Primary infection prophylaxis	
<i>Pneumocystis carinii</i> , <i>Toxoplasma</i>	Trimethoprim-sulfamethoxazole 1 DS daily. Alternatives for patients with allergy to Bactrim-DS are dapsone 100mg PO once a day or atovaquone 1500mg once a day with food.
Oral and/or esophageal candidiasis	Fluconazole 100 mg daily
MAI complex (CD4 <50 cells/μL)	Azithromycin 1,200 mg weekly
Secondary infection prophylaxis	
Herpes simplex infections	Acyclovir 400 mg bid or 200 mg tid
Cytomegalovirus infection	Ganciclovir 1 g tid
<i>Mycobacterium avium</i> complex	Clarithromycin 500 mg bid plus ethambutol 15 mg/kg daily, with or without rifabutin 300 mg daily
<i>Toxoplasma gondii</i>	Sulfadiazine 1-1.5 g q6h, pyrimethamine 25-75 mg daily
	Leucovorin 10-25 mg daily-qid
<i>Cryptococcus neoformans</i>	Fluconazole 200 mg daily
<i>Salmonella</i> bacteremia	Ciprofloxacin 500 mg bid
Hematopoietic growth factors	
For selected patients in whom the risk of febrile neutropenia ≥40%	G-CSF 5 μg/kg or GM-CSF 250 μg/m ² SC daily beginning after completion of chemotherapy and continuing until neutrophil recovery
Antiretroviral agents	
Selecting patients for therapy	*Follow NIH guidelines
Role of therapy in controlling malignancy	
Kaposi sarcoma	Essential
Lymphoma	Unknown
Other tumors	Unknown
May be used with myelosuppressive drugs	General principles of HIV treatment: An INSTI, NNRTI, or PI combined with 2 NRTIs. First Choice: NRTIs: emtricitabine/tenofovir (Truvada) or abacavir/lamivudine (Epzicom); with an INSTIs: dolutegravir or raltegravir. Second choice: NNRTIs: rilpivirine (weak CYP3A4 inducer); efavirenz. Efavirenz can be combined with emtricitabine/tenofovir in a single capsule (Atripla). Strong inducer of CYP3A4.
Avoid with myelosuppressive drugs/regimens	Zidovudine
Avoid with neurotoxic drugs/regimens	Didanosine, zalcitabine, stavudine
May alter the metabolism of cytotoxic drugs metabolized by cytochrome P-450 enzymes	All PIs and NNRTIs

bid, two times daily; DS, double strength; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; INSTI, integrase strand transfer inhibitor; MAI, *Mycobacterium avium-intracellulare*; NIH, National Institutes of Health; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTIs, nucleoside reverse transcriptase inhibitors; PI, protease inhibitor; tid, three times daily; qid, four times daily; SC, subcutaneous.

infected B cells most likely reach the CNS in increased numbers as a result of the progression of the HIV infection. There is loss of capacity by specific T cells for the production of IFN-γ in response to EBV peptides with increased expression of EBNA-2, LMPs, and EBERs

(EBV latency type III). This pattern is seen when EBV transforms primary B cells in vitro. The expression of type III latency upregulates genes involved in transformation, including *Bcl-2* and *IRF-7*, and inactivation of *p53* and *Rb* tumor suppressor gene products (⁵⁶).

FIGURE 44-3 Computed tomography positron emission tomography scan in a 51-year-old HIV-positive patient demonstrating extensive involvement by Burkitt lymphoma of the chest, abdomen, and pelvis.

Clinical Presentation and Diagnosis

Patients with AIDS and PCNSL present with acute organic brain syndrome, in contrast to immunocompetent patients, in whom neurologic deterioration can be slow and progressive. Headaches, seizures, and focal neurologic signs and symptoms are common. Personality changes are frequent, and nausea and vomiting indicate an increased intracranial pressure. When the rare comatose state occurs, it indicates an acute intracranial catastrophe, such as intratumoral hemorrhage.

Patients with a primary lesion in the brain and no history of systemic lymphoma usually have a brain lesion as the sole manifestation of the disease (Fig. 44-5). Radiologic diagnostic methods paired with analysis of the cerebrospinal fluid are the cornerstones of the diagnosis of PCNSL. Diagnostic MRI of the brain is preferred to CT scan because of the capacity of the former to detect small lesions. Whenever MRI is not available, CT scan is acceptable because it allows detection of larger lesions (≥ 1 cm) and provides information about safety of performing a lumbar puncture. Prior to and after HAART, the most important differential diagnosis of PCNSL has been cerebral toxoplasmosis, the

most frequent cause of cerebral infection and masses in severely HIV-immunosuppressed patients⁽⁵⁷⁾. In both PCNSL and cerebral toxoplasmosis, multiple lesions can occur, and both can also have enhancing ring lesions, so distinction between the two can be difficult. A positive serology for toxoplasmosis can be helpful if titers are $>1:256$. If the toxoplasmosis serology is negative, the presence of EBV DNA by PCR in the cerebral spinal fluid and a positive single-photon emission CT-thallium scan of the brain have high specificity for diagnosis of the PCNSL^(58, 59). More recently, flow cytometry examination of the cerebrospinal fluid has been used to detect occult disease⁽⁶⁰⁾.

