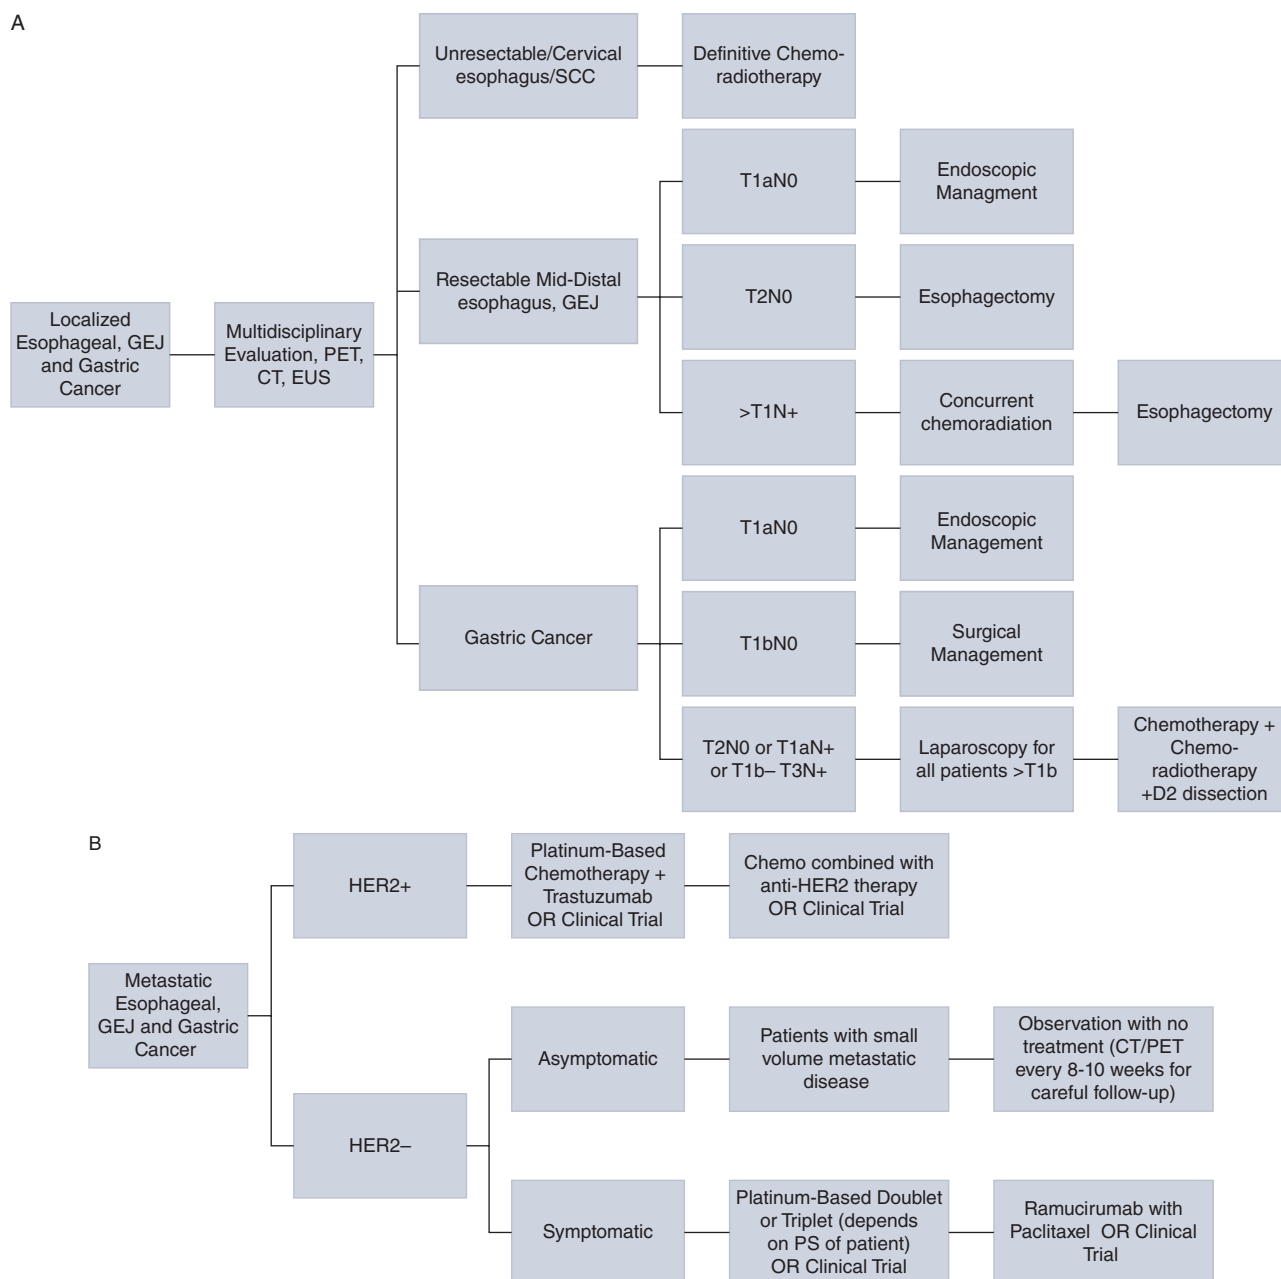

FIGURE 20-3 The University of Texas MD Anderson Cancer Center Treatment algorithms for (A) localized gastroesophageal cancer and (B) metastatic gastroesophageal cancer. CT, computed tomography; EUS, endoscopic ultrasound; GEJ, gastroesophageal junction; HER2, human epidermal growth factor receptor 2; PET, positron emission tomography; PS, performance status; SCC, squamous cell carcinoma.

Epidemiologic Characteristics

Although squamous cell cancer is the most common histologic type in many parts of the world, it is relatively uncommon outside of Asian and middle-Eastern countries. Squamous cell cancer is 20 times more common in China than in the United States ⁽⁷⁸⁾. Esophageal cancer has a poor survival rate; only 17.5% of patients in the United States ⁽³⁾ and 10% of patients in Europe ⁽⁷⁹⁾ survive at 5 years.

Etiologic Characteristics and Risk Factors

The most significant risk factors associated with almost 90% of esophageal squamous cell cancers are tobacco use, alcohol use, and a diet low in fruits and vegetables ^(9, 80). Smoking and alcohol can synergistically increase the risk of esophageal squamous cell cancer. Dietary associations with esophageal squamous cell cancer, such as foods containing N-nitroso compounds, have long been implicated ⁽⁸¹⁾. Betel nut chewing,

widespread in certain regions of Asia ⁽⁸²⁾, and the ingestion of hot foods and beverages (such as tea) ⁽⁸³⁾ in other endemic regions, such as Iran, Russia, and South Africa, have been associated with esophageal squamous cell cancer. Long-standing achalasia increases the risk of squamous cell cancer by 16 times ⁽⁸⁴⁾. On average, squamous cell cancer develops 41 years after ingestion of lye. Tylosis, a rare disease associated with hyperkeratosis of the palms of the hands and soles of the feet, is associated with a high rate of esophageal squamous cell cancer ⁽⁸⁵⁾.

Unlike squamous cell cancer, the risk factors for esophageal adenocarcinoma remain elusive. The strongest and most consistent risk factors include gastroesophageal reflux disease (GERD), smoking, obesity ⁽⁸⁶⁾, and dietary exposure to nitrosamines; these are found in almost 80% of cases in the United States ⁽⁸⁷⁾. According to a Denmark study, more than 50% of esophageal adenocarcinoma cases were found to have no history of symptomatic reflux disease ⁽⁸⁸⁾. However, a large study conducted in Sweden demonstrated an association between reflux symptoms and esophageal adenocarcinoma (odds ratio, 7.7) and adenocarcinoma of gastric cardia (odds ratio, 2.0) ⁽⁸⁹⁾. A high-fat, low-protein, high-calorie diet can also increase the risk. Some data have suggested that interactions between risk factors may be more important than individual risk factors. A study was performed on 305 esophageal adenocarcinoma patients and 339 age- and sex-matched controls; the strongest individual risk factor identified was reflux ⁽⁹⁰⁾.

Barrett esophagus (BE) is generally believed to be a consequence of severe and chronic GERD. The presence of BE is associated with an increased risk of esophageal adenocarcinoma. The median age of BE diagnosis is 40 to 55 years, and it is most common in men ⁽⁹¹⁾.

Clinical Presentation

The presenting symptoms of esophageal cancer usually include dysphagia, weight loss, bleeding, throat pain, and hoarseness. Early symptoms are usually nonspecific, and the patient may present with subtle symptoms, for example, food “sticking” transiently and reflux/regurgitation of food or saliva. This may precede frank dysphagia, which by all accounts is the most common complaint and becomes apparent when the esophageal lumen is narrowed to one-third of its normal diameter. For proximal esophageal tumors, increasing cough may be a sign of tracheoesophageal fistula. Chronic GI blood loss resulting from esophageal cancer may result in iron deficiency anemia.

Pathologic Characteristics

Esophageal cancer includes adenocarcinoma, squamous cell cancer, mucoepidermoid carcinoma, small cell cancer, sarcoma, adenoid cystic carcinoma, and primary lymphoma. Adenocarcinoma is now more

prevalent than squamous cell cancer in non-Asian countries and mostly develops in the distal esophagus ⁽⁹²⁾. In general, squamous cell cancer is found in the upper half of the esophagus, whereas adenocarcinoma predominates closer to the GEJ. This chapter will focus on carcinomas of the esophagus/GEJ, whereas other chapters in this book will be dedicated to other types of malignancy of the esophagus/GEJ.

Staging and Prognosis

Esophageal cancer is a treatable disease but is rarely curable. Since the mid-1990s, the histologic type and location of cancer of the upper GI tract have changed. The incidences of proximal gastric, GEJ, and distal esophageal adenocarcinomas have steadily increased up until the last several years, where it now appears to have reached a steady state. The most current version of the AJCC TNM staging (version 7, [Table 20-6](#)) now includes primary tumors of the GEJ or proximal gastric cancer extending 5 cm into the stomach as part of esophageal cancer staging ⁽²⁶⁾.

Clinical staging uses EGD with EUS, CT, and FDG-PET. In patients with proximal esophageal cancer, additional bronchoscopy is recommended to evaluate potential tracheal invasion or document and palliate tracheoesophageal fistula. Among patients with disease extending into the gastric cardia, most experts agree that laparoscopic peritoneal staging is also necessary to evaluate occult peritoneal seeding that is not well visualized with noninvasive modalities ([Figs. 20-4 to 20-9](#)).

In various studies, FDG-PET has been consistently shown to have better specificity than CT at diagnosing metastatic disease and LN status. Positron emission tomography serves the primary purpose of detecting occult metastases that are present in 15% to 20% of newly diagnosed esophageal cancer patients ^(93, 94). Multiple studies have been performed in esophageal cancer patients after preoperative treatment, with PET being examined for predicting prognosis ^(93, 95) and treatment response ⁽⁹⁶⁾. Other studies have shown conflicting results. For example, one study showed that complete response by PET was prognostic of the outcomes of patients receiving definitive chemoradiotherapy ⁽⁹⁷⁾; however, another study found no correlation of posttreatment PET with survival or pathologic response ⁽⁹⁸⁾. Fluorodeoxyglucose PET can better reveal bone metastasis than bone scans ⁽⁹⁹⁾ and commonly reflects images of multiple foci of intense uptake. Studies have shown significant correlations between FDG uptake and tumor invasion depth and LN metastasis and survival rates, with a high degree of accuracy in the neck and upper thoracic and abdominal regions ⁽¹⁰⁰⁾. Unlike with gastric cancer, FDG-PET results have been found to be important predictors of response and prognosis. In a retrospective analysis,

Table 20-6 American Joint Cancer Committee TNM Staging System for Gastroesophageal Junction and Esophageal Cancers

Primary Tumor (T)						
TX	Primary tumor cannot be assessed					
T0	No evidence of primary tumor					
Tis	High-grade dysplasia					
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa

Swisher et al reported the results of FDG-PET use in 103 consecutive patients with locally advanced esophageal cancer who underwent preoperative chemoradiotherapy (¹⁰¹). At surgery, 58 patients (56%) had experienced a pathologic response to chemoradiotherapy (surgical pathologic results $\leq 10\%$ viable residual cancer cells). Pathologic response was associated with FDG-PET standardized uptake value (SUV) (3.1 vs 5.8, $P = .01$). A postchemoradiotherapy FDG-PET SUV ≥ 4 had the highest accuracy and was an independent predictor of survival (HR, 3.5; $P = .04$) on multivariate analysis (¹⁰¹).

Perhaps the strongest endorsement for using FDG-PET as predictor of response came from the Metabolic Response Evaluation for Individualization of Neoadjuvant Chemotherapy in Esophageal and Esophagogastric Adenocarcinoma (MUNICON-1) trial. Lordick et al (³⁴) evaluated the feasibility and applicability of FDG-PET in clinical practice in 110 evaluable patients with locally advanced esophageal adenocarcinoma. Patients with adenocarcinoma of the esophagogastric junction types I and II (tumors extending to the esophagus 5 cm above and 2 cm below the GEJ) underwent 2 weeks of induction chemotherapy with FLP. Fluorodeoxyglucose PET scans were obtained for all patients at baseline and after induction chemotherapy. Metabolic response was defined as an SUV decrease by $\geq 35\%$. Responders underwent more chemotherapy with FLP or folinic acid, 5-FU, and oxaliplatin (FOLFOX) for 12 weeks followed by surgery. Nonresponders discontinued further chemotherapy after the 2 weeks of initial induction

chemotherapy and underwent surgery. In this study, there were 54 responders (metabolic response rate, 49%). One hundred four patients (54 responders and 50 nonresponders) underwent surgery. At 2.3 years of follow-up, the median OS was not reached for responders and was 25.8 months (HR, 2.13; $P = .015$) for nonresponders. The median event-free survival durations for responders and nonresponders were 29.7 months and 14.1 months, respectively (HR, 2.18; $P = .002$). Major pathologic remissions ($<10\%$ residual tumor) were noted in 58% of responders and 0% of nonresponders (³⁴). In the MUNICON-1 study, the response to induction therapy was valuable for stratifying patients to appropriate therapy, further establishing the clinical utility of FDG-PET in limiting exposure to unnecessary toxicity and maximizing therapeutic benefits. The MUNICON-2 and -3 trial results might be useful in establishing the role of PET in restaging esophageal cancer patients undergoing induction therapy (¹⁰²).

The role of tumor markers (N-cadherin [¹⁰³], activin A, nuclear factor- κ B [¹⁰⁴]) and cytogenetics in esophageal cancer staging and prognosis is another subject of active investigation. Esophageal cancer has certain molecular markers that may be predictive. Large population-based studies to validate these preliminary results remain incomplete. Until then, the clinical interpretation of currently available data should be done with caution.

Treatment

The gold standard for treating high-grade dysplasia (HGD) and early or superficial esophageal cancer is esophagectomy. However, endoscopic mucosal resection (EMR)/endoscopic submucosal dissection (ESMD), with or without photodynamic therapy (PDT), has become a popular alternative to surgery for early esophageal disease. Despite the recognized epidemiologic and clinical differences between esophageal squamous cell cancer and adenocarcinomas, there is still inadequate evidence that treatment for esophageal cancer should be based on histologic type. Locally advanced cervical esophageal cancer is preferably managed with definitive chemoradiotherapy. For all other esophageal cancers, current evidence supports the use of preoperative chemoradiotherapy to enhance surgical survival outcome in patients with locally advanced resectable disease. Surgery remains the best chance for long-term survival. Ongoing international clinical research with novel cytotoxic and targeted agents will continue to further define and improve survival outcomes of patients with locally advanced curable esophageal and GEJ cancers. Unfortunately, the main therapeutic goal is symptom palliation in patients with locally advanced, unresectable disease.

Endoscopic mucosal resection has gained popularity in Asia for the treatment of superficial or early

esophageal cancer as well as BE with HGD. By providing large tissue specimens that can be examined to determine the characteristics and extent of the lesion and the adequacy of resection, EMR is both therapeutic and diagnostic. Endoscopic mucosal resection has been reported in several small prospective case series to be effective, with an initial complete remission (CR) rate of 59% to 99% (^{105, 106}). The ideal clinical characteristics for EMR are small (<2 cm diameter), solitary, flat lesions that are confined to the mucosa (T1a). Because EMR has a relatively high recurrence rate, it is recommended that BE and HGD or early esophageal cancer patients be followed up endoscopically every 3 months during the first year and annually thereafter. Complications associated with EMR are bleeding (4%-46%), perforation (1%), and stricture (20%) (¹⁰⁷).

Resectable Disease

Surgery

Only 23% of patients with esophageal cancer present with clinically resectable localized disease (¹⁰⁸). Surgical resection is the mainstay of treatment for these patients (¹⁰⁹) and should only be recommended as upfront treatment in T1b/T2 tumors without nodal involvement by EUS. Recent data indicate that the overall 5-year survival rate of esophageal cancer patients after curative surgery is about 25% (^{38, 39, 110}). Therefore, preoperative chemotherapy or preoperative chemoradiotherapy have become the mainstay strategies for treatment to improve surgical outcome, whereas definitive chemoradiotherapy has been recommended for patients with cervical tumors or unresectable disease.

Cancers of middle or lower third of the esophagus (squamous cell carcinoma or esophageal adenocarcinoma, except GEJ cancers) generally require total esophagectomy, which is a challenging procedure with a high complication rate. No uniform surgical approaches to curative resection exist, but the most common procedures in North America include transhiatal, transthoracic (Ivor-Lewis), and tri-incisional esophagectomy. Transhiatal esophagectomy involves anastomosis of the stomach to the cervical esophagus (¹¹¹). Ivor-Lewis transthoracic esophagectomy involves abdominal mobilization of the stomach and transthoracic excision of the esophagus, with anastomosis of the stomach to the upper thoracic or cervical esophagus. Limitations of the Ivor-Lewis procedure include a limited proximal resection margin and a higher risk of bile reflux because of the intrathoracic location of the anastomosis (¹¹²). The modified Ivor-Lewis procedure involves a left thoracoabdominal incision with a gastric pull-up into the left chest (¹¹³). Another surgical approach is tri-incisional esophagectomy in which transhiatal and transthoracic approaches are combined, allowing for transthoracic esophagectomy with node dissection and cervical esophagogastric anastomosis (¹¹⁴). For patients

with potentially resectable disease, R0 resection is generally believed to be necessary to achieve durable survival (¹¹⁵). R0 resection is defined as resection of the primary tumor with negative proximal, distal, and circumferential margins. In one retrospective case-control analysis, 220 patients underwent limited transhiatal or extensive mediastinal lymphadenectomy with transthoracic esophagectomy. At a median of 4.7 years of follow-up, there was a trend toward higher DFS (39% vs 27%) and OS (39% vs 29%) rates in patients with more extensive nodal dissection (^{39, 116}). Despite a lack of prospective randomized studies, there is a growing consensus that more extensive nodal dissection is needed; including the removal of all cancerous tissue from the mediastinum improves DFS and OS durations through better control of locoregional recurrence. Also, aggressive lymphadenectomy is generally recommended to increase the accuracy of pathologic staging. In the latest version of the AJCC staging manual, an adequate number of LNs is required for defining stage of disease. In the United States, en bloc resection of the mediastinal and upper abdominal LNs is considered standard for transthoracic esophagectomy, and three-field lymphadenectomy is not considered a standard treatment for patients with esophageal cancer.

Preoperative Chemotherapy

Preoperative chemotherapy theoretically increases the curative resection rates by downsizing and downstaging the primary tumor and LN metastases, reducing the local and distant relapse rates through suppression and elimination of micrometastases, improving tumor-related symptoms with early initiation of antineoplastic therapy, and appraising *in vivo* the chemosensitivity of the primary tumor that will influence the choice of chemotherapy in the adjuvant setting. Preoperative therapy is hypothesized to result in tumor downstaging, which allows for higher R0 resection and pathCR rates (¹¹⁷).

The two largest studies evaluating the role of preoperative chemotherapy were the US Intergroup trial (INT0113) (^{118, 119}) and UK Marsden Royal College (MRC)-OEO-2 randomized controlled trials (¹²⁰). Both studies determined the survival benefit of preoperative chemotherapy compared with surgery alone in patients with resectable esophageal squamous cell cancer and adenocarcinoma. Cisplatin plus 5-FU (CF) was administered in both studies. The two studies had completely divergent findings. INT0113 found no clinical/pathologic benefit or survival improvement with preoperative chemotherapy followed by surgery compared with surgery alone (¹¹⁸). The median survival was 14.9 months for patients who received preoperative chemotherapy and 16.1 months for those who underwent immediate surgery ($P = .53$). The recent updated analysis of INT0113 confirmed the lack of benefit of preoperative chemotherapy (¹¹⁹). The MRC-OEO-2 trial,

however, reported a statistically significant improved R0 resection rate (78% vs 70%) and median OS time (17.2 vs 13.3 months) in patients who underwent preoperative chemotherapy (¹²⁰). Results of both INT0113 and OEO-2 studies did not help determine the role of preoperative chemotherapy in patients with resectable esophageal cancer. In the United Kingdom and other countries in Europe, preoperative chemotherapy has become the acceptable standard of care.