During the early years of the AIDS pandemic, it was difficult to perform invasive procedures in patients afflicted by an infectious process of which little was known and much was feared. These difficulties resulted in a series of practices borne out of necessity rather than rational approaches to the management and treatment of these patients such as the routine empirical treatment of brain lesions with anti-toxoplasmosis therapy and gauging the diagnosis of the patient based on the clinical response to the anti-toxoplasmosis treatment. Today, there is little room for continuation

FIGURE 44-4 Same patient as in Fig. 44-3. The computed tomography positron emission tomography scan after four courses of hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone (hyperCVAD) alternated with high-dose methotrexate-ara-C and leucovorin rescue, reveals a dramatic improvement with no residual hypermetabolic activity. The patient went on to complete eight courses of treatment with hyperCVAD-HD methotrexate-Ara-C-leucovorin rescue. He remains in complete remission of the Burkitt lymphoma 4 years after treatment and on highly active antiretroviral therapy.

of such practices, and they should be avoided. They cause unnecessary delays in diagnosis and complicate the patient's management because there are potential side effects associated with treatment for an illness the patient may not have. Therefore, unless there is an absolute contraindication, the standard of care for a patient with a brain lesion and AIDS is the performance of a stereotactic biopsy of the brain, particularly in patients with a negative serology for toxoplasmosis.

Treatment of Primary Central Nervous System Lymphoma

Highly active antiretroviral therapy is the first step in the treatment of these patients. There is a clear correlation between the immune status of the patient and prognosis. The use of steroids and anticonvulsants is debated among some investigators concerned with the potential of steroids to confound the histologic diagnosis. However, a few days of steroids (4-5 days) can be of clinical benefit, particularly when there is an obvious mass effect. Anticonvulsive therapy administered

for a few days can allow the stabilization of the neurologic condition of the patient controlling the risk of focal or grand mal seizures. Even solitary lesions of PCNSL tend to infiltrate surrounding tissues. Thus, there is no role for surgical resection in the treatment of this disease.

Before HAART, whole-brain radiotherapy was standard of care for PCNSL, until replaced by best comfort measures, as the brains of severely immunocompromised patients tolerated poorly the administration of radiotherapy. Similarly to immunocompetent patients with PCNSL, high-dose methotrexate and rituximab have replaced the administration of radiotherapy in patients with HIV and PCNSL. Investigators have suggested a modification of a standard regimen used for the treatment of patients without HIV, which includes rituximab 500 mg/m² on day 1 and methotrexate 3.5 g/m² and vincristine 1.4 mg/m² given only on day 2. Leucovorin rescue is given in standard fashion, and HAART treatment is initiated or continued. This modified regimen is administered for five to six cycles depending on the tolerance of the patient followed by four courses of

Table 44-6 Short-Course Dose-Adjusted EPOCH^a

Drug	Dose	Route	Treatment Days
Infused agents ^b			
Etoposide	50 mg/m ² /d	CIV	1, 2, 3, 4 (96 h)
Doxorubicin	10 mg/m ² /d	CIV	1, 2, 3, 4 (96 h)
Vincristine ^c	0.4 mg/m ² /d	CIV	1, 2, 3, 4 (96 h)
Bolus agents			
Cyclophosphamide (cycle 1)	750 mg/m ² /d	IV	5
Cyclophosphamide dose adjustment (after cycle 1) ^d nadir ANC <500/μL or platelets <25,000/μL for 2 to 4 days.	↓ 187 mg/m ² . Route and treatment days remains unchanged. below previous cycle	NA	NA
If the nadir ANC <500/μL or platelets <25,000/μL for more than 5 days, reduce cyclophosphamide by 50% of the initial full dose.	375 mg/m ² below previous cycle. Under route and Treatment Days put NA.		
Prednisone	60mg/m ² /d	PO	1,2,3,4,5.
Rituximab	375 mg/m ²	IVPB	1 and 5.
Filgrastim	5 μg/kg/d	SC	6→ANC >5000/μL past nadir)
Next cycle ^e			Day 21

Intrathecal therapy: Intrathecal therapy with 12 mg of methotrexate or 100 mg of cytarabine is administered intrathecally on days 1 and 5 every 3 weeks beginning in cycle 3 for eight doses for patients without central nervous system involvement. For patients with central nervous involvement please refer to original reference.

ANC, absolute neutrophil count; BSA, body surface area; CIV, continuous intravenous infusion; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride; IV, intravenous; IVPB, intravenous piggyback; NA, not applicable; PO, oral; SC, subcutaneous.

^aData are for cycle 1 except where noted in "cyclophosphamide dose adjustment."

^bEtoposide, doxorubicin, and vincristine can be admixed in the same solution. Etoposide, doxorubicin, and vincristine are never dose-adjusted for hematologic toxicity.

^cVincristine dose should never be routinely capped.

^dDose based on previous cycle ANC nadir (complete blood count) twice-weekly) maximum cyclophosphamide dose, 750 mg/m².

^eBegin day 21 if ANC ≥ 1,000/μL and platelets ≥ 75,000/μL.

monthly maintenance with radiotherapy administered in a stereotactic manner at the discretion of the treating physician ⁽⁶¹⁾.

Hodgkin Lymphoma: An Aids-Defining Illness?