The two most recent randomized studies of preoperative and perioperative chemotherapy, the French Actions Concertées dans les Cancer Colorectaux et Digestifs (ACCORD) 7 (⁵⁸) and UK MAGIC trials (³⁹), are the strongest validations of the benefits of preoperative and perioperative chemotherapy. These two studies are described in detail in the “Gastric Cancer” section of this chapter. In addition to the MAGIC and FRENCH trials, a third Japanese trial on squamous cell carcinoma patients (JCOG 9907) deserves mention because it was positive. Patients were given two cycles of CF preoperatively. Postoperatively, CF was

administered to node-positive patients only. Of the above mentioned three trials, this one showed the highest 5-year survival rate in both arms (¹²¹).

Investigators at MRC are currently conducting two large phase III randomized controlled studies. MRC-OEO-5 is evaluating the use of preoperative chemotherapy, comparing two preoperative chemotherapy regimens, CF versus ECX (epirubicin, cisplatin, and capecitabine) (¹²²). Meanwhile, other researchers in the United Kingdom are evaluating the addition of targeted therapy to perioperative chemotherapy. The MRC ST03 trial will determine whether the addition of bevacizumab to perioperative ECX improves survival. Table 20-7 lists the ongoing studies of locally advanced resectable gastric, GEJ, and distal esophageal adenocarcinomas.

Preoperative Radiation

Preoperative radiotherapy was studied in the early 1980s. However, in several phase III studies, a benefit similar to that of surgery alone was not shown. In a

Table 20-7 Key Esophageal Cancer Trials

Study	No. of Patients	Treatment Arm Control Arm	HR for OS (P value)	OS (%)
Pre- and perioperative chemotherapy				
Kelsen et al (¹¹⁹) (INT-113)	467	3 × CF → S S	0.75 (NR)	5-year OS: 36% vs 23%

recent quantitative meta-analysis comprising five randomized trials and 1,147 patients, it was again demonstrated that there is no improvement in survival with preoperative radiotherapy alone in potentially resectable esophageal cancer (^{123, 124}).

Preoperative Chemoradiotherapy

In the United States, pre- or perioperative chemotherapy is not as common as preoperative chemoradiotherapy for locally advanced esophageal and GEJ cancer. Preoperative chemoradiotherapy has the goal to improve pathCR rate, locoregional control, and survival.

The CALGB 9781 trial provided additional support for preoperative chemoradiotherapy, although it was stopped early because of a slow accrual rate. Fifty-six patients were randomly assigned to surgery alone ($n = 26$) or CF chemotherapy and concurrent radiotherapy ($n = 30$). At a median follow-up of 6 years, an intent-to-treat analysis showed a median OS duration of 4.5 versus 1.8 years ($P = .002$) in favor of trimodality therapy. The 5-year OS rates were 39% (95% CI, 21%-57%) versus 16% (95% CI, 5%-33%) in favor of trimodality therapy (¹²⁵). GebSKI et al (¹²⁶) reported improved survival with preoperative chemotherapy and chemoradiotherapy. The HR for all-cause mortality with preoperative chemoradiotherapy versus surgery alone was 0.81 (95% CI, 0.70-0.93; $P = .002$), corresponding to a 13% absolute difference in survival at 2 years, with similar results for different histologic tumor types (squamous cell cancer: HR, 0.84, $P = .04$; adenocarcinomas: HR, 0.75, $P = .02$). The HR for preoperative chemotherapy was 0.90 (95% CI, 0.81-1.00; $P = .05$), which indicates a 2-year absolute survival benefit of 7%. There was no significant effect on all-cause mortality for preoperative chemotherapy in squamous cell cancer (HR, 0.88; $P = .12$), but there was a benefit in adenocarcinoma (HR, 0.78; $P = .014$) (¹²⁶). With chemoradiotherapy, evidence seems to suggest that treating physicians can expect a pathCR rate of 20% to 30%, a median OS duration of 16 to 24 months, and a therapy-related mortality rate of 5% to 10%.

The Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS) trial was a well-executed study that established level 1 evidence for preoperative chemoradiotherapy. Three hundred sixty-eight localized esophageal cancer (adenocarcinoma or squamous) patients were randomly assigned to receive either preoperative paclitaxel and carboplatin with concurrent radiation 41.4 Gy ($n = 178$) or surgery alone ($n = 188$). With a median follow-up time of 45.4 months, the median OS for preoperative chemoradiotherapy group was 49.4 months versus 24.0 months for the surgery-alone group (HR, 0.657; 95% CI, 0.495-0.871; $P = .003$). Five-year OS was again in favor of the chemoradiotherapy group (47%) versus the surgery-alone group (34%) (¹²⁷). The complete

resection rate was higher in the chemoradiotherapy group (92%) versus the surgery-alone group (69%), and 29% of patients in the chemoradiotherapy group had pathCR. In a subgroup analysis, the patients with squamous cancer demonstrated the best outcomes (HR was 0.453 for squamous cancer vs 0.732 for adenocarcinoma) (^{127, 128}).

Preoperative Chemotherapy Versus Preoperative Chemoradiotherapy

Meta-analyses have been performed to further support the available evidence for preoperative therapy (^{126, 129, 130}). Cumulatively, these three meta-analyses determined that the most consistent significant survival benefit resulted from the combination of surgery and preoperative chemoradiotherapy and, to a lesser extent, preoperative chemotherapy.

Since these studies, results from the Preoperative Chemotherapy or Radiochemotherapy in Esophagogastric Adenocarcinoma (POET) trial, presented by Stahl et al (¹³¹), have provided further support for three-step preoperative therapy, although the study was closed prematurely because of slow accrual. The POET trial was designed to evaluate the survival outcomes of patients treated with preoperative chemotherapy compared with preoperative chemoradiotherapy. One hundred nineteen patients were randomly assigned to chemotherapy followed by chemoradiotherapy and surgery ($n = 59$) or chemotherapy followed by surgery ($n = 60$); the R0 resection rates were 72% and 70% ($P =$ not significant), the pathCR rates were 16% and 2% ($P < .001$), and the N0 rates were 64% and 38% ($P < .001$), respectively. The 3-year OS rate trended toward improvement with induction chemotherapy, chemoradiotherapy, and surgery (47% vs 28% with chemotherapy and surgery; $P = .07$) (¹³¹). Patients in the chemoradiotherapy arm had a significantly higher probability of a pathCR (15.6% vs 2.0%). Postoperative mortality rates did not differ between the chemoradiotherapy and chemotherapy arms (10% vs 4%; $P = .26$). These results suggest that preoperative chemoradiotherapy confers a survival advantage over preoperative chemotherapy in distal esophageal and GEJ adenocarcinoma. Maximizing duration and amount of therapy before surgery theoretically could improve the ability to deliver all planned effective therapies and initiate palliative therapy early and improve pathCR, local control, cure, and survival rates.

The use of induction chemotherapy before chemoradiotherapy and surgery has been evaluated in several phase II studies. Ajani et al (⁷³) performed a feasibility study of preoperative induction combination chemotherapy with chemoradiotherapy to improve curative resection, local control, and survival in 2001. Thirty-seven potentially resectable cancers of the esophagus and GEJ were treated with induction chemotherapy

followed by chemoradiotherapy and curative surgery. Induction chemotherapy consisted of two cycles of CF plus paclitaxel (CFP). After chemoradiotherapy, consisting of 45 Gy of radiation and concurrent CF, patients underwent surgery. Thirty-five (95%) of the 37 patients underwent surgery (R0 resection). The pathCR rate was 30% (11 of 37 patients); an additional five patients (14%) had only microscopic cancer. Downstaging was significant; the rates of T3 before surgery and at surgery were 89% and 9%, respectively ($P = .01$), and the rates of N1 were 66% and 20%, respectively ($P = .01$)⁽⁷³⁾. Patient selection is important because the current three-step strategy exchanges moderate toxicity for modest survival improvement.

In Europe and the United Kingdom, the treatment approach varies accordingly to tumor histology. For resectable squamous cell carcinoma, patients are commonly treated with preoperative chemoradiotherapy⁽¹³²⁾, whereas for resectable adenocarcinomas, either preoperative CRT or perioperative chemotherapy is administered. In the United States, preoperative chemoradiotherapy is the standard of care irrespective of histology.

Postoperative Therapy

Few studies have been performed to evaluate postoperative chemotherapy versus surgery alone. Reflecting the incidence of esophageal cancer during the 1980s and 1990s, these studies included more patients with squamous cell cancer than with adenocarcinoma; this is a shortcoming of these early studies. In a study by Poulliquen et al, no survival improvement was found in the patients who were administered postoperative chemotherapy (CF)⁽¹³³⁾.

The second study, a randomized trial, JCOG 9204, compared the outcomes of patients who underwent surgery alone versus patients who underwent surgery followed by adjuvant CF. The 5-year DFS rates favored the postoperative chemotherapy group (55% vs 45%; $P = .037$). However, the difference in the 5-year OS rate was not statistically significant (61% vs 52%; $P = .13$). The duration of adjuvant therapy was suboptimal, and approximately 25% of patients assigned to the postoperative chemotherapy group failed to receive the full course of therapy⁽¹³⁴⁾.

Another retrospective case-control study was designed to evaluate the effect of postoperative chemotherapy in 211 patients who underwent R0 esophagectomy with radical lymphadenectomy. Of 211 patients, 94 received postoperative chemotherapy, whereas the other 117 patients received surgery alone. The OS was compared between the two groups after they were stratified by the numbers of metastasis-positive LNs. In the subgroup of patients with more than eight positive LNs, postoperative chemotherapy significantly improved the OS compared with surgery

alone. Therefore, the authors suggested that postoperative chemotherapy was beneficial only in patients with more than eight metastatic LNs⁽¹³⁵⁾, reducing the risk of relapse. However, postoperative chemotherapy did not improve the OS compared with surgery alone.

Many studies have been performed to evaluate the role of postoperative radiotherapy versus surgery alone. In two studies, conducted by Teniere et al⁽¹³⁶⁾ and postoperative radiotherapy did not improve survival. Results from two other randomized studies revealed conflicting findings. Xiao et al⁽¹³⁷⁾ demonstrated that postoperative radiotherapy improved the 5-year OS in esophageal cancer patients with stage III disease. In contrast, Fok et al found shorter survival durations in patients who underwent postoperative radiotherapy as a direct result of irradiation-related death and the early appearance of metastatic disease⁽¹³⁸⁾. Thus, the utility of postoperative radiotherapy may be limited. Of these studies, only the one by Zieren et al evaluated quality of life, which was found to be better in the surgery-alone group.

Malthaner et al⁽¹³⁹⁾ performed a meta-analysis of 34 randomized controlled trials and six meta-analyses in which patients with locally advanced esophageal cancer underwent pre- or postoperative chemotherapy, radiotherapy, or chemoradiotherapy. No significant difference in survival was observed in the postoperative radiotherapy group.

The available evidence suggests that postoperative chemotherapy or radiotherapy does not result in a benefit. However, few randomized comparisons have been performed with surgery alone versus surgery and postoperative treatment. In the INT-0116 study⁽³⁸⁾, 556 patients with resected GEJ and gastric adenocarcinoma were randomly assigned to surgery plus postoperative chemoradiotherapy or surgery alone. Adjuvant treatment consisted of 5-FU plus LV for 5 days, followed by 45 Gy of radiation with modified doses of 5-FU/LV on the first 4 and the last 3 days of radiotherapy. One month after radiotherapy, two 5-day cycles of 5-FU/LV were given 1 month apart. The median OS improved with postoperative chemoradiotherapy from 27 to 36 months (HR, 1.35; 95% CI, 1.09-1.66; $P = .005$), and the HR for relapse was 1.52 (95% CI, 1.23-1.86; $P < .001$). INT-0116 included 111 patients (20%) with GEJ or lower esophageal adenocarcinoma⁽³⁸⁾. Extrapolation of these results as supporting evidence for postoperative chemoradiotherapy in esophageal cancer should be performed with caution.

On the basis of the available evidence, patients with esophageal cancer gain limited survival benefit with postoperative chemotherapy and chemoradiotherapy after R0 resection. The limited contribution of postoperative therapy is probably due to the moderate toxicity, which leads to treatment-related complications or an inability to complete therapy.

The limited ability to deliver therapy after surgery, as demonstrated by results from both the INT-0116 and MAGIC studies^(38, 39), suggests that all effective therapy should be administered before surgery.

Definitive Chemoradiotherapy

The potential activity of chemotherapy against micrometastases and its ability to act as a radiotherapy-sensitizing agent formed the basis for combining chemotherapy and radiotherapy to treat locally advanced cancer. In the RTOG 85-01 study, patients with locally advanced esophageal adenocarcinoma or squamous cell cancer were randomly assigned to chemoradiotherapy with CF or radiotherapy alone. The 5-year OS rates were 0% and 26% for radiotherapy and chemoradiotherapy, respectively⁽¹⁴⁰⁾.

A comprehensive review of the pattern of care for esophageal cancer in the United States from 1992 to 1994 surveyed 400 patients with locally advanced esophageal cancer treated at 63 institutions⁽¹⁴¹⁾. The study confirmed that using combined concurrent chemoradiotherapy as a nonoperative strategy to achieve superior survival and local tumor control was better than radiotherapy alone⁽¹⁴¹⁾. The report also suggested a trend toward survival improvement with chemoradiotherapy before surgery compared with chemoradiotherapy or surgery alone.

In the INT-0123 (RTOG 94-05) study, patients ($n = 236$) were administered concurrent CF (similar to RTOG 85-01) but were assigned randomly to different radiation doses, either 50.4 or 64.8 Gy. No association was found between higher radiation doses and higher median survival (13 vs 18 months for 50.4 vs 64.8 Gy, respectively) or 2-year survival (31% vs 40%, respectively). Higher radiation dose was also more toxic⁽¹⁴²⁾. The reason for the failure of the higher radiation dose to improve survival is unclear.

The multi-institutional RTOG 0113 trial evaluated induction chemotherapy followed by definitive chemoradiotherapy in patients with localized unresectable esophageal cancer. The primary goal was to determine whether any approach would result in a >78% 1-year OS, surpassing the historical 66% rate from RTOG 94-05. Seventy-two evaluable patients were randomly assigned to induction with CFP followed by CFP and 50.4 Gy of radiation (CFP arm, $n = 37$) or induction with paclitaxel plus cisplatin (PP) followed by PP and 50.4 Gy of radiation (PP arm, $n = 35$). The median OS durations for the CFP and PP arms were 28.7 and 14.9 months, respectively (18.8 months in RTOG 9405). The study did not reach its preset objective because the 1-year OS rates of the CFP and PP arms did not meet or surpass 78% (CFP 1-year OS, 76%). The 2-year OS rates for the CFP and PP arms were 56% and 37%, respectively. Toxicity was quite high in both arms (43% to 54% and 27% to

40% of patients experienced grade 3 and 4 toxicities, respectively). Therefore, neither combination (CFP or PP) was recommended for further evaluation⁽¹⁴³⁾.

Definitive Chemoradiotherapy Versus Chemoradiotherapy Plus Surgery

Stahl et al⁽¹³¹⁾ performed a randomized comparison of chemotherapy followed by chemoradiotherapy and then surgery (surgical arm, $n = 86$) and chemotherapy followed by chemoradiotherapy and no surgery (nonoperative arm, $n = 86$) in 172 patients with locally advanced esophageal squamous cell cancer. The median follow-up duration was 6 years. The OS rates were similar for the surgical and nonsurgical arms ($P < .05$). The 2-year local PFS rate was higher in the surgical arm than the nonsurgical arm (64% vs 41%; HR, 2.1; 95% CI, 1.3-3.5; $P = .003$). The treatment-related mortality rate was significantly higher in the surgical arm (12.8% vs 3.5%; $P = .03$). The clinical tumor response to induction chemotherapy was the only independent prognostic factor for OS (HR, 0.30; 95% CI, 0.19-0.47; $P < .0001$). The results of this study suggested that adding surgery to chemoradiotherapy improves local tumor control but not survival in patients with locally advanced esophageal squamous cell cancer. Tumor response to induction chemotherapy is associated with a favorable prognostic group in these high-risk patients, regardless of treatment. Of course, the difficulty of incorporating these results into clinical practice is detecting residual disease or response after preoperative therapy.

Another randomized comparison in only responders to chemoradiotherapy (45 Gy conventional or 60 Gy split-course radiation) was conducted by Bedenne et al⁽¹⁴⁴⁾. Patients with resectable esophageal squamous cell cancer were treated with two cycles of CF along with concurrent radiotherapy (conventional/split course). Patients who experienced a response ($n = 259$) were then randomly assigned to surgery or more chemoradiotherapy. The 2-year OS rates were 34% and 40% (HR, 0.90; $P = .44$), the median OS durations were 18 and 19 months ($P =$ not significant), the 2-year local control rates were 66% and 57% ($P < .01$), and the 3-month mortality rates were 9.3% and 0.8% ($P = .002$), respectively. The authors concluded that in patients who experience a response to chemoradiotherapy, surgery after chemoradiotherapy results in no added benefit over continued chemoradiotherapy⁽¹⁴⁴⁾.

Most data are not yet sufficiently mature to allow conclusions about optimal therapy for locally advanced squamous cell cancer of the noncervical esophagus. In a phase III study by the Chinese University Research Group for Esophageal Cancer (CURE), investigators from China are comparing the survival benefits of esophagectomy versus chemoradiotherapy. From 2000 to 2004, 80 patients were randomly assigned

to esophagectomy ($n = 44$) or chemoradiotherapy ($n = 36$). A two- or three-stage esophagectomy with two-field lymphadenectomy was performed. Chemoradiotherapy consisted of CF and concurrent 50 to 60 Gy of radiation. Tumor response was assessed by EGD, EUS, and CT. Salvage esophagectomies were performed for incomplete response or recurrence. The median follow-up time was 1.4 years. No difference in the early cumulative survival rate was found between the two groups (Relative risk, 0.89; 95% CI, 0.37-2.17; $P = .45$), nor was there a difference in DFS. Patients treated with surgery only had a slightly higher recurrence rate in the mediastinum, whereas those treated with chemoradiotherapy had a higher rate in the cervical or abdominal region⁽¹⁴⁵⁾.

Surgery is the foundation of treatment for locally advanced resectable esophageal cancer. Early results from European studies suggested that patients with esophageal squamous cell cancer will not benefit from surgery after chemoradiotherapy⁽¹⁴⁶⁾. The caveat of the nonsurgical approach to solid tumors is detecting minimal residual disease. Therefore, until more confirmatory evidence and clinical tools become available for detecting minimal residual disease or molecular or imaging predictive markers in patients who require surgery after preoperative therapy, the treatments for squamous cell cancer and adenocarcinoma will remain similar.

The University of Texas MD Anderson Cancer Center Approach to Resectable Esophageal and Gastroesophageal Junction Cancers

All patients with newly diagnosed invasive cancer undergo careful staging, which includes endoscopic assessment of the location and size of the primary tumor and EUS staging, CT, and PET/CT. Patients with cervical or proximal esophageal cancer also undergo bronchoscopy as part of a recommended staging workup. For distal esophageal disease or gastric cardia cancer, staging laparoscopy is performed in some patients, but the decision is made on a case-by-case basis. Again, as in locally advanced gastric cancer, all patients with only localized disease are further evaluated by a multidisciplinary team that includes thoracic surgeons and radiation oncologists. Furthermore, patients with localized disease are discussed at the weekly Esophageal Multidisciplinary Tumor Board.

Currently, at the MDACC, treatment modalities for locally advanced resectable esophageal cancer include chemoradiotherapy and then surgery. For GEJ adenocarcinoma, postoperative chemoradiotherapy and perioperative chemotherapy are additional options available to patients. Patients with locally advanced cervical esophageal cancer are treated with primary definitive chemoradiotherapy, even those with

resectable disease. Salvage surgery is considered only in patients with persistent or locally recurrent disease. Results from the RTOG 85-01 and 94-05 studies established that adding chemotherapy to radiotherapy improved survival and local relapse rates and that the optimal radiation dosage is 50.4 Gy in 28 fractions. With the results of the CROSS trial, we now recognize that a minimum dose of 41.4 Gy may be sufficient in the preoperative setting, although our preference is to use a higher dose. If at all possible, all locally advanced resectable esophageal cancers are treated on protocol at the MDACC or with preoperative chemoradiotherapy followed by surgical resection. Figure 20-3A summarizes the MDACC approach to resectable gastroesophageal cancer.

Advanced and Metastatic Gastric, Gastroesophageal Junction, and Esophageal Cancers

The prognosis of patients with advanced or metastatic gastric, GEJ, and esophageal cancers is poor; thus, clinicians should be cognizant of the patient's quality of life and weigh the risks and benefits of therapy. The overall 5-year survival rate of upper GI cancer patients is less than 5%. The standard of care for advanced disease is chemotherapy. Many frontline combination chemotherapy regimens are available, but no head-to-head comparison has been performed for most of these; thus, the optimal choice is not obvious, and treatment remains regionally variable. However, with the advent of molecular targeted therapy, it may be possible to select therapy based on the disease's molecular characteristics. The results of the Trastuzumab in Gastric Cancer (ToGA) study⁽¹⁴⁷⁾ raised the exciting possibility of personalized treatment for upper GI cancers; however, other results have since been disappointing. Until more specific and accurate molecular markers of response and prognosis become available, patient outcome with systemic therapy is best predicted by clinical characteristics, such as performance status.

The medical treatment of metastatic gastric cancer is primarily palliative and confers a modest effect on OS. Multiple agents are active in the treatment of gastric cancer, including fluoropyrimidines (5-FU, capecitabine, and S-1), anthracyclines, platinum agents, taxanes, irinotecan, and some targeted therapies such as trastuzumab for human epidermal growth factor receptor 2 (HER2)-overexpressing gastric cancers. Combination regimens are associated with higher response rates and, according to one meta-analysis, are also associated with increased survival when compared with single-agent chemotherapies⁽¹⁴⁸⁾. By and large, the trials addressing the value of targeted therapies, for example targeting epidermal growth factor receptor (*EGFR*) and vascular endothelial growth

factor (VEGF), were done in unselected (not biomarker enriched) populations and have, not surprisingly, yielded disappointing results.

First-Line Therapy

Only a minor amount of level 1 evidence exists for the treatment of gastric cancer in the first-line setting. In fact, only docetaxel (¹⁴⁹), cisplatin/oxaliplatin (¹⁵⁰), and trastuzumab (¹⁴⁷) are supported by high level evidence.

A phase III trial involving 445 patients with metastatic cancer randomized patients to receive CF or CF plus docetaxel. The investigators found that the addition of docetaxel was superior in terms of response rate (37% vs 25%; $P = .01$), time to tumor progression (5.6 vs 3.7 months; $P < .001$), and OS (9.2 vs 8.6 months; $P = .02$) (¹⁴⁹). One could question the clinical significance of a less than 1 month absolute improvement in OS, particularly in the context of significant toxicities, most notably a high rate of febrile neutropenia (30%). Importantly, this regimen should not be used in patients who have a reduced performance status.

Another randomized phase III trial including 1,002 patients tried to improve on the regimen of ECF by substituting oral capecitabine for infusional 5-FU and by using the nonnephrotoxic oxaliplatin rather than cisplatin. The combination of epirubicin/oxaliplatin/capecitabine (EOX) was found to be less toxic and at least as effective as ECF. The median survival times in the ECF (control), ECX, EOF (epirubicin/oxaliplatin/5-FU), and EOX arms were 9.9, 9.9, 9.3, and 11.2 months, respectively. The 1-year survival rates were 37.7%, 40.8%, 40.4%, and 46.8%, respectively. In the secondary analysis, OS was longer with EOX than with ECF, with an HR for death of 0.80 in the EOX group (95% CI, 0.66-0.97; $P = .02$). Progression-free survival and response rates did not differ significantly among the regimens (¹⁵⁰).

The third randomized phase III trial enrolled 305 patients in Japan to either S-1 alone or S-1 and cisplatin. Median OS was significantly longer in patients assigned to S-1 plus cisplatin (13.0 months) than in those assigned to S-1 alone (11.0 months; HR for death, 0.77; 95% CI, 0.61-0.98; $P = .04$). Progression-free survival was significantly longer in patients assigned to S-1 plus cisplatin than in those assigned to S-1 alone (median PFS, 6.0 vs 4.0 months; $P < .0001$) (¹⁵¹). This trial provided evidence for the superiority of the addition of cisplatin when compared to a fluoropyrimidine alone and established the use of a fluoropyrimidine in addition to a platinum as a reasonable treatment option.

Trastuzumab was the first targeted agent with documented clinical activity in the advanced gastric and gastroesophageal cancer setting. This treatment is useful in the HER2-enriched population; however, approximately 20% of gastric cancers and 30% of

gastroesophageal cancers overexpress HER2, so that a relatively small proportion of patients benefit from the treatment. The ToGA trial randomized 584 patients whose tumors overexpressed HER2 by immunohistochemistry (IHC) or fluorescence in situ hybridization (FISH) to receive a fluoropyrimidine (5-FU or capecitabine) plus cisplatin with or without trastuzumab. The chemotherapy was administered every 3 weeks for six cycles, and trastuzumab was administered every 3 weeks until disease progression (¹⁴⁷). The investigators found that the addition of trastuzumab to chemotherapy increased OS from 11.1 to 13.8 months (HR, 0.74; 95% CI, 0.60-0.91; $P = .0046$). The secondary end points of PFS (6.7 vs 5.5 months; $P = .0002$) and response rate (47.3% vs 34.5%; $P = .0017$) were also improved. On extended follow-up, the HR of OS for the addition of trastuzumab has decreased to 0.80 (¹⁵²), indicating that although real, the response to trastuzumab may be short lived. The difference in median OS was reduced from 2.7 months to merely 1.4 months, representing an approximate 50% decrease in the effect of trastuzumab, which suggests that only a few patients benefit. Based on this trial, the combination of trastuzumab and chemotherapy has become the standard of care in patients whose tumors overexpress HER2.

In contrast to the positive results with trastuzumab in HER2-overexpressing gastroesophageal cancers, bevacizumab failed to demonstrate an OS benefit when it was added to a combination of cisplatin and fluoropyrimidine in patients with advanced gastric and GEJ adenocarcinoma (¹⁵³). A total of 774 patients were randomized, and the median OS was 12.1 months with bevacizumab plus fluoropyrimidine-cisplatin and 10.1 months with placebo plus fluoropyrimidine-cisplatin (HR, 0.87; 95% CI, 0.73-1.03; $P = .1002$). Both median PFS (6.7 vs 5.3 months; HR, 0.80; 95% CI, 0.68-0.93; $P = .0037$) and overall response rate (46.0% vs 37.4%; $P = .0315$) were significantly improved with bevacizumab versus placebo (¹⁵³). In a preplanned subgroup analysis, the investigators were able to show that a benefit in terms of OS existed for “Pan-American” patients but not for European and Asian patients. This might point to differences in tumor biology, but is also dependent on other factors. A subsequent retrospective biomarker analysis of the AVAGAST trial showed that patients with high baseline plasma VEGF-A levels and low baseline expression of neuropilin-1 seemed to have an improved OS. For both biomarkers, subgroup analyses demonstrated significance only in patients from non-Asian regions (¹⁵⁴). It is important to note that neither of these biomarkers has been validated. Unlike the ToGA trial, the AVAGAST trial did not use a biomarker-enriched patient population, underscoring the importance of appropriate patient selection in randomized controlled trials and the use of predictive

biomarkers to direct care. Similarly, the AVATAR trial, which included an all Asian patient population, did not show any survival benefit of adding bevacizumab to the cisplatin-capecitabine combination⁽¹⁵⁵⁾.

Equally disappointing results were also reported from two *EGFR*-targeting trials: the Erbitux (cetuximab) in Combination with Xeloda (capecitabine) and Cisplatin in Advanced Esophagogastric Cancer (EXPAND) and Revised European American Lymphoma (REAL-3) trials^(156, 157). The EXPAND trial randomized 904 patients to receive capecitabine and cisplatin, with or without cetuximab. This study did not achieve its primary end point, with the median PFS for 455 patients allocated to capecitabine-cisplatin plus cetuximab being 4.4 months compared to 5.6 months for 449 patients who were allocated to receive capecitabine-cisplatin alone (HR, 1.09; 95% CI, 0.92-1.29; $P = .32$)⁽¹⁵⁶⁾. The REAL-3 study was terminated prematurely because a statistically significant lower OS was noted in patients treated with modified epirubicin/oxaliplatin/capecitabine (EOC) and panitumumab. The final analysis of this study, which randomized patients with advanced gastroesophageal adenocarcinoma, was published⁽¹⁵⁷⁾. Median OS of patients allocated to EOC was 11.3 months (95% CI, 9.6-13.0 months) compared with 8.8 months (95% CI, 7.7-9.8 months) in 278 patients allocated to modified EOC and panitumumab (HR, 1.37; 95% CI, 1.07-1.76; $P = .013$). There was a nonsignificant trend to worse outcomes in patients treated with panitumumab, again highlighting the importance of patient selection in randomized controlled trials. A biomarker analysis of the REAL-3 trial did not identify any biomarkers whose presence predicted resistance to modified EOC and panitumumab; however, only a few biomarkers were evaluated in this study⁽¹⁵⁸⁾.

The role of lapatinib, a dual *EGFR* and HER2 tyrosine kinase inhibitor (TKI), was investigated in combination with capecitabine plus oxaliplatin (CapeOx) in 545 patients with HER2-positive advanced/metastatic gastroesophageal adenocarcinomas in the TRIO-013/LOGiC trial. The addition of lapatinib to CapeOx did not improve efficacy (OS and PFS) among untreated HER2-positive metastatic gastric cancer patients⁽¹⁵⁹⁾.

In summary, the standard of care in the first-line setting remains a combination of fluoropyrimidine and platinum-containing chemotherapy, with the addition of trastuzumab in the HER2-enriched population. The results of targeted therapy trials have mostly been disappointing, but none of these trials looked at an appropriately biomarker-enriched population.

Second-Line Therapy

The validity of the use of second-line chemotherapy and its benefit in gastric cancer has long been questioned; however, all recently published trials

demonstrated an OS prolongation, albeit very modest, when chemotherapy was compared to best supportive care (BSC)⁽¹⁶⁰⁻¹⁶³⁾. Arbeitsgemeinschaft Internistische Onkologie (AIO), a small German phase III study, compared the efficacy of irinotecan plus BSC to BSC alone in patients with advanced gastric or GEJ adenocarcinoma⁽¹⁶¹⁾. Only 40 patients were randomized, and the study closed early due to poor accrual. The HR for death was 0.48, with a 95% CI of 0.25 to 0.92, favoring the active treatment with irinotecan ($P = .023$). The median survival time was 4.0 months (95% CI, 3.6-7.5 months) in the irinotecan arm and 2.4 months (95% CI, 1.7-4.9 months) in the BSC arm⁽¹⁶¹⁾. There were no documented responses to irinotecan in this trial.

The second trial, COUGAR-02, randomized 186 patients to docetaxel plus BSC versus BSC alone. Docetaxel significantly improved OS compared with BSC alone, with a median OS of 5.2 months (95% CI, 4.1-5.9 months) for docetaxel and 3.6 months (95% CI, 3.3-4.4 months) for BSC (HR, 0.67; 95% CI, 0.49-0.92; $P = .01$)⁽¹⁶²⁾.

The role of angiogenesis inhibition as a target in gastric cancer was investigated in the Ramucirumab Monotherapy for Previously Treated Advanced Gastric or Gastro-Oesophageal Junction Adenocarcinoma (REGARD) trial, which randomized 355 patients to receive ramucirumab or placebo⁽¹⁶⁰⁾. This study demonstrated a marginal improvement in median OS (5.2 months in patients in the ramucirumab group and 3.8 months in patients in the placebo group; HR, 0.776; 95% CI, 0.603-0.998; $P = .047$). Interestingly, the average patient on study treated with ramucirumab received treatments for 2 weeks longer than the average patient on placebo. In the recently published Ramucirumab in Metastatic Gastric Adenocarcinoma (RAINBOW) trial, ramucirumab was added to weekly paclitaxel as a second-line therapy in 665 patients with advanced or metastatic gastric cancer, demonstrating a significant improvement in both PFS and OS over paclitaxel alone⁽¹⁶³⁾. A statistically significant prolongation of OS was demonstrated (HR, 0.81; 95% CI, 0.68-0.96; $P = .017$). Median OS times were 9.6 and 7.4 months in the ramucirumab-plus-paclitaxel arm and placebo-plus-paclitaxel arm, respectively. The PFS was also significantly longer for patients receiving ramucirumab plus paclitaxel (HR, 0.64; 95% CI, 0.54-0.75; $P < .001$) with an overall good safety profile, further supporting its role in combination with chemotherapy.

Another study that demonstrated an OS benefit for patients treated with chemotherapy (either docetaxel or irinotecan) versus BSC was published by Kang et al⁽¹⁶⁴⁾. Median OS was 5.3 months among 133 patients in the chemotherapy arm and 3.8 months among 69 patients in the BSC arm (HR, 0.657; 95% CI, 0.485-0.891; one-sided $P = .007$). There was no median OS difference between docetaxel and irinotecan (5.2 vs 6.5 months; $P = .116$).

In the randomized phase III Taiwan Cooperative Oncology Group (TCOG) GI-0801/Biweekly Irinotecan Plus Cisplatin (BIRIP) trial, BIRIP was compared to irinotecan alone after S1-based chemotherapy failure in patients with advanced gastric cancer (¹⁶⁵). Significant PFS improvement was demonstrated (primary end point met) with cisplatin added to irinotecan as second-line treatment of advanced gastric cancer in 130 patients, providing the first evidence supporting combination chemotherapy in the second-line setting (median PFS, 3.8 vs 2.8 months, $P = .04$; disease control rate, 75.0% vs 54.0%; $P = .02$).

In the second-line setting, targeted HER2 therapy with TKIs has been a failure (^{166, 167}). Lapatinib has been investigated in a large 420-patient study (TyTAN trial), which randomized HER2-positive patients to lapatinib plus paclitaxel (L+P) versus paclitaxel alone. Median OS was 11.0 months for L+P and 8.9 months for paclitaxel alone in the intent-to-treat population (HR, 0.84; $P = .2088$). In a preplanned subgroup analysis, median OS in the HER2 IHC 3+ subgroup was 14.0 months for the combination therapy and 7.6 months for paclitaxel alone (HR, 0.59; $P = .0176$) (¹⁶⁷). Interestingly, it has recently been demonstrated that although the study mandated IHC HER2 positivity, 35% of patients in TyTAN had tumors classified as IHC 0/1 (¹⁶⁷).

Equally disappointing, the most recent UK Gefitinib for Oesophageal Cancer Progressing After Chemotherapy (COG) trial in patients with adenocarcinoma of the esophagogastric junction types I/II (tumors extending to the esophagus 5 cm above and 2 cm below the GEJ) in the second-line setting (¹⁶⁸) randomized 449 patients to receive gefitinib or placebo. The primary end point was OS. Secondary end points were PFS and quality-of-life outcomes. However, the median OS was 3.73 months for patients who received gefitinib and 3.63 months for those who received placebo (HR, 0.9; $P = .29$). There was a minor prolongation of PFS by 0.4 months for patients who received gefitinib compared to those who received placebo (HR, 0.80; $P = .02$).

Multiple studies highlight the importance of identification and targeting of driver mutations and their usefulness in the creation of appropriate biomarkers to direct care (^{169, 170}). *MET* amplification and/or overexpression of its protein product has long been implicated in the pathogenesis of gastric cancer, supporting its role as a poor prognostic factor (⁴¹). This has been studied in two phase II trials using the monoclonal antibodies rilotumumab and onartuzumab. Rilotumumab demonstrated prolonged PFS for patients whose tumors had high total c-MET expression (¹⁷¹), whereas onartuzumab failed to prolong PFS in patients with MET-positive tumors (¹⁷²). Recently, the investigational oral MET TKI AMG 337 trial is generating excitement based on early-phase results, where 8 of

13 patients who were found to have *MET*-amplified gastroesophageal adenocarcinomas showed partial to near-complete responses to the small-molecule inhibitor AMG-337 (¹⁷³).

The role of poly (ADP-ribose) polymerase (PARP) inhibitors in gastric cancer was investigated in a phase II study where 124 patients who progressed on fluoropyrimidines (second-line metastatic setting) were randomized to olaparib plus paclitaxel versus paclitaxel alone (¹⁷⁴). There was no improvement in PFS, but the addition of olaparib significantly improved OS (HR, 0.56; 95% CI, 0.35-0.87; $P = .010$). A phase III trial is ongoing.

Third-Line Therapy

Apatinib is a small-molecule multitargeted TKI with activity against VEGF receptor (VEGFR). After showing improved PFS and OS in heavily pretreated metastatic gastric cancer patients in a phase II trial (¹⁷⁵), apatinib was evaluated in a phase III trial in 271 patients with advanced gastric cancer (¹⁷⁶). Patients had prior failure to second-line chemotherapy and were stratified according to the number of metastatic sites (\leq or >2 sites). This trial met its primary end point, showing significant improvement in OS and PFS. The median OS time was 6.5 months for apatinib and 4.7 months for placebo (HR, 0.71; 95% CI, 0.54-0.94; $P = 0.015$), and the median PFS was 2.6 months for apatinib and 1.8 months for placebo (HR, 0.44; 95% CI, 0.33-0.61; $P < .0001$). This is the first phase III evidence for efficacy of a third-line therapy in advanced gastric cancer and further supports the angiogenesis inhibition as a target in this disease.

The role of mammalian target of rapamycin (mTOR) inhibitor everolimus was investigated in heavily pretreated metastatic gastric cancer patients with disappointing results. The RAD001 (Everolimus) Monotherapy Plus Best Supportive Care in Patients With Advanced Gastric Cancer (GRANITE-1) study randomized 656 patients to everolimus plus BSC versus placebo plus BSC. Unfortunately, this study did not achieve its primary OS end point (5.4 months with everolimus and 4.3 months with placebo; HR, 0.90; 95% CI, 0.75-1.08; $P = .124$) (¹⁶⁶). Notably, the estimated percentage of patients remaining progression free at 6 months was higher with everolimus (12.0% vs 4.3%), as were the disease control rate (43.3% vs 22.0%) and the tumor shrinkage rate (37.8% vs 12.3%). These results suggest everolimus has activity in this heavily pretreated population. Identification of specific biomarkers for various patient subpopulations with advanced gastric cancer may help define those patients who would receive the most benefit from everolimus treatment (¹⁶⁶).

Table 20-8 lists major phase III trials for advanced/metastatic esophageal, GEJ, and gastric cancer

Table 20-8 Major Phase III Gastric Cancer Trials Involving Chemotherapy Agents in the Advanced/Metastatic Setting

Trials	No. of Patients	Treatment Arms	HR for OS (P value)	Primary End Point Comparison in Months
Advanced gastric cancer: first line				
Van Cutsem et al (¹⁴⁹) (V325 study group)	445	DCF vs CF	TTP: 1.47 (< .001) OS: 1.29 (.02)	TTP: 5.6 vs 3.7 OS: 9.2 vs 8.6
Cunningham et al (¹⁵⁰)	1,002	ECF vs ECX vs EOF vs EOX	0.80 (.02)	OS: 9.9 vs 9.9 vs 9.3 vs 11.2
Koizumi et al (¹⁵¹) (SPIRITS)	305	S-1 + cisplatin vs S-1	0.77 (.04)	OS: 13.0 vs 11.0
Ajani et al (¹⁷⁸) (FLAGS)	1,053	Cisplatin + S-1 vs cisplatin + 5-FU	0.92 (.20)	OS: 8.6 vs 7.9
Advanced gastric cancer: second line				
Thuss-Patience et al (¹⁶¹) (AIO)	40	Irinotecan + BSC vs BSC	0.48 (.012)	OS: 4.0 vs 2.4
Cook et al (¹⁶²) (COUGAR-02)	168	Docetaxel + ASC vs ASC	0.67 (.01)	OS: 5.2 vs 3.6
Kang et al (¹⁶⁴)	202	Docetaxel or irinotecan vs BSC	0.657 (.007)	OS: 5.3 vs 3.8
Higuchi et al (¹⁶⁵) (TCOG GI-0801/BIRIP)	130	Biweekly irinotecan + cisplatin vs irinotecan	1.00 (.9823)	PFS: 3.8 vs 2.8 OS: 10.7 vs 10.1

ASC, active symptom control; BSC, best supportive care; CF, cisplatin and 5-fluorouracil; DCF, docetaxel, cisplatin, and 5-fluorouracil; ECF, epirubicin, cisplatin, and 5-fluorouracil; ECX, epirubicin, cisplatin, and capecitabine; EOF, epirubicin, oxaliplatin, and 5-fluorouracil; EOX, epirubicin, oxaliplatin, and capecitabine; 5-FU, 5-fluorouracil; HR, hazard ratio; OS, overall survival; PFS, progression-free survival; TTP, time to progression.

involving chemotherapy agents, and [Table 20-9](#) lists trials involving targeted agents in the first-, second-, and third-line settings.