Epidemiology, Clinical Features, and Therapy

People infected with HIV have a 10-fold higher risk of developing HL than do HIV-seronegative persons. However, in contrast to KS and NHL, the risk is more pronounced in patients with HIV who only have moderate immunosuppression. In general, patients with HIV have a higher incidence of an unfavorable histology, including mixed cellularity and lymphocyte depletion subtypes of HL, when compared with that seen in patients without HIV infection. Instead of observing a decrease in HL in patients in the post-HAART era, as with certain NHL subtypes, investigators have noted an increase in the incidence of HL in HIV patients ⁽⁶²⁾. This observation has made the relationship between immunodeficiency and HL uncertain. Despite the WHO inclusion as an AIDS-defining malignancy, HL is not considered by most experts as a

true AIDS-associated disease. From the pathogenesis point of view, EBV is often associated with HIV-related HL, in the range of 80% to 100%. The Reed-Sternberg cells of HIV-related HL express the EBV-encoded LMP-1, known to have oncogenic properties ⁽⁶³⁾. In the post-HAART era, it has been postulated that an increase in CD4⁺ cells as a result of antiretroviral therapy fosters the development of the appropriate cellular milieu seen in HL in patients without HIV infection. These CD4⁺ cells, generated as a result of immune reconstitution by HAART, produce ligands for membrane receptors in the Reed-Sternberg cells that activate the classical NF-κB pathway ⁽⁶³⁾.

Clinically, patients with HIV and HL are young and have stage III or IV disease with B symptoms (fever, night sweats, and loss of >10% of body weight). Bone marrow involvement is frequent at the time of diagnosis ⁽⁶⁴⁾. In the pre-HAART era, the immunodeficiency of the patients limited the use of standard chemotherapeutic regimens in patients with HL. In the post-HAART era, the standards of care applicable to patients without HIV disease and HL have been applied successfully to patients with AIDS and HL once the HIV disease is controlled. Prior to HAART, Levine and colleagues in the ACTG evaluated the efficacy of ABVD

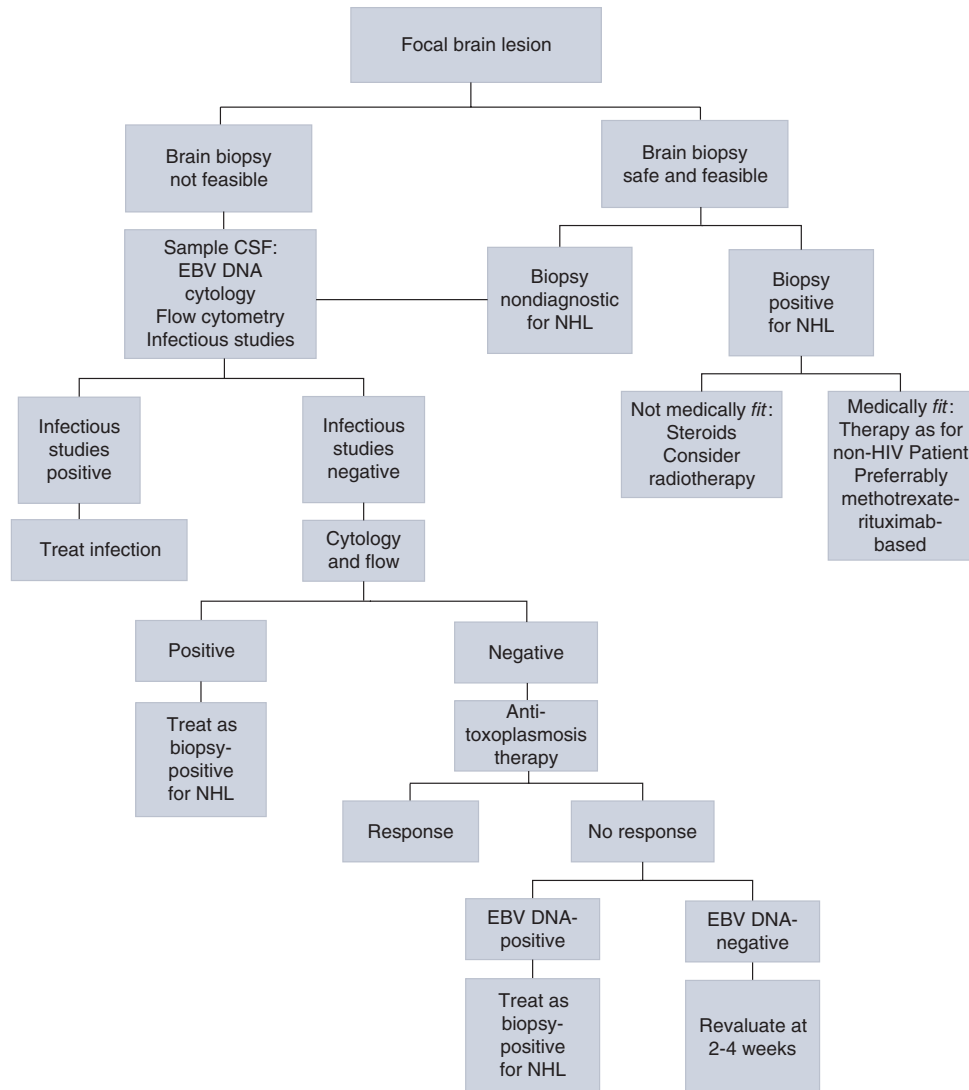

FIGURE 44-5 Evaluation of brain lesions in patients with human immunodeficiency virus (HIV) disease. CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; NHL, non-Hodgkin lymphoma. (Adapted with permission, from Sparano JA. Clinical aspects and management of AIDS-related lymphoma. *Eur J Cancer*. 2001;37:1296-1305.)