The University of Texas MD Anderson Cancer Center Approach to Advanced Gastric, Gastroesophageal Junction and Esophageal Cancers

In terms of our approach to metastatic gastric, GEJ, or esophageal cancer, clearly in the context that this is no longer a curative situation, our approach is to provide palliation of symptoms and prolongation of life. In a select subgroup of patients who have small-volume disease and who are asymptomatic, it is reasonable to take a careful watch-and-wait strategy as long as the patient is comfortable with this approach. Otherwise, we would treat differently based on HER2 status. Clearly, in HER2-positive gastric cancer, there is an OS benefit with the addition of anti-HER2 therapy to first-line chemotherapy. It is our practice to typically use trastuzumab and not lapatinib because of the negative results of the lapatinib trial in combination with platinum-based doublet. Although no convincing

data exist as to the benefit of the addition of HER2 therapy in gastric cancer, we extrapolate from the breast cancer trials and continue anti-HER2 therapy beyond progression, typically switching to an alternative agent. In the context of HER2-negative metastatic disease, our options continue to be limited. A reasonable option in the first-line setting is a platinum-based doublet with the addition of docetaxel or epirubicin depending on the performance status of the patient. In the second line, we use ramucirumab combined with a second chemotherapy agent. [Figure 20-3B](#) summarizes the MDACC approach to advanced gastric, GEJ, and esophageal cancer.

Although genetic profiling of tumors is becoming a more widely used tool in the treatment of gastric, GEJ, and esophageal cancer, patients are often found to have multiple and nontargetable mutations. Even when a potentially targetable mutation is found and the patient is treated with a given drug, we have found that responses are rare, likely because of our poor knowledge of driver mutations. Therefore, we do not consider genetic evaluation as a critical part of treatment, but rather emphasize the enrollment of patients into available clinical trials.

Table 20-9 Major Phase III Gastric Cancer Trials Involving Targeted Agents in the Advanced/Metastatic Setting

Trials	No. of Patients	Treatment Arms	HR for OS (P value)	Primary End Point Comparison in Months
Advanced gastric cancer: first Line				
Bang et al (¹⁴⁷) (ToGA) ^a	584	CX/CF + trastuzumab vs CX/CF	0.74 (.0046)	OS: 13.8 vs 11.1
Ohtsu et al (¹⁵³) (AVAGAST)	774	CF + bevacizumab vs CF	0.87 (.1002)	OS: 12.1 vs 10.1 PFS: 6.7 vs 5.3
Lordick et al (¹⁵⁶) (EXPAND)	904	CX + cetuximab vs CX	1.004 (.9547)	OS: 9.4 vs 10.7
Waddell et al (¹⁵⁷) (REAL -3)	553	mEOC + panitumumab vs EOC	1.37 (.013)	OS: 8.8 vs 11.3
Hecht et al (¹⁵⁹) (TRIO - 013 / LOGiC)	545	CapeOx + lapatinib vs CapeOx + placebo	0.91 (.35)	OS: 12.2 vs 10.5
Advanced gastric cancer: second line				
Fuchs et al (¹⁶⁰) (REGARD)	355	Ramucirumab + BSC vs BSC	0.776 (.0473)	OS: 5.2 vs 3.8
Wilke et al (¹⁶³) (RAINBOW)	665	Paclitaxel + ramucirumab vs paclitaxel	0.81 (.017)	OS: 9.6 vs 7.4
Ohtsu et al (¹⁶⁶) (GRANITE-1)	656	Everolimus + BSC vs placebo + BSC	0.90 (.1244)	OS: 5.4 vs 4.3
Bang et al (¹⁶⁷) (TyTAN)	261	Lapatinib + paclitaxel vs paclitaxel	0.84 (.2088)	OS: 11.0 vs 8.9
Dutton et al (¹⁶⁸) (COG)	449	Gefitinib vs placebo	0.90 (.29)	OS: 3.73 vs 3.63
Advanced gastric cancer: third line				
Qin et al (¹⁷⁶) (apatinib)	271	Apatinib + BSC vs BSC	0.71 (.015)	OS: 6.5 vs 4.7 PFS: 2.6 vs 1.8
Ohtsu et al (¹⁶⁶) (GRANITE-1)	656	Everolimus + BSC vs placebo + BSC	0.90 (.1244)	OS: 5.4 vs 4.3

^a HR reduced to 0.8 on follow-up analysis.

BSC, best supportive care; CapeOx, capecitabine and oxaliplatin; CF, cisplatin and 5-fluorouracil; CX, cisplatin and capecitabine; EOC, epirubicin, oxaliplatin, and capecitabine; HR, hazard ratio; mEOC, modified epirubicin, oxaliplatin, and capecitabine; OS, overall survival; PFS, progression-free survival.

Supportive Measures for Advanced Gastric, Gastroesophageal Junction, and Esophageal Cancers

For patients with advanced gastric, GEJ, and esophageal cancers, the most important objective is symptom palliation rather than cure. The goal of symptom palliation is to optimize quality of life. Current or potential signs or symptoms that affect quality of life should be assessed during the initial evaluation of patients with unresectable disease. Available treatment options include external-beam radiotherapy without concurrent chemotherapy (¹⁷⁷); chemotherapy; endoscopic palliation with luminal dilation, stents, or laser or chemical ablation; and palliative surgery. Palliative surgery is rarely performed because it is rare that the potential benefits clearly outweigh the risks of surgery. Several special issues to consider in this group of patients include (1) problems specifically associated

with local disease, (2) nutrition, (3) diagnosis and treatment of tracheoesophageal fistulas, and (4) management of oral secretions.

All patients, especially those who present with more than 15% weight loss from their normal baseline, should undergo formal nutritional evaluation, and alternative nutritional support methods should be considered. Adequate nutrition and hydration are crucial to ensure that patients complete the full course of therapy. Jejunostomy feeding tubes (J-tubes), which are inserted primarily via a surgical procedure, can be considered in patients with gastric and GEJ cancer; they can be placed during the initial laparoscopic evaluation. Percutaneous gastrostomy feeding tubes, placed by endoscopic (percutaneous endoscopic gastrostomy) or radiologic (G-tube) guidance, can be considered for esophageal cancer. The continued use of jejunostomy, gastrostomy, or nasogastric feeding tubes is considered the first choice if nutrition cannot be supported orally.

All patients with advanced gastric, GEJ, and esophageal cancers are candidates for definitive chemoradiotherapy. Chemotherapy agents used in combination with radiotherapy include cisplatin, paclitaxel, carboplatin, or 5-FU. Patients with borderline performance status may not be candidates for definitive chemoradiotherapy, even with consistent nutritional support via feeding tubes. Therapy should be based on the patient's most pressing symptoms. Malnutrition should be addressed, whenever feasible, with gastrostomy or a jejunostomy tube. Upper GI bleeding and pain can be palliated with radiotherapy, alone or with endoscopic cauterization. Finally, effective chemotherapy can directly improve symptoms such as dysphagia and pain, as well as indirectly improve nutrition and minimize bleeding risk and aspiration.

SUMMARY

Gastric cancer remains the third most common cause of cancer-related death worldwide. Its incidence in the United States is decreasing, resulting in a significant increase in distal esophageal and GEJ adenocarcinoma. In fact, according to the current version of the AJCC TNM staging manual, esophageal cancer now includes GEJ to 5 cm below the gastric cardia.

Two different pathogeneses of gastric cancer have been proposed, correlating to two histologic types, intestinal and diffuse. *Helicobacter pylori* infection, chronic inflammatory state, cytokines, and host response, leading to acquisition of different genetic mutations and abnormalities, are the likely steps leading to intestinal-type invasive adenocarcinoma. On the other hand, diffuse-type gastric cancer may result from defective intracellular adhesion molecules, which is the consequence of loss of E-cadherin protein expression in gastric cancer.

Most patients with newly diagnosed gastric cancer have distant or locally advanced disease; hence, curative resection may not be possible. Because of mass screening programs in high-risk countries such as Japan, more cases of early gastric cancer are being identified. Gastric cancer treatment is based on disease stage. Early gastric cancer is cured by gastrectomy with lymphadenectomy, but similar outcomes have been reported for EMR/ESMD, which is gaining popularity in Japan and other Asian countries. Although surgery is the only chance for durable survival from gastric cancer, by itself, it is not adequate.

The results of two pivotal trials have shaped the current practice of resectable gastric cancer treatment. The INT-0116 study was the first to establish postoperative chemoradiotherapy as standard practice in the United States, whereas MRC ST02/MAGIC led to the use of perioperative chemotherapy. Postoperative chemotherapy alone after R0 resection is more widely

accepted in the United States. Many ongoing large international clinical trials will likely answer some of the questions regarding the role of postoperative versus preoperative therapy.

The focus of future research is on optimizing the chemotherapy regimen, defining the role of radiation therapy, and exploring the effect of treatment timing (preoperative, postoperative, or both). Neoadjuvant therapy is under study in a European trial comparing preoperative 5-FU and cisplatin versus surgery alone. In the United Kingdom, the MAGIC B/ST03 study is exploring ECX with or without bevacizumab followed by surgery and adjuvant ECX with and without maintenance bevacizumab. The Korean ARTIST-2 trial will shed light on whether postoperative chemotherapy (S-1 versus S-1/oxaliplatin) with or without radiotherapy contributes to improved outcomes after surgery. Similarly, a Japanese study is evaluating preoperative cisplatin plus S-1 followed by surgery and postoperative S-1 versus surgery and postoperative S-1 alone (KYUH-UHA-GC04-03). In the Dutch CRITICS study, all patients receive induction chemotherapy followed by surgery, and randomization will compare postoperative chemoradiotherapy and perioperative chemotherapy. Most interesting of all is the TOPGEAR trial, which is under way in Europe and Canada and directly compares preoperative chemotherapy alone (ECF) versus chemoradiotherapy (two cycles of ECF followed by concurrent fluoropyrimidine-based chemoradiotherapy) in patients with resectable adenocarcinoma of the stomach and GEJ; both groups will receive three further cycles of ECF postoperatively.

Only 30% to 40% of patients with esophageal cancer have potentially resectable disease at presentation, and in many series, only 5% to 20% of those undergoing surgery alone for clinically localized disease are alive at 3 to 5 years. The last AJCC TNM staging system (7th edition) for esophageal cancer introduced several important changes: (1) disease extending approximately 5 cm into the gastric cardia is now part of esophageal cancer staging, (2) the grade and number of LNs involved are important in surgical staging, and (3) esophageal squamous cell cancer and adenocarcinoma have their own staging groups.

Barrett esophagus-dysplasia-cancer is the favored mechanism of esophageal tumorigenesis. Both long-segment Barrett esophagus and short-segment Barrett esophagus are treated by treating GERD, which is frequently associated with Barrett esophagus, with a proton pump inhibitor, careful surveillance and monitoring (the frequency of monitoring should be based on the presence of high-risk characteristics), and therapy for any high-grade dysplasia or invasive cancer. High-grade dysplasia and early esophageal cancer are not common in the United States but are treated with esophagectomy or EMR/ESMD (commonly used in

high-risk countries such as Japan and Korea). Although no large randomized controlled prospective studies have compared EMR/ESMD with primary esophagectomy, the results of a retrospective case-control series suggest that the initial curative resection rates are similar. Endoscopic therapy is most effective when used to treat small (<2 cm diameter), solitary, flat lesions that are confined to mucosa (T1a).

The use of EMR for diagnosis and therapy has been validated in many studies. Endoscopic mucosal resection combined with PDT is the most popular treatment for patients with early esophageal cancer who are not surgical candidates because of comorbidity or who decline surgery. However, surgery remains the best chance for durable survival for patients with locally advanced esophageal and GEJ cancers. After multidisciplinary evaluation, patients with locally advanced disease that is deemed potentially resectable should be considered for combined-modality therapy. Evidence from several small randomized controlled studies and meta-analyses suggest that pre- or perioperative chemotherapy or preoperative chemoradiotherapy can improve surgical survival outcomes.

The results of the RTOG 85-01 trial established that chemoradiotherapy is more effective at reducing local recurrence and improving survival than radiotherapy alone. In addition, the results of the RTOG 9405 trial established a standard dose of radiation of 50.4 Gy. The POET study concluded that the addition of preoperative chemoradiotherapy improves pathCR rates and hence survival. Moreover, the results of the CROSS trial also emphasized the beneficial role of chemoradiotherapy before surgery, which led to a significant increase in OS irrespective of tumor histology.

Cervical esophageal cancer staging should include bronchoscopy. Because surgery for cervical esophageal cancer includes removal of portions of several neck organs, including the voice box, most patients with localized disease undergo definitive chemoradiotherapy. The results of several randomized studies from Europe suggest that esophageal squamous cell cancer be treated differently than adenocarcinoma. However, as of this writing, esophageal squamous cell cancer and adenocarcinoma treatments remain the same. The incidence of distal esophageal, GEJ, and proximal gastric adenocarcinoma was on a steep increase until recently. Stage for stage, esophageal cancer has a poorer prognosis than gastric cancer. Therefore, it is important that all patients with localized esophageal cancer be accurately staged and that management decisions be made by a multidisciplinary panel. Ongoing international and national randomized studies will further elucidate the role of adjuvant therapy in esophageal squamous cell cancer.

In summary, complete surgical resection of the tumor provides the best chance for cure; however,

only a minority of patients present with resectable disease. We strongly believe that a multidisciplinary approach and preoperative therapy are the cornerstones of management in the West. Gastrectomy is the recommended treatment in relatively early localized gastric cancer (T1b); however, in more advanced gastric cancers (T2N0, T1aN+, or T1b-T3N+), adjunctive therapy besides gastrectomy is recommended. The evidence-based approach should include perioperative chemotherapy or postoperative chemoradiotherapy for selected patients. All patients should be encouraged to enroll in clinical trials. Similarly, for resectable esophageal and GEJ cancers, preoperative chemoradiotherapy will enhance surgical outcomes and improve the pathCR rate.

The development of response or survival biomarkers appears to be more advanced for esophageal cancer. Positron emission tomography after induction therapy and pathCR are solid predictors of response and prognosis, respectively. Advanced or metastatic gastric, GEJ, and esophageal cancers are treated similarly. More than 60% of patients who present with newly diagnosed gastric, GEJ, and esophageal cancers will have advanced unresectable or metastatic disease. Although a cure is not possible, systemic therapy can prolong survival compared with BSC. In recent decades, advances have been made in the treatment of gastric cancer, with expansion of effective agents in several cytotoxic classes—docetaxel, oxaliplatin, capecitabine, and S-1. So far, the only targeted therapy that has demonstrated a survival benefit is trastuzumab in patients with HER2-positive disease.

Over the last 5 to 7 years, more chemotherapy combinations have been introduced for frontline treatment, including ECF and its derivatives (ECX, EOF, and EOX), DCF (docetaxel, cisplatin, and 5-FU) and its less toxic modifications (mDCX [modified] and mDX [modified], CF and its modern derivatives (XP and FLO [5-FU, leucovorin, and oxaliplatin]), and S-1 plus cisplatin. On the basis of the results of the FLAGS study⁽¹⁷⁸⁾, S-1 is not in use in Western countries. Unfortunately, despite the wealth of chemotherapy regimens, no clear consensus exists as to which chemotherapy regimen is best. Currently, patients in the United States are likely to undergo frontline therapy with platinum-, fluoropyrimidine-, or taxane-based chemotherapy regimens. Meanwhile, patients in Europe are likely to receive ECF or its derivatives and taxane-based chemotherapy regimens. The positive results of the ToGA trial have likely transformed frontline therapy for patients with HER2-positive metastatic gastric, GEJ, and esophageal cancers. However, only 20% of gastric, GEJ, and esophageal cancer patients have HER2 overexpression. In hopes of improving outcomes, biologic therapies have been introduced targeting markers shown to be prognostic in gastric cancer. The results of ongoing

randomized controlled phase III trials using targeted agents, in combination and alone, could transform the treatment of patients with advanced disease. Unfortunately, none of the trials have been done in a biomarker-enriched population.

Despite the rarity of upper GI cancers in the United States, they are common in many other countries. Both gastric and esophageal cancers carry an ominous prognosis; thus, they are still considered a major public health problem. Advancements have been made in the areas of surgery and radiotherapy that have improved the mortality rates of upper GI cancer patients. Many more reference chemotherapy regimens are available for the treatment of advanced disease. The recent TCGA analysis has uncovered four genotypes of gastric cancer; however, it is not sufficient to change our treatment strategies, and more work needs to be done. A multimodality approach to therapy will be the cornerstone to screening, diagnosing, staging, treating, and supporting patients with upper GI cancers. Figures 20-3A and 20-3B summarize the MDACC approach to gastric, GEJ, and esophageal cancers.

Surgery remains the treatment modality of choice for stage I and II cancers. Treatment consisting of definitive chemoradiotherapy can also be considered for selected patients. Metastatic gastric, GEJ, and esophageal cancers (stage IV) are not curable, but survival and cancer-related symptom control can be improved with systemic chemotherapy. Effective palliation may be achieved with various combinations of chemotherapy, radiotherapy, and therapeutic endoscopy. In particular, systemic chemotherapy can result in temporary palliation. Objective response rates of 30% to 50% and a median survival duration of <1 year have been reported for platinum-based combination regimens with 5-FU, a taxane, or a topoisomerase inhibitor. The search for new classes of cytotoxics has almost stopped, but it is clear that cytotoxic therapy continues to contribute and it is here to stay. The incorporation of biologic agents that modulate the immune system of the host and the uncovering of true driver mutations of gastric cancer in individual patients appear promising, along with many other biologics that can potentially inhibit signaling pathways. Therefore, all patients should be offered the opportunity to participate in clinical trials.

PANCREATIC CANCER

When clinicians use the term *pancreatic cancer*, they refer to adenocarcinoma of the pancreas, one of the most challenging malignancies facing oncologists today. This disease is characterized by significant morbidity and poor prognosis.

At the University of Texas MD Anderson Cancer Center (MDACC), we manage patients with pancreatic cancer with a multidisciplinary team and view palliation as the primary goal. However, for patients with potentially resectable disease, we take an aggressive approach whenever appropriate. In the setting of advanced disease, cure is not possible, but as our understanding of carcinogenesis, invasion, and metastasis expands, more effective therapeutic strategies are expected to emerge. This chapter reviews our current knowledge about pancreatic cancer, including its epidemiology, risk factors, molecular biology, diagnosis and staging, and clinical strategies for therapy.

HARD FACTS ABOUT PANCREATIC CANCER

Pancreatic cancer, the most common pancreatic neoplasm, is an aggressive and often rapidly fatal malignancy. In the United States, it represents 2% of all cancer cases but accounts for 5% of all cancer deaths (¹). Currently, it is the fourth leading cause of cancer death, ranking behind lung, colorectal, and breast cancer. While evidence suggests marginal

improvements in 5-year survival rates over the last 25 years (2% in 1974-1976, 3% in 1983-1985, and 4% in 1992-1997), life expectancy remains short and is generally measured in months (²). By 2030, deaths due to pancreas cancer are projected to increase dramatically and will become the second leading cause of cancer-related death (³). Significant improvements in survival have been hampered by a number of factors, including inefficient screening strategies, technically challenging and often debilitating surgery, and minimally effective chemotherapy and radiotherapy.

Pancreatic cancer is a dynamic disease, and sudden changes in clinical status occur frequently. Patients may rapidly develop worsening pain, biliary obstruction, or stent occlusion with cholangitis, thromboembolism, peritoneal carcinomatosis, or intractable ascites. Any of these problems may preclude the timely delivery of cytotoxic therapy and limit survival. Therefore, most efforts should focus on symptom control, but for patients with adequate performance status (PS), treatment is encouraged.

EPIDEMIOLOGY

There are approximately 45,000 new cases of pancreatic cancer each year in the United States and 330,000 cases worldwide. Incidence rates are highest in industrialized societies and Western countries. Of note, the risk of pancreatic cancer among African Americans, in whom pancreatic cancer mortality rates are higher than most other ethnic groups in the United States, is

considerably higher than the rates for African blacks (⁴). These observations implicate environmental factors conspiring with genetic background as causes of the increased risk.

The risk of developing pancreatic cancer is low in the first three to four decades of life but increases sharply after the age of 50. Average age at the time of diagnosis is 72 years. Pancreatic cancer is uncommon in patients under 40. In the past, pancreatic cancer occurred more frequently in men, but now the disease is becoming more common in women, probably secondary to the increased use of tobacco by women.

RISK FACTORS FOR PANCREATIC CANCER

Surprisingly, relatively little is known about the risk factors for the development of pancreatic cancer. Table 21-1 summarizes genetic and environmental factors associated with an increased risk.

Tobacco

Aside from age, the only consistently reported risk factor for pancreatic cancer is cigarette smoking. Cigarette smoking is estimated to account for roughly 30% of pancreatic cancer mortality (⁵). Experimental models have demonstrated that nitrosamines found in tobacco smoke are carcinogenic for the pancreas. Research performed at MDACC has shown that smoking-related aromatic DNA adducts and other types of DNA damage may be critical in carcinogenesis.

Diabetes Mellitus

Diabetes has been implicated both as an early manifestation of pancreatic cancer and as a predisposing factor. A meta-analysis published between 1975 and 1994 showed that pancreatic cancer occurred with increased frequency in patients with long-standing diabetes (diagnosed at least 5 years prior to the diagnosis or death due to pancreatic cancer) (⁶). It is believed that insulin resistance and secondary hyperinsulinism may be involved in pancreatic carcinogenesis.

Chronic Pancreatitis

Early clinical studies have suggested an association between chronic pancreatitis and pancreatic cancer. In a study of 715 patients with chronic pancreatitis diagnosed between 1971 and 1995, there was a 13- to 18-fold increase in pancreatic cancer rates (⁷).

Studies have suggested that hereditary pancreatitis, in particular, may affect the risk. Lowenfels and Maisonneuve studied 246 patients with hereditary pancreatitis from 10 countries. The estimated cumulative risk of pancreatic cancer by age 70 was approximately 40%, with a mean age at diagnosis of 57 years (⁸). Molecular data strongly suggested that mutations in the trypsinogen gene *PRSS1* play an important role in hereditary and possibly acquired forms of pancreatitis (⁹).

Diet

Positive associations have been discovered between pancreatic cancer and meat and carbohydrate intake. However, there is no consensus on the contribution of

Table 21-1 Acquired and Genetic Risks Factors Associated With Pancreatic Cancer

Acquired Risk Factors	Relative Risk	Comments
Tobacco smoking	2-5	Risk increases with increasing exposure
Diabetes mellitus	2	Not all authorities concur; many patients have altered glucose metabolism on presentation
High body mass index	2	
Chronic pancreatitis	13-18	Not all authorities concur with this degree of increased risk
Inherited Disorders	Relative Risk	Known Defects
Hereditary pancreatitis	10-53	PRSS1
FAMMM syndrome	22	p16INK/CDKN2
HNPCC	8	MLH1, MSH2, MSH6
Peutz-Jeghers syndrome	13-30	LBK1/STK11
Familial adenomatous polyposis	4-5	APC
Li-Fraumeni syndrome	?	p53
Familial breast and ovarian cancer	3-5	DNA repair pathways, BRCA2

FAMMM, familial atypical mole and melanoma; HNPCC, hereditary nonpolyposis colon cancer.

dietary fat. Epidemiologic studies of pancreatic cancer have shown a protective role for high fruit and vegetable intake. This effect may be related to dietary folate and other methyl donor groups.

Body Mass Index

Epidemiologic studies have also implicated a high body mass index as increasing risk for pancreatic cancer. This may be explained by relative hyperinsulinemia thought to promote pancreatic carcinogenesis⁽¹⁰⁾.

Familial Pancreatic Cancer and Other Genetic Syndromes

Patients with pancreatic cancer who have two first-degree relatives with a history of pancreatic cancer are defined as having familial pancreatic cancer. The estimated relative risk for other family members is increased 10- to 20-fold over the general population. In addition, hereditary nonpolyposis colorectal cancer, ataxia-telangiectasia, Peutz-Jeghers syndrome, familial breast and ovarian cancer, and familial atypical multiple-mole melanoma are all associated with increased risk of pancreatic cancer⁽¹¹⁾.

The familial breast and ovarian cancer syndrome, associated with mutations in the *BRCA* genes, accounts for 17% of cases⁽¹²⁾. The *BRCA1* and *BRCA2* proteins are key components of homologous recombination through the repair of DNA double-strand breaks. Cells deficient in these proteins demonstrate genomic instability and a tendency toward malignant transformation⁽¹³⁾. The poly(ADP-ribose) polymerase (PARP) enzyme is integral for single-stranded DNA repair, and inhibition results in DNA breaks that require intact *BRCA* proteins for repair. In the presence of mutant *BRCA* proteins, PARP inhibition results in synthetic lethality⁽¹⁴⁾.

Preclinical work has demonstrated the sensitivity of *BRCA* mutated pancreatic cancer cell lines to cross-linking chemotherapeutic agents, such as mitomycin-c and cisplatin⁽¹⁵⁾. This finding has translated clinically as studies have shown superior overall survival and response in patients with advanced pancreatic cancer with *BRCA* mutations treated with platinum⁽¹³⁾. Furthermore, studies with PARP inhibitors have shown promise either alone or in combination with cytotoxic chemotherapy⁽¹⁶⁾. Currently, an ongoing study is investigating the efficacy of a single-agent PARP inhibitor, rucaparib, in patients with advanced pancreatic cancer with known *BRCA* mutations.

Occupational Exposures

Exposure to carcinogens in the workplace has been implicated in pancreatic cancer, but with the possible

exception of formaldehyde, the available evidence is insufficient to identify any specific exposure to increase the risk.

Prior Gastrointestinal Surgery

Surgical procedures such as gastrectomy and cholecystectomy have been reported to increase risk and are possibly linked to elevated levels of cholecystokinin and hypergastrinemia. However, other studies have not demonstrated such an association⁽¹⁷⁾.

MOLECULAR EVENTS IN HUMAN PANCREATIC CARCINOGENESIS

The molecular events leading to pancreatic cancer have not been fully elucidated, but mutations in a few oncogenes and tumor suppressors appear critical for carcinogenesis. Investigators from Johns Hopkins performed a comprehensive genomic analysis of pancreatic cancer reported in the journal *Science*. They noted an average of 63 alterations, the majority of which were point mutations. These alterations defined a core set of 12 cellular signaling pathways and processes that were altered in the majority of pancreatic cancers. These included the *K-ras*, *wnt/notch*, hedgehog, *TGF-β*, integrin, and JNK signaling pathways⁽¹⁸⁾. Recently, Waddell et al characterized pancreatic cancer into four subtypes termed stable, locally rearranged, scattered, and unstable⁽¹⁹⁾.

Oncogene Mutation: The *ras* Oncogene

Pancreatic cancer has the highest frequency of *K-ras* mutation among all human cancers. Greater than 85% of cases have an activating point mutation in the *K-ras* gene, most commonly a G-to-T transversion at codon 12⁽²⁰⁾. This leads to constitutive activation of RAS, leading to growth-promoting signal cascades via the mitogen-activated protein (MAP) kinase pathway. Preclinical models have implicated this mutation as a very early event in carcinogenesis. The *ras* oncogene mutations were also retrospectively seen in pancreatic juice collected 3.5 years prior to a patient's diagnosis of pancreatic cancer⁽²¹⁾.

Tumor Suppressor Gene Mutation and Inactivation

The *p16* tumor suppressor gene is inactivated in approximately 95% of pancreatic cancers; this typically occurs later in carcinogenesis. The second most frequently inactivated tumor suppressor gene, *p53*, located on chromosome 17p, also appears to be a late event in tumorigenesis. The *DPC4* gene (*SMAD4*) is

inactivated in 55% of pancreatic adenocarcinomas and, like *p53*, is a relatively late event in tumorigenesis. In a comprehensive mutational analysis of 42 pancreatic ductal cancers, Rozenblum and colleagues found individual mutational frequencies of tumor suppressor genes *p16*, *p53*, *DPC4*, and *BRCA2* were 82%, 76%, 53%, and 10%, respectively (²¹).

The Multistep Sequence of Pancreatic Carcinogenesis

Current data suggest a temporal sequence of molecular events in pancreatic carcinogenesis leading from an “adenomatous” or proliferative ductal cell phenotype to pancreatic intraepithelial neoplasia (Pan-IN) and finally to invasive cancer. This theory has been supported by the recognition of noninvasive proliferative ductal lesions (Pan-IN1) that demonstrate mutations commonly found in pancreatic cancer. Growing evidence suggests that the gradual accumulation of genetic and biochemical alterations in early lesions causes progression to higher levels of dysplasia (Pan-IN2 and Pan-IN3) and ultimately to cancer.

Other Molecular Events in Pancreatic Carcinogenesis, Invasion, and Metastasis

The overexpression of epidermal growth factor receptor (*EGFR*), vascular endothelial growth factor (VEGF), matrix metalloproteinases, cyclooxygenase 2 (COX-2), hedgehog signaling, and insulinlike growth factor type 1 (IGF-1) pathways have been implicated in pancreatic cancer. Studies conducted at MDACC have also demonstrated that the nuclear transcription factor- κ B (NF- κ B) is commonly activated in pancreatic cancer (²²).

Hedgehog Signaling Pathway

Hedgehog signaling is an essential pathway during embryogenesis of the normal pancreas, and its dysregulation has been reported in precancerous PanIN-1 and -2 as well as in primary and metastatic pancreatic adenocarcinomas. Inhibition of hedgehog signaling by cyclopamine-induced apoptosis and blocked proliferation in vitro and in vivo (²³). Although debatable, hedgehog inhibition also depletes tumor-associated stroma and may play a role in the delivery of chemotherapeutic agents like gemcitabine (²⁴). Clinical trials of hedgehog inhibitors have failed to create a meaningful impact in this disease. Recent data indicated that stromal depletion may actually be deleterious, suggesting a critical need for accurate interpretation of preclinical data before incorporation into the clinical trial setting (²⁵).

Insulinlike Growth Factor Type 1 Pathway

Insulinlike growth factor type 1 upregulates cell proliferation and invasiveness through activation of the phosphoinositide 3-kinase (PI3K)/Akt signaling pathway and downregulates the tumor suppressor chromosome 10 (PTEN). Akt mediates the gemcitabine and erlotinib resistance mechanisms. At MDACC, we recently concluded a clinical trial with dalotuzumab (MK-0646), which targets the IGF-1 pathway.

Targeted therapy has been a major focus of clinical research, taking priority over the study of more conventional cytotoxic agents. Preliminary studies with agents designed to abrogate RAS function have been disappointing (²⁶). Likewise, administration of inhibitors of matrix metalloproteinases has failed to demonstrate a meaningful clinical impact (²⁷). Recent studies of *EGFR*, VEGF, NF- κ B, or COX-2 inhibitors are discussed in further detail in this chapter. Immune therapies may have a significant impact as well.

PATHOLOGY

Pancreatic acinar cells account for approximately 80% of the cell number and volume of the gland, with islet cells accounting for 1% to 2%. The ductal system is made up of single-layer, cuboidal epithelial cells comprising 10% to 15% of the gland's structure, with a sparse interlacing network of blood vessels, lymphatics, nerves, and collagenous stroma. In carcinoma, this architecture is markedly altered: The predominant histologic feature is a dense collagenous stroma with atrophic acini, remarkably preserved islet cell clusters, and a slight-to-moderate increase in the number of normal-appearing and cancerous ducts (Fig. 21-1). The diagnosis of ductal adenocarcinoma rests on the identification of mitoses, nuclear and cellular pleomorphism, discontinuity of ductal epithelium, and evidence of perineural, vascular, or lymphatic invasion.

Almost all malignant neoplasms of pancreatic origin (95%) arise from the exocrine portion of the gland. Tumors arising from the islets of Langerhans (endocrine) cells are much more infrequent, and primary nonepithelial tumors (eg, lymphomas or sarcomas) are extremely rare. The histologic classification of exocrine pancreatic neoplasms is presented in Table 21-2.

CLINICAL PRESENTATION

The clinical presentation of pancreatic cancer is primarily dependent on the location of the tumor within the pancreas. The majority (85%) develop within the pancreatic head. About 10% are located in the pancreatic body and 5% in the tail. Nonspecific, poorly localized, epigastric or back pain is the most common initial

FIGURE 21-1 Photomicrograph of ductal adenocarcinoma of the pancreas with well-preserved islet cells and pancreatic architecture above and infiltrating tumor with poorly formed glandular structures below.

presentation. It is usually caused by invasion or compression of the celiac, splanchnic, or mesenteric plexi. Tumors in the head or neck typically cause pain in the epigastric area or in the right upper quadrant of the abdomen. Cancers of the body may cause unremitting,

severe back pain, and tumors in the pancreatic tail are associated with left upper quadrant pain.

Painless jaundice, another common presentation, is generally associated with tumors in the pancreatic head or uncinate process. When the tumor does not arise in proximity to the intrapancreatic portion of the bile duct, diagnosis may be delayed and characterized by abdominal pain or back pain without jaundice.

Acute pancreatitis, while uncommon, can be caused by a ductal adenocarcinoma; in patients with no other reason for acute pancreatitis (lack of gallstones, no history of alcohol or precipitating drugs) ⁽²⁸⁾. Symptoms of chronic pancreatitis are relatively common, including diarrhea, bloating or constipation, abdominal distention, and weight loss. Patients with tail lesions often present with signs or symptoms of metastatic disease.

DIAGNOSIS AND STAGING OF PANCREATIC CANCER

Pancreatic cancer can be difficult to diagnose, particularly in patients with nonspecific complaints. Therefore, patients who present to the oncologist for treatment recommendations may harbor feelings of frustration and anger, having endured a significant delay from the onset of symptoms to diagnosis. Upper endoscopy may have been performed to rule out peptic ulcer disease or other pathology. Endoscopy is seldom helpful unless the pancreatic tumor has invaded the adjacent gastric or duodenal mucosa, leading to ulceration. In this uncommon situation, biopsies may demonstrate adenocarcinoma, and subsequent cross-sectional body imaging reveals an underlying pancreatic mass. Even more rarely, extrinsic compression on the gastric or duodenal wall may be appreciated endoscopically. Unfortunately, upper endoscopy may be misleading and demonstrate mild esophagitis, gastritis, or duodenitis, with or without evidence of *Helicobacter pylori*. Alternatively, patients complaining of right upper quadrant pain may undergo ultrasonography, potentially revealing gallstones, prompting cholecystectomy. This procedure is usually of temporary benefit and delays the discovery of a pancreatic tumor until pain returns. Last, for patients presenting with complaints of back pain, a musculoskeletal evaluation commonly ensues, with the procurement of plain x-rays, myelograms, or magnetic resonance imaging (MRI) of the spine.

For those patients who present with obstructive jaundice, suspicion of pancreatic cancer is sufficiently high that the diagnostic workup usually proceeds in an orderly fashion with directed imaging studies. These usually include an abdominal ultrasound, computed tomographic (CT) scan of the abdomen, or both. In some centers, discovery of a mass in the head of the pancreas without obvious metastatic disease or evidence for unresectability will prompt an exploratory

Table 21-2 Histologic Classification of Primary Exocrine Pancreatic Tumors

Malignant
Ductal adenocarcinoma

Papillary cystic neoplasm

laparotomy prior to biopsy confirmation of malignancy. This approach is not embraced at MDACC for reasons outlined further in this chapter.

Tissue Acquisition

With rare exception, all patients seen at MDACC are advised to undergo tissue confirmation. Cross-sectional imaging (multidetector CT) should always be performed before interventional endoscopic or radiologic procedures to prevent procedure-related inflammatory changes from confounding assessment. For patients presenting with obstructive jaundice, tissue may be obtained at the time of endoscopic retrograde cholangiopancreatography (ERCP) via brushings of the bile duct at the level of stricture. If brushings are nondiagnostic and CT or MRI suggests that the tumor may be nonmetastatic, we advise endoscopic ultrasound (EUS) with EUS-guided fine-needle aspiration (FNA) ⁽²⁹⁾. This can be performed by experienced operators with minimal risk of duodenal perforation. Moreover, it is thought to decrease the risk of peritoneal or needle-track seeding, which has been reported among patients undergoing transcutaneous ultrasound- or CT-directed biopsies ⁽³⁰⁾. Alternatively, when CT or MRI clearly demonstrates an unresectable, locally advanced cancer, CT- or ultrasound-guided transcutaneous biopsy may substitute for EUS-guided aspiration. If a patient presents with obstructive jaundice and biliary stricture without radiographic evidence of a pancreatic mass, EUS examination is also advised.

When there is radiographic evidence of metastatic disease and an obvious pancreatic mass, we recommend biopsy of a metastatic site, such as the liver. This confirms both the diagnosis and the presence of metastatic disease with one procedure.

Misdiagnosis of Pancreatic Cancer

It is not uncommon for patients to be misdiagnosed with pancreatic cancer. The most common mistake we see is in the setting of bulky peripancreatic adenopathy without a parenchymal pancreatic mass. Adenocarcinomas of the pancreas do metastasize to regional lymph nodes, but lymph nodes are typically small to medium in size. Bulky lymph nodes are seen in other gastrointestinal (GI) malignancies, such as tumors of the esophagus, stomach, duodenum, and occasionally, colon. Lymphoma, non-small cell lung cancer, and carcinomas of unknown primary origin may also lead to bulky peripancreatic lymphadenopathy, thus mimicking a primary pancreatic neoplasm. Thin-cut, dynamic-phase, contrast-enhanced CT will usually rule out the presence of a primary mass in the pancreas in this setting. Another helpful radiographic finding may be the presence or absence of atrophy of the pancreatic

body and tail. Although commonly seen in adenocarcinomas originating in the head of the pancreas, this finding is usually absent in the setting of bulky peripancreatic adenopathy, neuroendocrine tumors, and acinar cell tumors. Importantly, patients with neuroendocrine tumors of the pancreas are sometimes misdiagnosed as having a poorly differentiated carcinoma of the pancreas.

High-Quality Computed Tomographic Imaging

The single most important imaging modality is multidetector (multislice) CT. This technique is used to objectively define (anatomically) potentially resectable disease. For optimal pretreatment staging, a CT report in a patient with suspected pancreatic cancer should include the following:

1. The presence or absence of a primary tumor in the pancreas or periaampullary region
2. The presence or absence of peritoneal and hepatic metastases
3. Description of the patency of the superior mesenteric vein (SMV) and portal vein (PV) and the relationship of these veins to the tumor
4. Description of the relationship of the tumor to the superior mesenteric artery (SMA), celiac axis, and hepatic artery

Objective radiographic criteria can be used to define a potentially resectable primary tumor of the pancreatic head or uncinate process (Fig. 21-2). The MDACC

FIGURE 21-2 Computed tomographic image of tumor within the pancreatic head. Note the stent in the bile duct and the subtle low-density mass within the head. The superior mesenteric artery (SMA) has a fat plane completely surrounding it. This defines a potentially resectable tumor.

criteria include: (1) no extrapancreatic disease; (2) a patent SMV and PV (assuming the technical ability to resect and reconstruct this venous confluence); and (3) a definable tissue plane between the tumor and regional arterial structures, including the celiac axis and SMA. Using CT staging and objective criteria for assessment of resectability, many centers have reported resectability rates as high as 75% to 80%⁽³¹⁾. Of note, CT of the chest is not routinely part of our staging workup. However, if either plain chest x-rays or CT images of the lung bases reveal pulmonary nodules or other suspicious findings, a dedicated CT scan of the chest is obtained. Bone scans and brain imaging are rarely indicated and should not be part of routine staging.

Positron Emission Tomography

Positron emission tomographic (PET) scans are occasionally obtained in the setting of equivocal radiographic findings, such as indeterminate lesions in the liver or lungs. Lesions may be subcentimeter in size, and ¹⁸F-fluorodeoxyglucose negative, even when metastatic disease is present⁽³²⁾. Scanning by PET is commonly considered when a patient has undergone previous resection and subsequently develops a rising CA19-9 and soft tissue changes in the surgical bed with no other evidence of relapse.

Serum CA19-9 Determinations

CA19-9 measures the specific carbohydrate moiety of the mucin MUC-1⁽³³⁾. This is the most commonly elevated tumor marker in pancreatic cancer, but it is not specific and may be elevated in other GI tumors. Whether it should be measured prior to surgery as an independent predictor of resectability or as an adjunct to other clinical staging has not been rigorously studied. Most retrospective analyses generally suggested that a high preoperative CA19-9 level (>500-1,000 IU/mL) implies more advanced disease that is not amenable to resection. We retrospectively analyzed pretreatment CA19-9 levels obtained from 79 patients enrolled in a trial of gemcitabine-based preoperative chemoradiation. All patients had radiographically defined, biopsy-proven, resectable cancer without evidence of metastatic disease. It was found that serum levels greater than 668 IU/mL predicted either the development of overt metastatic disease prior to surgery or early relapse after surgical resection⁽³⁴⁾. Presently, serum CA19-9 measurements are obtained at presentation to MDACC. When postoperative CA19-9 levels do not normalize within this time frame, it portends early relapse⁽³⁵⁾. Patients clinically staged as having locally advanced disease but with markedly elevated CA19-9 levels (>5,000) are suspected of having occult metastatic disease. These patients are usually advised

to undergo a trial of systemic therapy with serial measurements of CA19-9 levels prior to considering chemoradiation. Improvement of CA19-9 of 50% has been correlated with an improved survival⁽³⁶⁾.