(doxorubicin, bleomycin, vinblastine, and dacarbazine) with G-CSF in 21 HIV-seropositive patients. There was an overall response rate of 62%, with 43% complete response and 19% partial response. The median survival in this cohort was 1.5 years. Almost half the patients experienced grade 4 neutropenia, and 29% of patients developed opportunistic infections⁽⁶⁵⁾. In this study, patients did not receive antiretroviral therapy while on treatment. Following the introduction of HAART during treatment, investigators reported that ABVD induced a 91% complete remission rate and a median time to relapse of over 36 months⁽⁶⁶⁾. Other investigators used the Stanford V regimen, administering only short-term chemotherapy (12 weeks) with adjuvant radiotherapy. Of 59 patients who received this therapy, 69% completed the treatment without

dose reduction or delays in the administration of the chemotherapy. Eighty-one percent of the patients achieved a complete remission, and with a median follow-up of 17 months, 33 (56%) of 59 patients were alive and free of disease⁽⁶⁷⁾. After the introduction of HAART, the response rates for patients treated with ABVD or BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone) became essentially similar, irrespective of the patient's stage of the disease. However, more treatment-related mortality occurred in patients who received BEACOPP⁽⁶⁸⁾. The available data suggest that ABVD with HAART should be the initial treatment of choice for HIV-related HL. High-dose chemotherapy and autologous stem cell transplantation are being explored for patients who have disease progression

while on treatment or relapse after remission induction. Thus, because of HAART, patients with HL and HIV disease can be treated with standard-of-care options that are similar to those used for HL patients who do not have HIV.

OTHER MALIGNANCIES AFFECTING HUMAN IMMUNODEFICIENCY VIRUS-INFECTED PATIENTS

Cervical Neoplasms

Epidemiology

In the early 1980s, reports appeared signaling an increased association between HIV infection and cervical intraepithelial neoplasia in HIV-infected women. It was not until 1993 that cervical cancer was officially added to WHO recommendations as an AIDS-related malignancy⁽⁶⁹⁾. Women with HIV disease have a higher incidence of infection with multiple types of oncogenic HPV and higher incidence of dysplastic changes of the cervix than women without HIV disease, events that can culminate in the development of cervical cancer (Table 44-7). There is no obvious association between the level of CD4⁺ cell count and cervical cancer, and the statistical correlations between the association of HIV and HPV-induced cervical cancer remains moderately strong at best. The decline observed for KS and PCNSL after HAART has not been seen in the incidence of HPV-related malignancies.

There are reasons why HPV, the etiologic agent of cervical cancer, causes this disease regardless of the immune status of the infected host. Human papillomavirus infects the basal keratinocytes of the stratified epithelium, and its replication is coupled to the process of keratinocyte differentiation in the infected squamous epithelium. From an initial low-copy number episome in basal keratinocytes, there is a dramatic increase in the concentrations of proteins E1 and E2 by the time the keratinocytes differentiate and enter the stratum spinosum layer of the epithelium. In addition, for oncogenic strains of HPV such as 16, 18, and 31,

there is also an increase in the expression of E6 and E7, which have a high oncogenic capacity manifested by the functional inactivation of p53 and Rb^(70,71). Regardless, this is a slow process, and it takes several years for an HPV-induced cervical lesion to transform into cancer. For these reasons, there is uncertainty regarding the relationship between HIV and cervical cancer as an AIDS-related malignancy.

Despite controversies regarding the relationship between HIV, HPV, and cervical cancer, the increased incidence of infections by oncogenic HPV types in patients with HIV in contrast to non-HIV-infected women highlights the importance of mandatory cervical screening of HIV-infected women. However, recent studies have suggested that HIV-infected women are not being offered cervical screening, even though older women without HIV for whom the relevance of the screening may not be considered as important are routinely screened. Clearly, educational efforts are necessary as the number of HIV-infected woman increases in the United States and elsewhere.

Cervical Cytology and Screening

Papanicolaou tests in HIV-infected women have a high prevalence of cytologic abnormalities, ranging from 20% to 40%. Women with negative Pap smears will, over the course of 3 to 5 years, develop cytologic abnormalities at a higher rate than will HIV-negative women, and there is evidence of a higher rate of progression to cervical cancer following the longevity induced by HAART⁽⁷²⁾. Therefore, it is imperative that patients with HIV infection be screened appropriately with Pap smears, colposcopy, and biopsy when needed for the early detection of cervical cancer. Pap smears interpreted as demonstrating “atypical squamous cells” cannot exclude a high-grade squamous intraepithelial lesion (HGSIL) and must be evaluated with colposcopic examination (see Fig. 44-4). Current US Public Health Service (USPHS) and Infectious Diseases Society of America (IDSA) guidelines recommend Pap smears every 6 months during the first year after HIV diagnosis; if both tests are normal, annual screening is suggested⁽⁷³⁾ (Fig. 44-6).

Treatment for Cervical Cancer

Because they rarely progress and often go away on their own, the American Society for Colposcopy and Cervical Cytopathology recommends close observation for cervical intraepithelial neoplasia (CIN) grade 1 lesions. However, treatment of invasive cervical cancer is the same as for HIV-seronegative women: surgery in early stages and a combination of surgery and chemoradiotherapy in intermediate stages. For CIN grade 2, the preferred mode of treatment is the loop