The Role of Laparoscopy

For patients with potentially resectable disease, some have advocated laparoscopy with biopsies and peritoneal washings as part of routine staging^(37, 38). In our experience, fewer than 20% of patients with tumors in the head of the pancreas will have occult metastatic disease when laparoscopy is performed. Given the expense and expected negative findings for 80% of patients, our approach has been to limit this procedure to patients with indeterminate findings on CT⁽³⁹⁾. An exception applies to the small subset of patients who present with radiographically resectable tumors in the body or tail of the pancreas who are more likely to have occult metastatic disease. The chance of a visible peritoneal metastasis or positive cytology on peritoneal washing is sufficiently high to justify laparoscopy as part of staging⁽⁴⁰⁾.

The TNM System Versus Clinically Oriented Staging

The TNM (tumor, node, metastasis) staging system for pancreatic cancer is outlined in Table 21-3. For patients undergoing resection, the TNM system is somewhat useful in providing prognostic information and, to a lesser degree, in guiding adjuvant therapy. Generally, patients are staged as having potentially resectable disease, locally advanced unresectable disease, or metastatic disease. For patients with resectable disease who are able to tolerate it, surgery is indicated. Surgery can be preceded by preoperative or adjuvant therapy. Patients with metastatic disease and adequate PS usually receive systemic therapy. For patients presenting with locally advanced disease, treatment should be individualized and may initially involve either chemoradiation or systemic therapy.

TREATMENT STRATEGIES FOR PANCREATIC CANCER

Resectable Pancreatic Cancer

It is widely known that surgery holds the only hope of cure for patients with pancreatic cancer. With some exceptions, resectable pancreatic cancers are limited to small tumors in the head of the pancreas. These are removed with a Whipple procedure⁽⁴¹⁾, more appropriately described as a pancreaticoduodenectomy. Caution is advised when considering a resection of a

Table 21-3 TNM Criteria for Pancreatic Adenocarcinoma TNM Definitions

Tx:	Primary tumor cannot be assessed		
T0:	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1:	Tumor <2 cm in greatest dimension		
T2:	Tumor >2 cm in greatest dimension

tail neoplasm; even when these tumors appear localized, they are associated with a higher likelihood of peritoneal seeding compared to a head lesion. Body lesions are almost never amenable to resection.

Unfortunately, there are potential drawbacks associated with up-front surgery:

1. *Surgical morbidity and mortality are inversely correlated to experience with the procedure.* Several studies have confirmed significant differences in the risk of major perioperative complications and death between hospitals that perform the operation frequently and those that do not (^{42, 43}). Moreover, long-term survival after pancreaticoduodenectomy is improved when performed at a high-volume center (⁴⁴). This is likely attributable to a combination of decreased operative mortality and superior patient selection.
2. *Positive surgical margins are associated with a very poor prognosis* (see Table 21-4). Surgical margins after pancreaticoduodenectomy can be either microscopically

Table 21-4 Median Survival Rates of Patients With a Gross (R2) or Microscopic (R1) Surgical Margin at the Time of Resection

Author	Number of Patients	Margin Status	Median Survival (Months)
Sohn	184	R1/R2	12

Takai	42	R1/R2	8

positive (R1 resection) or grossly positive (R2). Median survivals with a positive surgical margin usually range between 6 and 12 months, similar to, if not worse than, the survival of patients with locally advanced disease (^{45, 46}). Many patients undergo laparotomy without adequate preoperative assessment. Some will be found to have unresectable tumors intraoperatively or be left with a grossly positive surgical margin when it might have been possible to predict this prior to surgery. Patients may therefore have a delay in chemoradiation or systemic therapy while the patient recovers. With the exception of patients who present with gastric outlet obstruction or biliary obstruction not amenable to endoscopic or percutaneous stenting, we discourage surgical intervention without high-quality radiographic evidence of resectability. If the surgeon has failed to perform a complete resection, surgery may even be deleterious and compromise the patient's survival.

3. *A substantial proportion of patients do not recover sufficiently to receive postoperative adjuvant therapy.* Pancreaticoduodenectomy is a major surgical procedure with removal of portions of the stomach, duodenum, pancreas, and bile duct requiring extensive reconstruction of the upper alimentary canal. Pancreatic anastomotic leaks and delayed gastric emptying are common complications. Retrospective analyses and prospective clinical trials of adjuvant therapy demonstrated that a significant percentage of people do not adequately recover to receive postoperative therapy. For example, Johns Hopkins University demonstrated that of 870 patients who underwent resection for pancreatic cancer with curative intent between 1993 and 2005, only 53% received adjuvant therapy (⁴⁷). Furthermore, analyses of Medicare-eligible patients suggested that among patients 65 years of age or older, fewer than half receive adjuvant therapy (⁴⁸). It is reasonable

to assume that a substantial proportion of elderly patients have sufficient difficulty recovering from surgery and this has an impact on adjuvant therapy.

4. *Surgically resected patients remain at risk for local failure and metastatic disease.* Approximately 80% of resected patients will ultimately relapse and die of disease recurrence. The high risk of relapse stems from an inability to prevent locoregional failure and to eradicate microscopic metastatic disease. Factors predisposing to local recurrence have not been fully elucidated, but recent evidence implicated perineural invasion as an important mediating process. Invasion of nerve sheaths may occur as a pervasive superficial infiltration that cannot be appreciated intraoperatively, even by the most experienced surgeons.

Once patients relapse with distant disease or local failure, no curative strategy is available. Adjuvant therapy, while tending to improve median survival, has not made any significant advances over the past 20 years.

The Role of Adjuvant Therapy

Since the mid-1980s, efforts have been directed toward improving outcomes for patients with resected disease by delivering postoperative adjuvant therapy intended to reduce the risk of relapse and improve long-term survival. Early retrospective analyses of resected patients suggested local failure rates as high as 50% to 80%, which prompted many centers to advocate radiotherapy as a component of adjuvant therapy. The first randomized trial, performed by the Gastrointestinal Tumor Study Group (GITSG), demonstrated a significant survival advantage with chemoradiation based on 5-fluorouracil (5-FU) compared with resection alone (21 vs 11 months)⁽⁴⁹⁾. The 5-year survival rates were 18% versus 8%, respectively. The European Organization for Research and Treatment of Cancer (EORTC) 40891 trial produced conflicting results 15 years later. In this case, 218 patients receiving 5-FU chemoradiation did not demonstrate a survival advantage over those on observation, although this population was more heterogeneous than that of GITSG because patients with perianapillary cancer and those with an R1 resection were included⁽⁵⁰⁾.

Large randomized adjuvant trials were conducted by the European Study Group for Pancreatic Cancer (ESPAC). In the ESPAC-1 trial, 289 patients were randomized to observation, chemotherapy, chemoradiation, or chemoradiation followed by chemotherapy⁽⁵¹⁾. Interestingly, chemoradiation was found to have a deleterious effect on survival (median survival 15.9 vs 17.9 months, respectively, $P = .05$). On the other hand, chemotherapy appeared beneficial over observation, with a median survival of 20.1 months versus 15.5 months ($P = .009$). As a result of these studies, the

role of radiation in adjuvant therapy became controversial. Radiation has been abandoned in the adjuvant setting in many European centers.

After gemcitabine showed superiority to 5-FU in advanced disease, a number of randomized trials tested its role in the adjuvant setting. The Radiation Therapy Oncology Group (RTOG) 9704 trial compared gemcitabine with 5-FU given before and after 5-FU-based chemoradiation. Gemcitabine demonstrated a modest, but not significant, improvement in survival over 5-FU (20.5 months compared to 16.9 months, $P = .09$)⁽⁵²⁾.

The benefit of adjuvant gemcitabine was further confirmed with the long-term data from the CONKO 001 trial. Investigators showed a significant improvement in disease-free survival and overall survival with the use of gemcitabine postoperatively (13 and 22.8 months, respectively) compared to surgery alone (6.9 and 20.2 months)⁽⁵³⁾. ESPAC-3 further compared postoperative gemcitabine to 5-FU⁽⁵⁴⁾. No statistical difference in survival was noted after a median follow-up of 34 months, although gemcitabine appeared to be better tolerated.

Picozzi and colleagues reported their findings of a phase II study involving adjuvant interferon alpha-2b (IFN- α 2b), cisplatin, and continuous infusion 5-FU given concurrently with external beam radiation⁽⁵⁵⁾. In this study, 89 patients with R0 or R1 resections received IFN- α 2b on days 1, 3, and 5 each week for 5½ weeks, cisplatin weekly for 6 weeks, and infusional 5-FU for 38 days with radiation dosed to 50.4 Gy. Overall survival at 18 months was 69% with a median disease-free survival of 14.1 months and overall survival of 25.4 months. Of the patients, 95% experienced grade 3 or greater toxicity. Additional combination trials, however, did not show an improvement in survival compared to 5-FU monotherapy⁽⁵⁶⁾. Table 21-5 summarizes the adjuvant trials.

Preoperative Therapy for Potentially Resectable Disease

Sadly, there has been no significant progress in adjuvant therapy since the GITSG study was first reported in 1985. More recent studies have been fairly consistent with the GITSG findings: Median survival for resected patients treated with postoperative therapy hovers around 20 months and remains at 12 months for patients undergoing surgery alone. Of the patients who undergo potentially curative surgery, up to 50% do not recuperate enough to begin postoperative chemoradiation or require prolonged recovery to consider treatment. Moreover, rapid disease progression with early systemic relapse is not uncommon after surgery. Therefore, neoadjuvant therapy followed by surgery offers some theoretical advantages over immediate surgery.

Table 21-5 Summary of Randomized and Nonrandomized Adjuvant Trials

Study Year	Number of Patients	Patients With R1 Resection (%)	Treatment A Median Survival (Months)	Treatment B Median Survival (Months)	P Value	Local Failure Rate (%)

Patients who present with potentially resectable disease are generally physiologically fit and make attractive candidates for neoadjuvant therapy. Preoperative therapy allows delivery of chemotherapy or chemoradiation to a relatively well-perfused tumor bed and provides early treatment to microscopic metastases. Positive surgical margins are commonly reported after up-front resection; this is associated with poor prognosis, suggesting that surgery alone provides inadequate local control. Preoperative therapy may provide for sufficient tumor destruction, particularly at the periphery, to increase the chances of a margin-negative resection. Preoperative therapy also allows for observation of the tumor's underlying biology, and those with aggressive disease are spared a major surgical procedure.

Five preoperative trials have been completed at MDACC (Table 21-6)^(57–61). These trials, performed in sequence, have had nearly identical inclusion criteria, with standardized radiographic criteria for resectability, surgical technique, and assessment of resection margins. Our data demonstrated that preoperative therapy is associated with a relatively low local failure rate compared to adjuvant therapy and, over time, modest improvements in overall survival, especially with the use of gemcitabine over 5-FU or paclitaxel-based chemoradiation.

In the work of Evans et al, a total of 86 patients received gemcitabine followed by chemoradiation, and 74% of them were able to undergo pancreaticoduodenectomy⁽⁵⁷⁾. The median survival was 34 months

Table 21-6 Summary of Preoperative Trials Performed at MDACC

Author, Year	Number of Patients	Preoperative Regimen	Resection Rate (%)	% R1	Median Survival Resected Patients	Local Recurrence Rate (%)

5-FU, 5-fluorouracil; Gem, gemcitabine; XRT, radiotherapy.

compared to 7 months for those who did not receive resection. The pattern of failure favored distant metastases; thus, a second trial was designed to increase the amount of systemic therapy. This trial enrolled 90 patients to receive gemcitabine with cisplatin followed by chemoradiation, and 66% underwent resection. The addition of cisplatin did not improve survival beyond gemcitabine alone (31 vs 34 months). While these studies were not designed to be compared to adjuvant trials, the median survival in both preoperative studies was notably better than that seen in the adjuvant data we have to date. In the gemcitabine-based chemoradiation trial, complete pathologic responses were observed in two surgical specimens.

While preoperative chemoradiation has not been established as a standard approach, by using preoperative therapy, negative surgical margins are more frequently reported. While these are probably not sufficient to ensure cure, they are likely to be necessary for extended survival (Fig. 21-3).

MDACC Approach to Adjuvant Therapy

At MDACC, adjuvant therapy is delivered with the following principles:

1. Patients must demonstrate adequate recovery from surgery to be considered for further treatment. This includes ample oral caloric intake and no significant

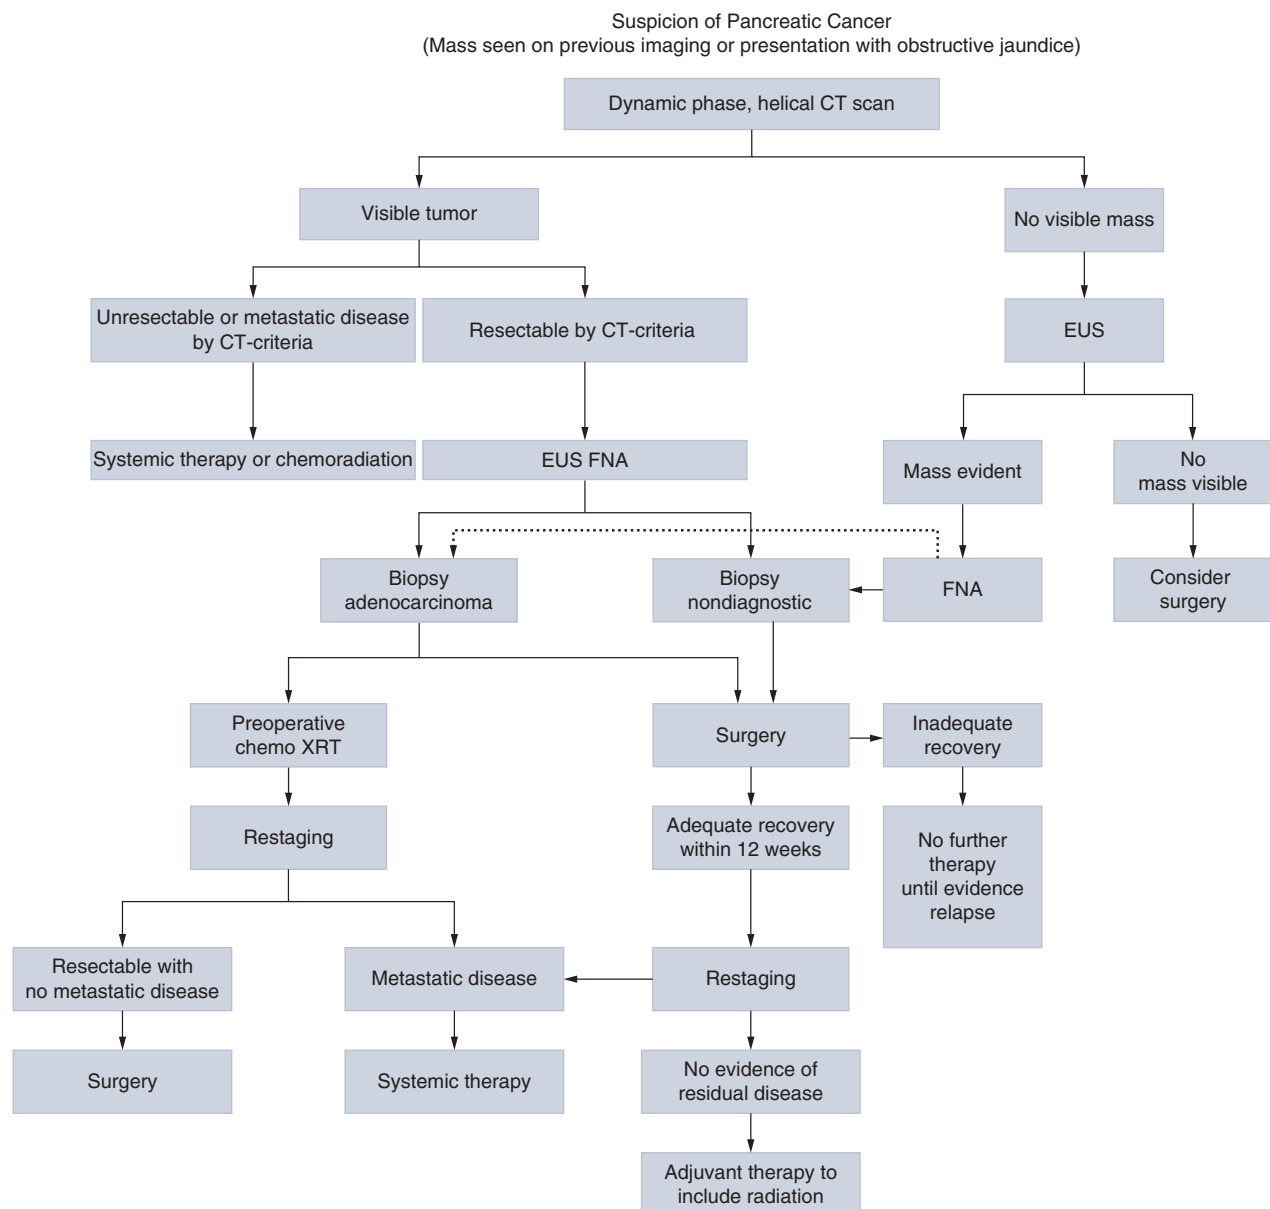

FIGURE 21-3 General algorithm for diagnostic workup and management of newly diagnosed pancreatic cancer.

impairment of the alimentary tract (delayed gastric emptying, dumping syndrome, uncontrolled pancreatic exocrine insufficiency). Adequate wound healing and absence of infection are also required. Patients should have a PS of 0 to 1.

2. Patients must have adequate hepatic and renal function with sufficient hematologic parameters to undergo cytotoxic therapy.
3. Restaging CT scans are obtained just prior to initiation of adjuvant therapy generally performed 6 to 10 weeks postoperatively. A serum CA19-9 level twice the upper limit of normal precludes patients from enrollment on adjuvant therapy on in-house protocols. Recent retrospective analysis suggested that 5% to 10% of patients who undergo surgery at MDACC will have early radiographic or serologic evidence of relapsing disease prior to initiation of adjuvant therapy. When this occurs, any further therapy is not considered adjuvant.
4. Chemotherapy plus or minus chemoradiation remains the foundation of adjuvant therapy.

At MDACC, patients are encouraged to enroll in postoperative trials of adjuvant therapy. To extrapolate from the experience in locally advanced unresectable disease, patients benefiting from chemoradiation are those who have experienced stable disease with induction chemotherapy. Therefore, our approach at this time includes induction chemotherapy with gemcitabine or a gemcitabine-based doublet for 3 months followed by restaging scans. If no radiographic or serologic evidence of relapse is present at that time, chemoradiation with 5-FU or capecitabine is advised. Radiation is administered in a dose of 50.4 Gy in 28 fractions.

Once postoperative therapy has been completed, patients are followed with restaging CT scans, chest x-ray, physical examination, and standard laboratory tests, including CA19-9 every 6 months for the first 5 years and annually thereafter. A rising CA19-9 after adjuvant therapy does not trigger further systemic therapy until clear evidence of relapse based on physical examination or radiographic studies. Scanning by PET is considered in this situation.

MDACC Approach to Preoperative Therapy

Patients with clinical and radiographic evidence of potentially resectable disease are generally advised to receive protocol-based preoperative therapy, which typically involves chemoradiation. Chemoradiation regimens have varied, and our most encouraging results have been achieved with our gemcitabine-based regimen. After chemoradiation is completed, patients are allowed to recover over 4 to 5 weeks prior to restaging studies. For patients with no clinical or radiographic

evidence of metastatic disease and no contraindications to surgery, laparotomy proceeds. At the time of exploration, when no visible evidence of distant disease is encountered, pancreaticoduodenectomy is performed. Postoperatively, further chemotherapy or radiation may be delivered based on the final pathology and the consensus of the multidisciplinary group. Patients are then followed expectantly with periodic restaging studies as outlined previously. Patients who relapse with adequate PS are offered further systemic therapy on or off protocol.

It is important to emphasize that we do not deliver preoperative therapy as a means of staging the primary tumor downward. The medical literature has scattered reports of neoadjuvant therapy being used to successfully stage down patients with locally advanced disease to the point of resectability⁽⁶²⁾. Caution is advised in interpreting these results because we believe it is possible to stage down patients with borderline or marginally resectable tumors (tumors that abut but do not encase the celiac artery or SMA). These tumors represent a discrete subset; their management, while similar, is more tailored. Figure 21-4 displays an algorithmic approach for resectable pancreatic cancer.