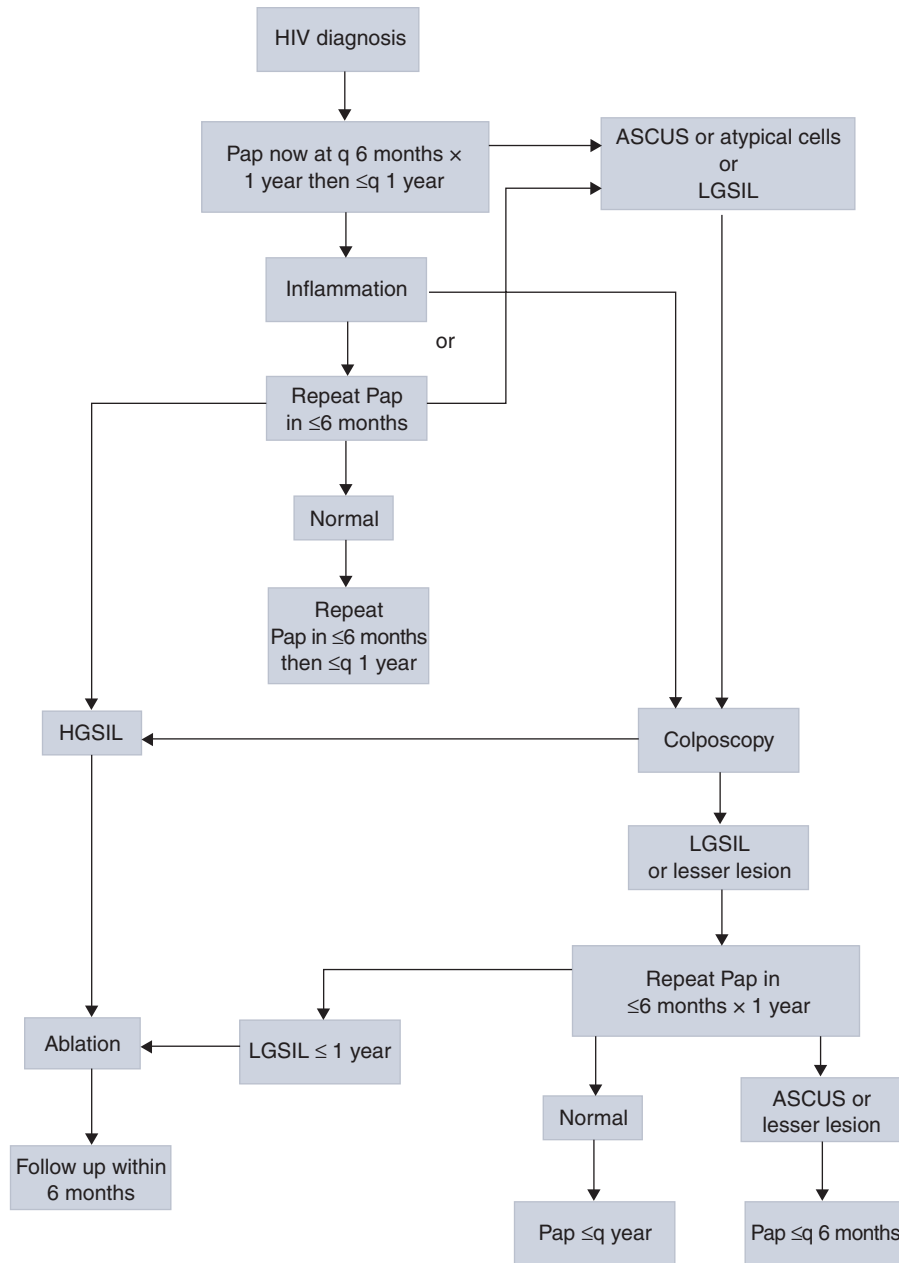

FIGURE 44-6 Screening/treatment algorithm for cervical cancer. ASCUS, atypical squamous cells of undetermined significance; HGSIL, high-grade squamous intraepithelial lesion; LGSIL, low-grade squamous intraepithelial lesion; q, every.

electrosurgical excision procedure. Cryotherapy and laser surgery can also be used, although these methods are usually reserved for larger lesions. Chemotherapy alone is used for more advanced cases, although the immune status of the patient can influence the response to treatment (74).

One of the most important advances against HPV-induced cervical cancer has been the development of preventive HPV vaccines. The HPV vaccines made of viral-like particles display a remarkable structural and antigenic similitude to HPV virions and can induce the production of high titers of neutralizing antibodies.

Two versions of HPV viral-like particle vaccines are available for immunization of humans against HPV. Gardasil (Merck, Sharp, and Dohme) has viral-like particles of HPV subtypes 16 and 18 (oncogenic subtypes) and 6 and 11 (the causes of genital warts). Cervarix (GlaxoSmithKline) contains viral-like particles of HPV subtypes 16 and 18. They are both administered intramuscularly and have demonstrated almost 100% protection in clinical trials prior to their approval by the FDA. They should be used prior to the initiation of sexual activity, and neither have demonstrated therapeutic efficacy in the treatment of preexisting

Table 44-8 Risk Factors for AIDS-Associated Anal Carcinoma

infections. Future work is aimed at increasing the immunogenicity of the viral-like particles and expanding the number of HPV oncogenic subtypes available for vaccination ⁽⁷⁵⁾.

Anorectal Carcinoma

Infection of the anogenital tract in men with oncogenic strains of HPV has the same consequence as it does in women. After HAART, the incidence of this disease has increased as patients live longer and the biological characteristics unique to the HPV oncogenic transformation are expressed over time (Table 44-8). The incidence of anal cancer has increased from 19.0 per 100,000 person-years in the pre-HAART era (1992-1995) to 48.3

persons per 100,000 person-years in the immediate post-HAART period (1996-1999) to 78.2 per 100,000 person-years more recently (2000-2003, *P* < .001) ⁽⁷⁶⁾.

The same subtypes of HPV and pathogenic mechanisms involved in the oncogenic activity of HPV in women apply to men. The screening and treatment of CIN 2 and 3 is of relevance in these patient populations. There has been a greater understanding of the need for anal screening of both men and women with HIV disease ⁽⁷⁷⁾ (Fig. 44-7). The treatment of HGSILs includes the use of local therapies such as podophyllotoxin, liquid nitrogen, and laser surgery (Fig. 44-8). Investigators have recommended that men with HIV infection and anal HPV-related lesions undergo screening with Pap smears every 6 months the first year following diagnosis and yearly thereafter. Invasive lesions are treated as in the general population with the use of chemoradiotherapy followed by salvage surgery when there is no response or relapse after initial treatment ⁽⁷⁸⁾.

Other Malignancies

Patients with HIV can develop other malignancies not necessarily associated with HIV. For example, lung cancer continues to increase in its incidence in this population. In general, smoking is one of the most important negative factors predicting for poor survival in HIV patients even in the presence of HAART. Patients with HIV who develop malignant tumors often do so at an earlier age and tend to have atypical presentations, and frequently their tumors follow a very aggressive course.

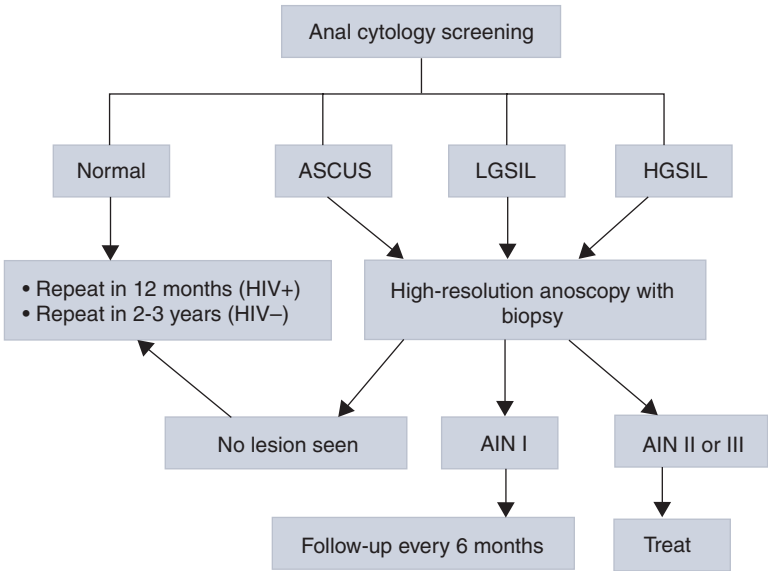

FIGURE 44-7 Protocol for screening anal intraepithelial neoplasia (AIN). IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

In patients with advanced HIV disease (<100 CD4⁺ cells/ μ L of blood), the initiation of HAART can be accompanied by a paradoxical worsening of established infections or appearance of new ones. This phenomenon is most frequent in patients who have tuberculosis or cryptococcal disease as their opportunistic infection but can happen with any other type of infection. This syndrome is known as immune reconstitution inflammatory syndrome (IRIS). The management of IRIS consists of the administration of specifically indicated therapies and a short course of steroids for 1 to 2 weeks with a rapid taper. The recommended dose of prednisone is 1 to 2 mg/kg/d. Antiretroviral therapy should only be interrupted in severe cases as most patients respond to the use of steroid or anti-inflammatory agents depending on the severity of the IRIS. Because the management of patients with

AIDS-related malignancies involves a multidisciplinary team and given the importance of the use of HAART in the management of patients with AIDS and malignancies, treating oncologists must be familiar with this condition to avoid unnecessary delays or interruptions in the HAART of their patients (⁷⁹).

MD ANDERSON CANCER CENTER AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME PANDEMIC

When the AIDS pandemic began, Houston quickly became an AIDS epicenter, occupying the fourth place among cities with the highest number of AIDS cases in the United States for several years. The Department of Epidemiology, under the leadership of Peter W. Mansell and its Director, Guy Newell, took a leading role in studying methods for prevention of AIDS

and public education efforts. Their work, together with the collaboration of R. Palmer Beasley, Dean of the University of Texas Health Science Center School of Public Health, the Department of Immunology and Biological Therapy, under the direction of Evan Hersh, and the collaboration of immunologists and virologists including James M. Reuben and Blaine F. Hollinger, was recognized with one of the first AIDS Treatment Evaluation Units Grants awarded for basic science and clinical research in AIDS. This work led to the creation of the Institute for Immunological Disorders under the direction of Peter W. Mansell and Adan Rios. Although the institute was ahead of its time, it opened doors for a humane treatment of AIDS patients and the development of new therapies and strategies for research of the disease. This base of knowledge was instrumental in development of community strategies subsequently applied in management and treatment of AIDS in the state of Texas. This effort extends to current times with the pioneering work done at the institution in the treatment of Burkitt lymphoma in HIV patients by Drs. Jorge Cortes, Debbie Thomas and

Houston AIDS community physicians using what is considered today a standard strategy for treatment of AIDS-related malignancies: the use of HAART in combination with the best known strategy for the treatment of the malignancy.

CONCLUSIONS

The complexities of the AIDS pandemic are captured in the history of the AIDS-related malignancies (Table 44-9). The introduction of effective anti-HIV therapy or HAART in 1996 brought a profound change in the overall management of cancer in HIV patients. One important predictor of good outcomes in the therapy of cancer and HIV is the administration of HAART (80). The common goals for treatment of patients with AIDS and cancer are to treat HIV with HAART and the cancer with the same standards of care that exists for patients without HIV disease, along with vigorous prophylaxis of opportunistic infections, supportive therapy including growth factors, and appropriate nutritional and emotional support.