MDACC Approach to Patients With Borderline Resectable Pancreatic Cancer

As high-quality, dynamic-phase, helical CT scanning has developed, an appreciation for the existence of a distinct subset of tumors best described as borderline resectable or marginally resectable has emerged. In this situation, some authorities believe that up-front surgery is more likely to lead to an R1 or R2 rather than an R0 resection. This entity is defined as ≤ 180 tumor abutment of the SMA or celiac axis, short segment abutment or encasement of the common hepatic artery that is amenable to segmental resection and reconstruction, or short segment occlusion of the SMV, PV, or SMV-PV confluence with a normal SMV below and PV above the tumor to allow for reconstruction⁽⁶³⁾. Up to 40% of patients with borderline resectable disease have been seen at MDACC, and these patients have a median survival of more than 40 months.

At MDACC, patients with marginally resectable tumors are typically treated with gemcitabine-based chemotherapy for an indefinite period of time, with restaging studies every 2 months. Treatment is continued to maximum benefit, as defined by a nadir in the CA19-9 level or best radiographic response. Thereafter, chemoradiation is delivered, and subsequent restaging studies are performed about 4 to 6 weeks after treatment is complete. Surgery will proceed if there has been some evidence of tumor response, and if no interval development of metastatic disease is apparent, an attempt at surgery will proceed. It remains

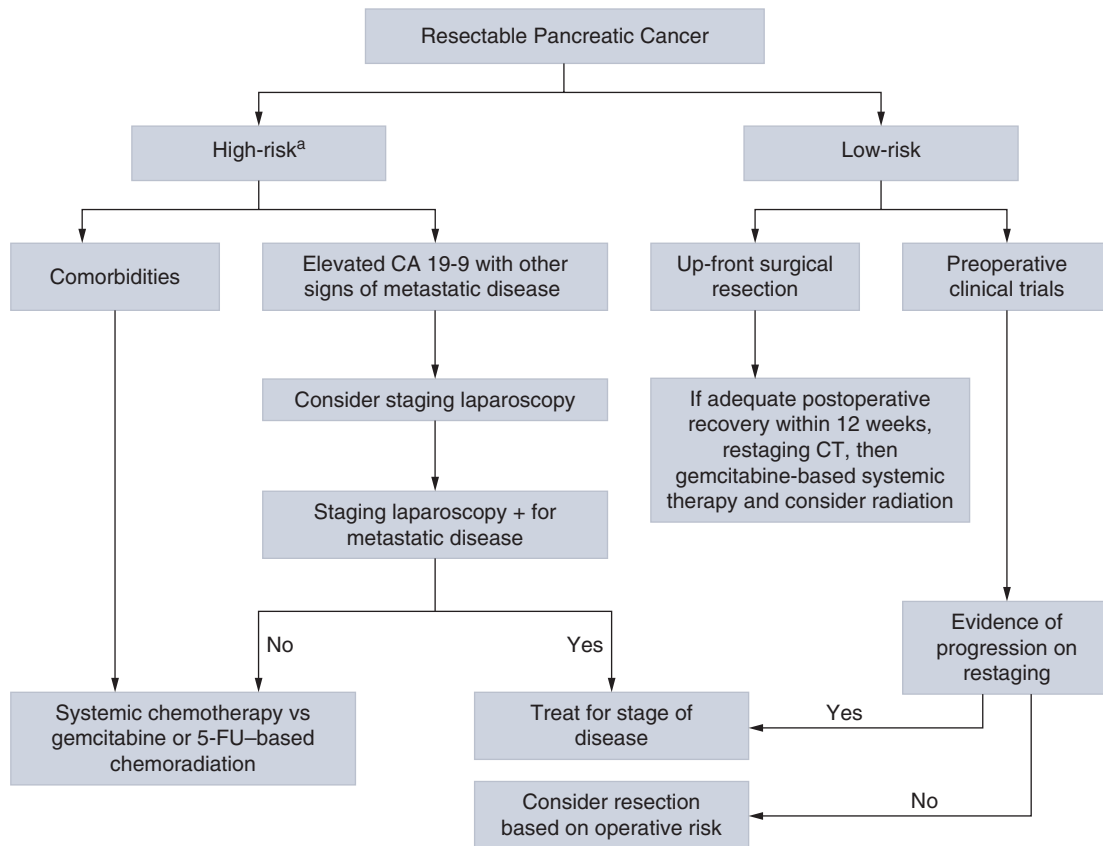

FIGURE 21-4 Treatment algorithm for the management of resectable pancreatic cancer. ^aHigh-risk clinical features: suspicion of metastatic disease; CA19-9 >1,000 with normal bilirubin; comorbidities suggesting high operative risk.

unclear whether the staging of such tumors downward to technical resectability is of biological significance; therefore, at least 6 months generally elapse at MDACC prior to the contemplation of surgery.

Management of Patients With Locally Advanced Disease

Patients are defined as having locally advanced pancreatic cancer when there is radiographic evidence of SMA or celiac artery encasement, occlusion of the SMV-PV confluence, or significant involvement of the common hepatic artery originating from the celiac trunk. There should be no clinical or radiographic evidence of metastatic disease. Currently, roughly half of all patients present with locally advanced disease. As with resectable pancreatic cancer, an understanding of certain principles will aid in decision making.

1. Locally advanced pancreatic cancer typically progresses over the course of some months. Local tumor progression with worsening pain, new or recurrent biliary obstruction, and gastric outlet obstruction represent difficult management problems. Development of metastatic disease is usually associated with worsening functional status and,

unless preceded by a long progression-free interval, is rarely responsive to further therapy.

2. Assessment of response to therapy can be challenging. These tumors may be composed of small nests of adenocarcinoma surrounded by large areas of desmoplasia (Fig. 21-5). Even when cytotoxic therapy is effective, the desmoplastic component of the residual mass may not regress, and the overall tumor mass may appear unchanged. Furthermore, distinguishing the primary tumor mass from surrounding inflammatory changes can complicate the reliable measurement of tumors.
3. All surgical interventions should be considered carefully and be based on PS and life expectancy. Palliative nonsurgical procedures may produce results similar to those of aggressive surgery.
4. One of the primary reasons for considering chemoradiation for patients with locally advanced disease is palliation of pain. However, the clinical benefit associated with chemoradiation has not been rigorously studied. Minsky et al reported significant variations in the estimation of pain relief, with 31% to 77% of patients having improvement in pain after receiving chemoradiation for unresectable disease ⁽⁶⁴⁾.

FIGURE 21-5 Photomicrograph of ductal adenocarcinoma of the pancreas with intense desmoplastic reaction. Even if the tumor cells regress in response to therapy, a residual fibrotic mass may remain. This confounds assessment of response to therapy using standard radiographic criteria.

Data Regarding Chemoradiation Based on 5-Fluoruracil

Support for chemoradiation originates from studies performed by the GITSG. In the original study, patients with locally advanced pancreatic cancer were randomly assigned to receive 40 Gy of radiation plus 5-FU, 60 Gy plus 5-FU, or 60 Gy alone. The median survival was 10 months in each of the chemoradiation groups and 6 months for patients who received 60 Gy without 5-FU (⁶⁵). Of note, these patients had undergone laparotomy and were surgically staged. Only those patients with disease confined to the pancreas and peripancreatic organs, regional lymph nodes, or regional peritoneum were eligible for the study. While this made for a more uniform study population, it also introduced significant selection bias: Enrollment was limited to rapidly recovering patients. In subsequent GITSG studies, neither doxorubicin used as a radiation sensitizer nor multidrug chemotherapy with streptozocin, mitomycin, and 5-FU (SMF) alone or continued after chemoradiation was found to be superior to 5-FU-based chemoradiation (⁶⁶). Additional chemotherapy

after 5-FU-based chemoradiation increased toxicity without apparent therapeutic benefit.

In contrast to the results from the GITSG, an ECOG study suggested no benefit of chemoradiation over 5-FU alone (⁶⁷). The ECOG study randomly assigned patients with locally advanced or incompletely resected pancreatic adenocarcinoma to receive chemoradiation (40 Gy and 600 mg/m²/d 5-FU for 3 days) or 5-FU alone (600 mg/m²/week). As in the GITSG studies, all patients were surgically staged and entered in the study within 6 weeks of surgery. The median survival was 8.3 months in the group that received chemoradiation and 8.2 months in the group that received 5-FU alone.

More recent trials of chemoradiation for locally advanced pancreatic cancer have investigated continuous infusion 5-FU in combination with EBRT (external beam radiation). The ECOG performed a phase I study to determine the maximal tolerated dose (MTD) of prolonged infusional 5-FU when combined with EBRT to 59.4 Gy. The MTD of 5-FU was 250 mg/m²/d, with GI toxicity the dose-limiting factor (⁶⁸). A subsequent study conducted in Japan demonstrated the feasibility of utilizing low-dose continuous infusion 5-FU (200 mg/m²/d) over 5.5 weeks combined with a single course of EBRT to 50.4 Gy. This was followed by weekly 5-FU treatments until disease progression. The median survival of treated patients was 10 months, similar to that of patients treated with bolus 5-FU and EBRT in the GITSG trials (⁶⁹). Thus, while infusional 5-FU may provide greater radiosensitivity than bolus 5-FU, no clear survival advantage has been established. In general, for selected patients, treatment programs consisting of EBRT and chemotherapy may result in median survivals of approximately 10 to 12 months and a 2-year survival rate of 20%. Long-term survivors are rare.

Concurrent Chemoradiation Versus Systemic Chemotherapy

Chemoradiotherapy was compared with chemotherapy in a randomized trial by the French Fédération Francophone de Cancérologie Digestive (FFCD) group. In this study, chemoradiotherapy was administered in a dose of 60 Gy concurrently with cisplatin and 5-FU (continuous infusion at 300 mg/m²/d). The chemotherapy arm consisted of gemcitabine (1,000 mg/m²/week). Surprisingly, the overall survival was shorter in the chemoradiotherapy arm (⁷⁰). Higher grade 3 to 4 toxicity rates were observed in the chemoradiotherapy arm compared with the chemotherapy arm (66% vs 40%, respectively), which may partially account for the worse survival.

In 2008, ECOG 4201 compared chemoradiotherapy and chemotherapy alone in a phase III trial. Patients with locally unresectable disease were randomly assigned between chemoradiotherapy with concurrent

gemcitabine followed by gemcitabine and gemcitabine alone. In the chemoradiotherapy arm, the total radiotherapy dose was 50.4 Gy with concurrent gemcitabine (600 mg/m²/week). The inclusion of 316 patients was planned, but the study closed after the inclusion of 74 patients because of low accrual. Median overall survival was slightly better in the chemoradiotherapy arm (11 vs 9.2 months, $P = .044$) (⁷¹). These results should be considered cautiously because of the limited number of patients included. A literature-based meta-analysis concluded that overall survival was not significantly different after chemoradiotherapy or chemotherapy (⁷²).

At the 2013 annual American Society of Clinical Oncology (ASCO) conference, Hammel and colleagues presented the final results of the phase III international LAP 07 study (⁷³). The objective was to determine whether consolidative chemoradiotherapy affected overall survival in patients with inoperable locally advanced pancreatic cancer when tumors were controlled after 4 months of induction gemcitabine-based chemotherapy. Patients were randomly assigned to gemcitabine (1,000 mg/m²/week \times 3) or gemcitabine plus erlotinib (100 mg/d) for 4 months. Participants with controlled disease were subsequently randomly assigned to further chemotherapy or chemoradiation (54 Gy [5×1.8 Gy/d] and capecitabine 1,600 mg/m²/d). Of the 442 patients initially randomly assigned, 269 patients (61%) entered the second-round randomization phase. A planned interim analysis was conducted after a median follow-up of 36 months and 221 deaths. Median overall survival in the chemotherapy arm was 16.4 months compared with 15.2 months for the chemoradiation group (hazard ratio [HR] 1.03, 95% CI, 0.79-1.34, $P = .8295$). It appeared neither radiation nor erlotinib improved survival in this population (⁷³). However, administration of radiation did delay the institution of second-line chemotherapy for progressive disease, which had an impact on quality of life.

Integration of Novel Agents Into Concurrent Chemoradiation Strategies

Given the limited benefit noted with 5-FU-based chemoradiation, there has been an effort to incorporate alternative agents into concurrent therapies, including gemcitabine, paclitaxel, capecitabine, and targeted agents, including bevacizumab, cetuximab, and erlotinib. Because of its role in metastatic disease, gemcitabine with EBRT has been extensively investigated for patients with localized cancer. Currently, there is no compelling evidence to suggest improved survival using gemcitabine-based chemoradiation over 5-FU for patients with locally advanced disease. Li et al conducted a small randomized trial that directly compared 5-FU-based chemoradiation with gemcitabine-based chemoradiation. Median

survival for the 18 patients randomized to receive gemcitabine with EBRT was 14.5 months, compared with 6.7 months in 16 patients treated with 5-FU. This trial should be interpreted with caution, given the small sample size and poor outcome of patients treated with 5-FU and EBRT (⁷⁴). Another prospective study compared FU with cisplatin-gemcitabine-based chemoradiation and did not demonstrate any difference in overall survival (⁷⁵).

At present, there is no standard approach, dose, or schedule for gemcitabine combined with radiation. Based on completed phase I and II studies, we have defined the MTD of gemcitabine, associated toxicity, and the size of radiation port (⁷⁶). 5-Fluorouracil or capecitabine-based chemoradiation is now standard at MDACC for locally advanced pancreatic cancer.

At MDACC, investigations of novel agents used after chemoradiation have been conducted. In RTOG 0411, patients with locally advanced pancreatic cancer were treated with capecitabine, bevacizumab, and radiation followed by maintenance with capecitabine and bevacizumab. The overall median survival reported was 11 months, which is similar to previous RTOG trials that did not include bevacizumab (⁷⁷).

Systemic chemotherapy alone may improve both pain control and PS and avoids the GI toxicity associated with chemoradiation. For those patients with stable or responding disease after 4 to 6 months of treatment, chemoradiation is often delivered to maximize locoregional tumor control. Chemoradiation is applied only to the patients most likely to benefit as defined by the absence of disease progression during systemic therapy. This strategy was validated by the Groupe Cooperateur Multidisciplinaire en Oncologie (GERCOR) group, who performed a retrospective analysis of patients with locally advanced cancer who received chemoradiation. Investigators noted that 30% of patients developed metastatic disease after induction chemotherapy and were not candidates for radiation. The remaining 70% received continued chemotherapy or consolidative chemoradiation. The overall survival in the two groups was 12 and 15 months ($P = .0009$) and the progression-free survival was 7 and 11 months, respectively. These data support the strategy of consolidative chemoradiation following induction chemotherapy in patients with locally advanced disease (⁷⁸). Retrospective data from MDACC also strongly suggested that patients who have received induction chemotherapy have a better outcome than those receiving primary chemoradiation (⁷⁹).

MDACC Approach to Locally Advanced Pancreatic Cancer

For patients who have poor PS, supportive care is encouraged, and radiation is contraindicated. In the

subgroup of patients with significant pain related to the primary tumor, aggressive use of narcotics is initiated. For patients with poor tolerance of narcotics or inadequate pain control with their administration, celiac or splanchnic nerve block is recommended. Once pain control has improved, therapeutic options are discussed. In our institution, consolidative chemoradiation continues to be used in select cases after an informative discussion with the patient regarding the issues mentioned. When so chosen, at least 3 to 4 months of induction chemotherapy with a gemcitabine-based regimen followed by capecitabine or 5-FU and radiation is the favored approach. Figure 21-6 shows the MDACC protocol for treatment of patients with locally advanced disease.

Management of Metastatic Disease

Compared with patients having other common malignancies, such as cancer of the colon or breast, patients with advanced pancreatic cancer are often much more debilitated. Palliation remains the primary goal of therapy. Management of metastatic disease should be guided by the following principles:

1. The disease course may be quite dynamic, and the clinical status of a patient can change quickly. Patients therefore require frequent reassessment, whether or not they are undergoing cytotoxic therapy.

2. Pancreatic cancer is quite resistant to systemic therapy, and responses to therapy are rarely observed in patients with poor PS or high tumor burden.
3. Peritoneal disease is usually not responsive to chemotherapy and carries a particularly poor prognosis. Metastatic disease predominantly located in the liver or lung is more likely to be responsive to systemic therapy. When the disease is metastatic to the lung only, its course may be somewhat more indolent.
4. Improvement in the treatment for pancreatic cancer is desperately needed, and patients with good PS should be encouraged to participate in clinical trials.

Systemic Therapy for Metastatic Disease—Lessons From the Past

Early published data frequently reported response rates to chemotherapy exceeding 20%. However, with the advent of high-quality CT and MRI, substantially lower response rates have been reported. Importantly, cooperative group studies dating to the 1980s have not clearly demonstrated meaningful survival advantage for patients treated with single-agent chemotherapy compared with 5-FU combinations or even best supportive care. Thus, for many years, no standard drug or drug regimen had emerged as an accepted frontline therapy for metastatic pancreatic cancer.

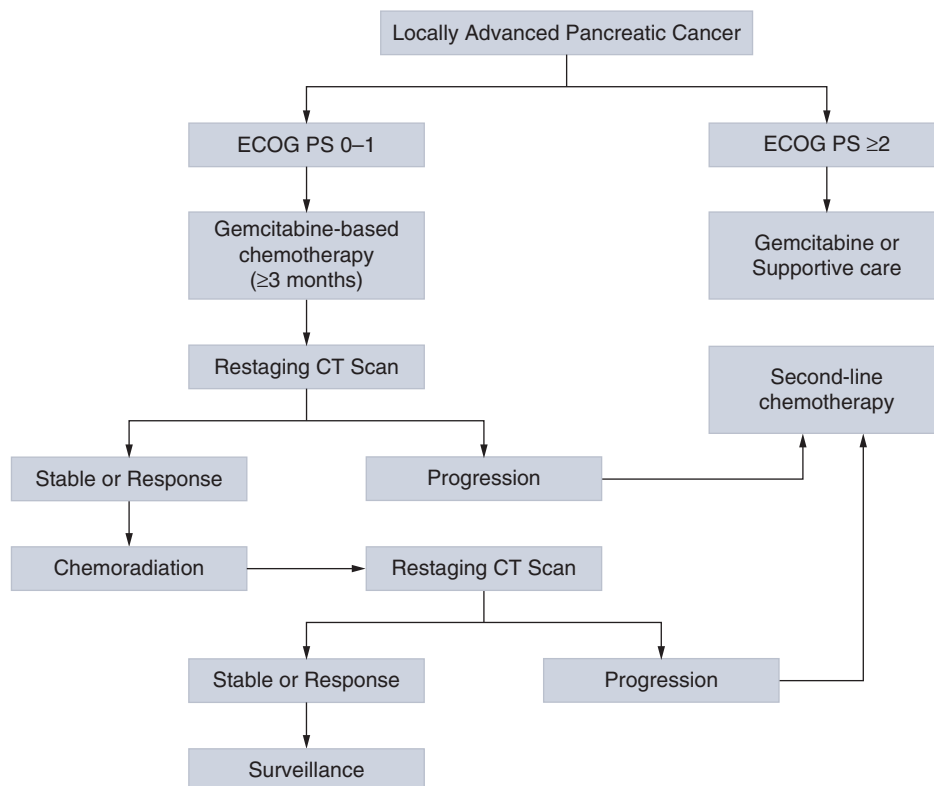

FIGURE 21-6 Treatment algorithm applied to the management of patients with locally advanced pancreatic cancer.

Gemcitabine for Metastatic Pancreatic Cancer

Chemotherapy for pancreatic cancer changed with the advent of gemcitabine, which was developed in the 1990s. In an early multicenter trial of gemcitabine in 44 patients, 5 objective responses (11%) were documented⁽⁸⁰⁾. In another study, gemcitabine again led to few objective responses (2 of 32 patients), but symptomatic improvement was also reported⁽⁸¹⁾. Based on these observations, two subsequent trials of gemcitabine for advanced pancreatic cancer were completed. In the randomized trial that led to gemcitabine's approval in the United States, weekly gemcitabine was compared to bolus weekly 5-FU in previously untreated patients⁽⁸²⁾. Patients treated with gemcitabine achieved a higher response rate (5.4% vs 0%) and a statistically significant improvement in median survival compared to those treated with 5-FU (5.65 vs 4.41 months, $P = .0025$). The 1-year survival rate for gemcitabine-treated patients was 18%, compared to 2% for those treated with 5-FU. Importantly, more clinically meaningful effects on disease-related symptoms were recorded with gemcitabine. This trial enrolled a heterogeneous patient population, with patients having either locally advanced, unresectable disease or metastatic disease. About 70% of the treated patients had metastatic pancreatic cancer, and this is the basis for its use as frontline therapy in patients with disseminated disease.