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus; KSHV, Kaposi sarcoma-associated herpesvirus.

^aData are based on the observed number of cases in HIV-positive individuals (men and women age 15-69 years), expected cases based on the incidence in a nonimmunocompromised population in New York State (NYS), relative risk, and etiologic factors. Data from the AIDS/Cancer Matched Cohort NYS, 1981-1991.

^bRelative risk for Kaposi sarcoma (KS) is lower than in other studies, probably because the background population in NYS is enriched with population groups (eg, Italians, Greeks, and Jews) that have an increased risk for classic KS.

^cHCV contributes to increased incidence of liver cancer, particularly in HIV-infected men with hemophilia, and in intravenous drug users.

^dThe increase in lung cancer might be confounded by the fact that HIV-infected individuals have been reported to smoke more cigarettes per day than HIV-negative individuals.

^eIn Africa, HPV and ultraviolet light exposure have been implicated in the high incidence of conjunctival squamous carcinoma, and HPV is also implicated as the cause of skin cancers seen after an organ transplant. Misdiagnosis of KS might also contribute to increased risk of skin cancer.

Carcinoma of Unknown Primary

Gauri R. Varadhachary

OVERVIEW

Carcinomas of unknown primary (CUPs), with their heterogeneous presentations, pose a challenge on the diagnostic and therapeutic fronts. Depending on the extent of evaluation, CUP comprises 3% to 5% of all tumors diagnosed (¹⁻³). A working definition for CUP is biopsy-proven metastatic cancer with no identifiable primary source by history; physical examination; chest radiography; complete blood cell count; chemistry; computed tomography (CT) of the chest, abdomen and pelvis; prostate-specific antigen (PSA) in men; and mammography in women (²). The natural history of disease for CUP is diverse and is dependent on multiple variables, such as, age, number of metastatic sites, dominant area of disease, and histology. This considerable heterogeneity presents a challenge to the systematic study of CUPs. In addition, the emergence of sophisticated imaging, robust immunohistochemistry (IHC), and genomic and proteomic tools have challenged the “unknown” designation. Depending on histologic features, sites of disease, and performance status, a small but significant minority of patients will be long-term survivors, and it is important to identify these groups of patients (^{4,5}).

This chapter discusses the evaluation of patients with CUP and optimal therapeutic strategies in the era of sophisticated diagnostics. The differing natural histories in CUP, depending on both the sites of disease and histology, are also discussed. Studies showed that, in this population, a search for the primary tumor beyond “routine” evaluation is unrewarding in the

majority of patients (⁵). This fact has caused much consternation for both patients and physicians. The foundation for cancer treatment traditionally relies on identification of the tumor origin, thereby allowing treatment to be chosen based on the known natural history as well as specific therapies that have been proven effective for the cancer; this is becoming even more important with the rapid emergence of targeted therapies. Without knowledge of the primary site, the oncologist is often hesitant to recommend therapy, especially given the disease heterogeneity. Although most patients with metastatic CUP have tumors that respond poorly to current treatments and will consequently have a poor prognosis, it has become evident over the last two decades that subsets of patients with CUP have a favorable prognosis and respond to chemotherapy or can be successfully treated with regional therapy alone. The current era of sophisticated diagnostics and introduction of targeted therapies has been particularly important in the CUP setting; this cancer entity is the epitome of personalized therapy.

EPIDEMIOLOGY

The incidence of CUP cancers as estimated from the cancer registries and databases of “unknown and unspecified cancers” is reported to be approximately 3%-4% of all cancers (⁶). This is probably an overestimation because this group includes a mix of patients: those with true CUP, those with primaries not yet diagnosed at the time of death, and those with difficult-to-diagnose tumors. Further, improved imaging

allowing identification of small primary tumors suggests that the incidence of true CUP is decreasing.

A minority of patients (10%) with CUP have a history of an antecedent cancer. In autopsies performed before the advent of CT, the occult primary tumor was identified in 60% to 80% of cases. In one autopsy series, the two most commonly identified primary sites were the pancreas (20%) and lungs (18%)^(7,8). Given the current high-quality CT imaging and positron emission tomographic (PET) scans, it is unclear whether these cancer profiles are still the majority.

The classification of CUP continues to evolve. The last four decades have seen a shift in our understanding of CUP. First, improved imaging increased our confidence for the entity termed *occult primary*. Later, “favorable” CUP subsets were determined, based primarily on histopathology, the pattern of spread of select CUP cancers, and serum markers. Subsequently, with the advent of novel IHC markers and advances in diagnostic pathology, tissue of origin (ToO) profiles were described that assigned additional putative primary sites to CUP cancers based on IHC patterns. Current research involves the application of proteomic and genomic tools to CUP cancers.

BIOLOGY, CHROMOSOMAL ABERRATIONS, AND MUTATIONAL PROFILING

Carcinomas of unknown primary, despite their heterogeneity, are a clinically unique oncologic entity; as such, they share many common features that set them apart from other malignancies. The central unifying clinical feature of CUP is the absence of a detectable primary tumor. Previous studies have shown that, even after an autopsy, the primary site will not be identified in 20% to 40% of cases; that number is likely much lower with significant improvements in imaging. At present, it is not known why primary carcinomas exhibit this unique biological behavior. One current hypothesis is that the acquisition of a “metastatic phenotype” is an early event in CUPs, soon after oncogenesis, thus enabling cells to metastasize early, before the development of a clinically detectable tumor⁽⁹⁾. It has also been hypothesized that the primary tumors may regress or involute before the metastases become clinically evident, attributed to a host immunologic response. A third hypothesis is that the primary tumor is exposed to antiangiogenic factors locally, whereas the metastases acquire the angiogenic phenotype after a period of dormancy⁽¹⁰⁾.