Fixed-Dose-Rate Gemcitabine

Gemcitabine is a prodrug that is phosphorylated to its active metabolites gemcitabine diphosphate and triphosphate. Gemcitabine diphosphate inhibits ribonucleotide reductase, thereby depleting intracellular pools of the triphosphate nucleotides. Gemcitabine triphosphate can incorporate into an elongating chain

of DNA and lead to premature chain termination and cell death. Gemcitabine triphosphate may also inhibit normal DNA repair mechanisms. This may explain its potent radiosensitizing properties and synergy with other DNA-damaging cytotoxic agents.

Once phosphorylated intracellular concentrations are highest when the drug is given at a fixed-dose rate (FDR) of 10 mg/m²/min. A randomized phase II trial in metastatic pancreatic cancer demonstrated that gemcitabine given at 2,300 mg/m² over 30 min compared to 1,500 mg/m² delivered over 150 min (10 mg/m²/min) led to a higher objective response rate (16.2 vs 2.7%) and a trend toward improved survival (6.1 vs 4.7 months)⁽⁸³⁾. Therefore, when used off protocol, it is administered at an FDR.

Gemcitabine Combinations: Cytotoxic Agents

In an effort to build on gemcitabine for advanced cancer, one approach has been to combine gemcitabine with other cytotoxic drugs. In addition, regimens using two to four other drugs with gemcitabine are reported in the literature. These include combinations of gemcitabine, capecitabine, and docetaxel (GTX) and gemcitabine, 5-FU, leucovorin, irinotecan, and cisplatin (G-FLIP). Randomized trials of gemcitabine versus gemcitabine-based doublets of cytotoxic therapy have shown no statistically significant survival advantage (Table 21-7). However, gemcitabine combined with a platinum does appear to have some benefit in patients with good PS⁽⁸⁴⁾.

Recent Trials Evaluating Combination Therapy

Cancer and Leukemia Group B (CALGB) 89904 was a four-arm phase II study comparing FDR gemcitabine

Table 21-7 Summary of Trials Combining Gemcitabine With a Second Cytotoxic Agent

Author, Year	Number of Patients	% of Patients With Metastatic Disease	Control Arm Median Survival (Months)	Combination Therapy Median Survival (Months)	P Value

5-FU, 5-fluorouracil; Gem, gemcitabine.

with the gemcitabine doublets cisplatin, docetaxel, and irinotecan. Six-month survival, the primary end point, did not differ significantly between the four arms (range 53%-57%)⁽⁸⁵⁾. Overall survival was also similar across groups. A phase III trial combining gemcitabine and cisplatin had a non-statistically significant improvement in progression-free and median survival over single-agent gemcitabine (median survival 7.5 vs 6.0 months, $P = .15$)⁽⁸⁶⁾. Similarly, a phase III trial evaluating the combination of gemcitabine and irinotecan versus gemcitabine alone failed to demonstrate a survival advantage over gemcitabine⁽⁸⁷⁾.

Previously, the GERCOR/GISCAD (Italian Group for the Study of Digestive Tract Cancer) phase III trial with FDR gemcitabine and oxaliplatin demonstrated a statistically significant higher response rate and progression-free survival in patients with locally advanced and metastatic disease; however, overall survival did not reach statistical significance (9.0 vs 7.1 months, $P = .13$)⁽⁸⁸⁾. ECOG 6201 enrolled 832 patients in three arms: gemcitabine in a 30-minute infusion, FDR gemcitabine, and FDR gemcitabine with oxaliplatin. Overall survival was not statistically different between the three groups: 4.9, 6.2, and 5.7 months, respectively⁽⁸⁹⁾.

It was not until September 2013 when the Food and Drug Administration (FDA) first approved a gemcitabine-based combination chemotherapy regimen with nab-paclitaxel. This was based on a follow-up phase III study published in the *New England Journal of Medicine* that showed an overall survival advantage of gemcitabine plus nab-paclitaxel over gemcitabine alone (8.5 months vs 6.7 months, HR for death, 0.72; 95% CI, 0.62 to 0.83; $P < .001$). The 1-year survival rates were 35% versus 22%, respectively. The response rate according to independent review was 23% versus 7% in the two groups ($P < .001$). The combination arm did have increased neutropenia, fatigue, and neuropathy⁽⁹⁰⁾.

Capecitabine, the orally bioavailable fluorinated pyrimidine, when combined with gemcitabine, demonstrated a modest clinical benefit over gemcitabine alone and appeared to improve median overall survival in patients with good PS⁽⁹¹⁾. In a phase III trial, Cunningham and colleagues randomized patients to receive gemcitabine versus gemcitabine plus capecitabine (gemcitabine 1,000 mg/m² IV weekly \times 3 every 4 weeks; capecitabine 1,660 mg/m²/d by mouth for 3 weeks and 1 week's rest)⁽⁹²⁾. The addition of capecitabine to gemcitabine significantly improved overall response rate and progression-free survival ($P = .03$ and $.004$, respectively) and trended toward an improved overall survival ($P = .08$).

Based on preclinical data showing effectiveness of combination chemotherapy in solid tumors, investigators tested a combination chemotherapy regimen consisting of oxaliplatin, irinotecan, fluorouracil,

and leucovorin (FOLFIRINOX) as compared with gemcitabine. There was random assignment of 342 patients with an ECOG PS of 0 or 1 to receive FOLFIRINOX (oxaliplatin, 85 mg/m² body surface area; irinotecan, 180 mg/m²; leucovorin, 400 mg/m²; and fluorouracil, 400 mg/m² given as a bolus followed by 2,400 mg/m² given as a 46-hour continuous infusion every 2 weeks) or gemcitabine at a dose of 1,000 mg/m² weekly for 7 of 8 weeks and then weekly for 3 of 4 weeks. The primary end point was overall survival. The median overall survival was 11.1 months in the FOLFIRINOX group as compared to 6.8 months in the gemcitabine group (HR for death, 0.57; 95% CI, 0.45 to 0.73; $P < .001$). The objective response rate was also improved in the FOLFIRINOX group, 31.6% versus 9.4% ($P < .001$). More adverse events were noted in the FOLFIRINOX group. At 6 months, 31% versus 66% of patients in the FOLFIRINOX versus gemcitabine group had a definitive degradation of the quality of life (HR, 0.47; 95% CI, 0.30 to 0.70; $P < .001$)⁽⁹³⁾.

FUTURE DIRECTIONS OF CHEMOTHERAPY IN PANCREATIC CANCER

Molecular Therapeutics for Pancreatic Cancer

While other cytotoxic drugs may provide some survival benefit when combined with gemcitabine, patient outcomes are predicted to be relatively small. Therefore, the investigation of targeted molecular therapies should be given priority. Treatment strategies being developed include interruption or modulation of known growth factors and signal transduction pathways involved with cell growth, invasion, and angiogenesis.

Epidermal Growth Factor Receptor Inhibition

Antibodies to the *EGFR* have been shown to compete with the growth-stimulatory ligands for binding to this receptor. Small molecular inhibitors of the tyrosine kinase activity of the *EGFR* have also been developed in a variety of solid tumors, including pancreatic cancer. In a large international phase III trial, erlotinib, an oral small molecule inhibitor of *EGFR*, in combination with gemcitabine led to a slightly longer median survival compared to gemcitabine alone (6.24 vs 5.91 months, $P = .038$)⁽⁹⁴⁾. Importantly, treatment-related toxicities were not significantly worse for the patients receiving the combination compared to monotherapy. This trial resulted in FDA approval for erlotinib in metastatic pancreatic cancer; it remains

the only targeted agent approved for this disease to date. Subsequent studies combining the anti-*EGFR* antibody cetuximab have been less successful. Southwest Oncology Group (SWOG) S0205, a phase III trial evaluating gemcitabine with cetuximab, reported an overall survival of 6 months for gemcitabine versus 6.5 months for the combination ($P = .14$). Progression-free survival and response rates were similar between the arms ⁽⁹⁵⁾.

Antiangiogenic Agents

Tumor angiogenesis is important in the establishment and progression of metastatic implants. It is now generally accepted that inhibition of these factors represents a feasible approach to impeding metastasis. One cytokine believed to be central to angiogenesis is VEGF, which is often overexpressed in pancreatic cancer. Inhibition of VEGF may have two roles: blocking VEGF receptors to inhibit tumor growth and impeding angiogenesis.

Bevacizumab, an anti-VEGF antibody, has been investigated in patients with advanced pancreatic cancer. Phase II data demonstrated promising response rates ranging from 11% to 24% and overall survivals of 8.1 to 9.8 months ⁽⁹⁶⁾. Unfortunately, a randomized phase III trial, CALGB 80303, did not mirror these results. Patients were assigned to receive gemcitabine alone versus gemcitabine plus bevacizumab (10 mg/kg). Median overall survival was similar (5.2 vs 5.8 months), with no significant improvement in response rate or progression-free survival ⁽⁹⁷⁾. More recently, a multicenter randomized phase III trial with gemcitabine, bevacizumab, and erlotinib was reported and also did not show a significant improvement in survival when compared to gemcitabine, erlotinib, and placebo (7.1 vs 6.0 months; HR 0.89; 95% CI, 0.74-1.07; $P = .2087$) ⁽⁹⁸⁾. There was, however, a significant improvement in progression-free survival (4.6 vs 3.6 months; HR, 0.73; 95% CI, 0.61-0.86; $P = .0002$).

Insulinlike Growth Factor Type 1 Targeted Therapies

The IGF-1 clinical trial with ganitumab showed a trend toward improved 6-month and overall survival when combined with gemcitabine as compared with gemcitabine plus placebo ⁽⁹⁹⁾. On the other hand, the addition of cixitumumab to gemcitabine plus erlotinib did not improve survival when compared with gemcitabine and erlotinib ⁽¹⁰⁰⁾. Our randomized phase II study of dalotuzumab showed promising activity when combined with gemcitabine as compared with gemcitabine plus erlotinib. Final analysis of correlative studies from this trial is under way.

Stromal Reengineering and Targeted Therapy

The traditional view of pancreatic cancer stroma has been as a hindrance to delivery of chemotherapy and accounting for the adverse prognosis associated with this cancer. Hedgehog inhibitors were particularly effective in causing stromal depletion ⁽¹⁰¹⁾. This theory, however, was disproven in the clinical setting, with randomized trials of two hedgehog inhibitors, IPI-926 and vismodegib, failing to improve survival when added to gemcitabine as compared with gemcitabine alone. Kalluri et al, from MDACC, recently showed that stromal depletion in genetic engineered mouse models resulted in accelerated tumor growth. In addition, they showed that stromal-depleted pancreatic cancers were sensitive to the CTLA-4 (cytotoxic T lymphocyte-associated antigen 4) antibody ipilimumab ⁽¹⁰²⁾. Similar findings were reported by Rhim et al, who demonstrated that stroma is protective in pancreatic cancer, and deletion of sonic hedgehog accelerated tumor growth; this effect was again reproduced by treatment with smoothened inhibitor ⁽²³⁾. Stroma as a target for therapy continues to be investigated in the clinic.

A recently investigated stromal component is the extracellular matrix component hyaluronan. Enzymatic depletion of hyaluronan by the pegylated hyaluronidase (PEGPH20) resulted in inhibition of cancer growth and prolonged survival when combined with gemcitabine in preclinical studies ⁽¹⁰³⁾. Currently, PEGPH20 is at an advanced stage of clinical development in combination with gemcitabine and nab-paclitaxel.

Second-Line Therapy for Pancreatic Cancer

There is an increasing recognition that second-line therapies have been inadequately researched in pancreatic cancer, representing an important avenue for drug development. Irinotecan liposome injection (MM-398) is a nanoliposomal encapsulation of irinotecan that has been successfully combined with 5-FU in a phase III study (NAPOLI-1) in the second-line setting for pancreatic cancer. The MM-398 with 5-FU and leucovorin achieved an overall survival of 6.1 months compared to 4.2 months' survival with 5-FU and leucovorin in those who progressed on gemcitabine (HR = 0.67, $P = .012$) ⁽¹⁰⁴⁾.

Another exciting development in second-line therapy is with ruxolitinib, a JAK1/2 inhibitor that is approved for the treatment of myelofibrosis. In the randomized phase II trial, patients with metastatic pancreatic cancer who had progressed on first-line gemcitabine received capecitabine with ruxolitinib or placebo ⁽¹⁰⁵⁾. On subgroup analysis, patients with a high C-reactive protein level—who represented 50%

of the total patient population—had a 6-month survival rate of 42% compared with 11% with placebo (HR = 0.47; $P = .005$). Interestingly, patients on ruxolitinib also experienced improved weight gain.

Immunotherapy for Pancreatic Cancer

Immune therapy has finally come of age, and immune targeting is rapidly changing the course of multiple cancers. Both innate and adaptive immune systems are involved in the immunosurveillance mechanisms, which include cytotoxic CD8 T cells, T helper 1 (Th1) cells, dendritic cells, tissue macrophages (M1), and natural killer cells. Cancers must escape these surveillance mechanisms to grow and have a clinically significant impact⁽¹⁰⁶⁾. Preclinical models of pancreatic cancer have informed us that immunosuppressive tumor-associated macrophages (TAMs), Treg cells, along with scarce effector (CD8) T cells occur at even the earliest preinvasive stages and persist through the development of invasive cancer. High concentrations of CD8 T cells, when infrequently present in pancreas cancer, are associated with a good prognosis⁽¹⁰⁷⁾.

Current immunotherapy approaches for pancreatic cancer have yielded promising results that are being investigated in clinical trials. These approaches include checkpoint inhibitors, pancreatic cancer vaccines, adoptive T-cell transfer, monoclonal antibodies acting at the immune checkpoint level, cytokines, and Treg depletion. Immune checkpoint targeting has the potential of changing the treatment paradigm for melanoma, non-small cell lung cancer, and gastric cancer. These agents either alone or in combination are currently in clinical trials.

In regard to checkpoint inhibitors, ipilimumab has been investigated in 27 cases of pancreatic adenocarcinoma, and one delayed response occurred. The PD1 antibody was studied in an expansion cohort of pancreatic cases ($n = 14$) without any therapeutic responses⁽¹⁰⁶⁾. These data, while discouraging, have highlighted the fact that predictive criteria for checkpoint inhibitors are needed. The CD40 agonist was combined with gemcitabine in a study, with four objective responses seen (of the 22 patients treated), and a greater number had metabolic responses on FDG-PET imaging⁽¹⁰⁸⁾. Anti-OX40 antibodies and IDO inhibitors are currently undergoing testing as well.

Algenpantucel-L, also known as hyperacute pancreatic adenocarcinoma vaccine, is a composite of two irradiated, live, human allogeneic pancreatic cancer cell lines that express murine α -1,3-galactosyl transferase. This results in α -galactosylated epitopes on cell surface proteins, which result in an immune response. A phase II study of this agent, in combination with gemcitabine and radiotherapy, for resected pancreatic cancer resulted in a 1-year overall survival of 86% and

disease-free survival of 62%⁽¹⁰⁹⁾. An increased anti-calreticulin antibody (anti-CALR Ab) level following algenpantucel-L treatment correlated with a statistically significant improvement in overall survival (35.8 months in patients with elevated levels of anti-CALR Ab vs 19.2 months in patients without elevated levels; $P = .03$). The addition of algenpantucel-L to standard adjuvant therapy for resected patients has been investigated in a phase III clinical study, and the results are anticipated.

Immunotherapy agent GVAX is composed of two irradiated, granulocyte-macrophage colony-stimulating factor (GM-CSF)–secreting allogeneic pancreatic cancer cell lines administered after treatment with low-dose cyclophosphamide (Cy/GVAX) to inhibit Treg cells. The GVAX induces T cells against numerous cancer antigens, including mesothelin-specific T-cell responses. CRS-207 is recombinant live-attenuated *Listeria monocytogenes* engineered to secrete mesothelin into antigen-presenting cells. These vaccines demonstrated synergistic activity in both antigen-specific T-cell induction and antitumor activity in preclinical models. These two vaccines were investigated in a randomized phase II trial for previously treated patients. This randomized study demonstrated that Cy/GVAX followed by CRS-207 significantly improved overall survival as compared with Cy/GVAX alone in patients with metastatic pancreatic cancer (6.1 months with Cy/GVAX followed by CRS-207 vs 3.9 months with Cy/GVAX alone [HR, 0.59; $P = .02$])⁽¹¹⁰⁾. In this study, mesothelin-specific T-cell immune responses correlated with improved survival. This strategy is now being investigated in a phase III randomized study.

Bruton tyrosine kinase (Btk) is a nonreceptor enzyme of the Tec kinase family that is expressed in B cells, myeloid cells, and mast cells, where it regulates cellular proliferation, differentiation, apoptosis, and cell migration. Inhibition of Btk leads to preferential differentiation of macrophages into M1 instead of immunosuppressive M2 macrophages; Btk inhibition thus decreases the TAMs that promote tumor invasion and metastasis. The BTK inhibitor ibrutinib results in stromal suppression and inhibition of pancreatic tumor growth in preclinical models⁽¹¹¹⁾. Based on this rationale, the BTK inhibitor, ACP-196, is being investigated in the clinical setting for first- and second-line therapy at MDACC.

MDACC APPROACH TO THE PATIENT WITH METASTATIC DISEASE

Metastatic pancreatic cancer is a disease characterized by anorexia, cachexia, and pain. Therefore, palliation must always be the primary goal for this group of patients and is facilitated by a multidisciplinary

approach. Symptomatic relief of biliary obstruction and pain should be addressed prior to consideration of systemic therapy. If pain is not well controlled with oral or transdermal narcotics or if these agents are poorly tolerated, patients should undergo an evaluation with an anesthesiologist or neurologist to consider ablation of the celiac or splanchnic plexus. In addition to aggressive pain control efforts, other supportive measures should be considered, including appetite enhancers, antidepressants, and central nervous system stimulants.

Biliary obstruction should be relieved by nonsurgical means whenever possible, and we advocate the insertion of expandable metal stents rather than polyethylene biliary stents. On occasion, percutaneous biliary drainage may be required in the setting of extrahepatic biliary obstruction.

When a patient develops gastric outlet obstruction, we try to estimate the prognosis at that juncture. If life expectancy is greater than 12 weeks, surgical intervention for definitive gastric bypass is considered. For patients with end-stage metastatic disease, the use of duodenal stents is encouraged. For patients with intractable symptomatic ascites, it is important to realize that this may not be caused by carcinomatosis and frequently results from PV or SMV thrombosis. Ascites secondary to portal hypertension will respond to diuretics, including spironolactone, whereas malignant ascites requires repeated paracentesis or an indwelling peritoneal catheter. Gastroparesis is another commonly occurring problem that requires promotility agents and dietary and behavioral modification.

MDACC Approach to Systemic Therapy for Advanced Pancreatic Cancer

Systemic therapy for metastatic disease should be actively discouraged in patients with poor PS (ECOG >2) or significant metastatic burden. End-of-life discussions are appropriate at the time of diagnosis.

Whenever possible, patients with good PS should be treated with systemic therapy in a clinical trial. The current trial includes the addition of the Btk inhibitor ACP-196 to gemcitabine and nab-paclitaxel for the first-line treatment. In the second-line setting, we are initiating studies with ACP-196, an orally bioavailable, small molecule inhibitor of Btk in combination with the PD1 antibody pembrolizumab.

In terms of nonclinical trial options, after progression on FOLFIRINOX, gemcitabine-based regimens like gemcitabine plus nab-paclitaxel are considered. After gemcitabine and nab-paclitaxel, FOLFOX or single-agent capecitabine are preferred. Patients who have experienced disease stability or response with gemcitabine-based first-line therapy can be considered for second-line therapy with gemcitabine-based

combinations (such as gemcitabine, docetaxel, and capecitabine [GTX])⁽¹¹²⁾.

For patients who are not candidates for multiagent chemotherapy, gemcitabine as first-line therapy is reasonable. At MDACC, our off-protocol approach is to deliver FDR gemcitabine (600-1,000 mg/m²) at rate of 10 mg/m²/min weekly. The utility of erlotinib has significantly declined at this time but is a consideration in the first- or second-line setting in combination with gemcitabine. When an objective response or stable disease is observed, chemotherapy is usually continued until there is radiographic or clinical evidence of disease progression, with restaging studies generally performed every 8 to 12 weeks. Gemcitabine-platinum doublets are offered only to those patients with excellent PS and those with BRCA-associated pancreatic cancer.

In summary, clinically meaningful advances in the treatment of metastatic pancreatic cancer have occurred in the past 5 years. These developments have changed the treatment paradigm for patients experiencing modest but significantly improved survival and quality of life. Continued efforts to enroll patients with advanced disease into well-designed clinical trials should remain a high priority for oncologists.