Several studies have demonstrated a specific nonrandom pattern of chromosomal aberrations that seems to be unique to CUPs. These data suggest that some of these genetic changes may be the underlying cause

of the metastatic phenotype. Carcinoma of unknown primary is characterized by greater genetic instability, with massive GAs, when compared with other distant metastases. In a study by Pantou and colleagues⁽¹¹⁾, cytogenetic profiling of tumors from 20 patients with CUP was performed, revealing an average of 11 chromosomal changes per case. Of the three histologic subtypes in this study, adenocarcinomas had not only the highest number of cytogenetic changes (16 vs 3) but also involvement of distinct sites (4q31, 6q15, 10q25, and 13q22) when compared with carcinomas or undifferentiated malignancies. The latter group was distinguished by the involvement of changes at 11q22. Overall, the most commonly rearranged chromosomal regions were 1q21, 3p13, 6q21-23, 7q22, 11p15-12, and 11q14-24. The number of cytogenetic alterations was found to be prognostically relevant. Median survival was significantly greater for patients with five or fewer cytogenetic changes compared with those with more than five changes (3 vs 18 months, $P = .003$). An older study of 12 CUP cell lines also demonstrated a preponderance of chromosome 1 abnormalities. These changes were observed on both the long arm (eg, 1p deletion, isochromosome 1p, and translocations with a 1p breakpoint) and on the short arm (1q21), suggesting the importance of chromosome 1 in the biology of CUPs⁽¹²⁾. Chromosome 1p aberrations are also commonly associated with advanced malignancies.

Chromosome 12 abnormalities have also been shown in CUP. This is of particular interest because one of the observed alterations, isochromosome 12p (i12p), is present in as many as 80% of germ cell tumors. Motzer and colleagues reported that 30% of patient tumors in their series had either i12p or 12q deletions. The presence of either of these two cytogenetic abnormalities was found to be predictive of a complete response to cisplatin-based chemotherapy (75% vs 17%, $P = .002$)^(13,14). In the current era of sophisticated IHC, we rarely miss a patient with an extragonadal presentation and seldom order cytogenetics to inform therapeutic plans.

The tumor suppressor gene *p53* is commonly mutated in human cancers, especially in advanced malignancies. Paradoxically, this does not seem to be true in CUP. Bar-Eli and colleagues found *p53* mutations to be less frequent than expected (26%) in CUP after evaluating 15 biopsy specimens and 8 cell lines⁽¹⁵⁾. However, work by other researchers evaluating IHC studies of *p53* in CUP has found this protein to be highly expressed in 70% of the tumors examined^(16,17). Nevertheless, *p53* expression has not been found to have prognostic relevance. Molecular studies have also demonstrated the overexpression of other oncogenes, such as *c-myc*, *ras*, *bcl-2*, and *Her2/neu*, in CUPs, but none have been found to have any correlation with either survival or response to chemotherapy⁽¹⁸⁾.

More recent data with next-generation sequencing likely has therapeutic implications for patients with CUP, and it is exciting times for CUP researchers to extend the therapeutic envelope. In a recent study, Ross and colleagues presented results from a retrospective study of 200 consecutive CUP tumor specimens that that underwent comprehensive genomic profiling (CGP) using the hybrid-capture-based FoundationOne 10 assay (¹⁹). The DNA extracted from these CUP tumor specimens was analyzed after hybridization capture of 3,769 exons from 236 cancer-related genes and 47 introns of 19 genes commonly rearranged in cancer. There were 125 adenocarcinomas of unknown primary site (ACUPs) and 75 nonadenocarcinomas (non-ACUPs). The authors reported that a large number of CUP samples (85%) harbored at least one clinically relevant genomic alteration (GA) with the potential to influence and personalize therapy. The mean number of GAs was 4.2 GAs per tumor. The ACUP tumors were more frequently driven by GAs in the receptor tyrosine kinase (RTK)/Ras/mitogen-activated protein kinase (MAPK) signaling pathway than non-ACUP tumors. The authors concluded that CGP can identify novel treatment paradigms and suggested that early testing may have utility in CUP management. These data do illustrate some important considerations in the management of CUP cancers, as discussed in this chapter.

NATURAL HISTORY AND CLINICAL PRESENTATION

The clinical course of patients with CUP varies widely. Median survival in large retrospective studies has ranged from 11 weeks to 11 months. In the University of Texas MD Anderson Cancer Center study, the 5-year overall survival (OS) rate was only 11%. Although survival is poor as a whole, there are certain prognostic variables that correlate with longer survival, including disease limited to one organ site, involvement of lymph nodes only, and histologic diagnoses of squamous or neuroendocrine carcinoma. Variables suggestive of a poor prognosis include male sex, histologic diagnosis of adenocarcinoma, and metastatic involvement of the liver, lungs, bone, pleura, or brain (Table 45-1) (⁴).

By performing multivariate analyses on a consecutive series of 1,000 patients with CUP with classification and regression tree (CART) analysis, Hess and colleagues (⁴) were able to more closely study the interactions between different clinical variables and how this influenced survival.

Patients with CUP present with symptoms and signs similar to those of patients with advanced malignancies of known origin. In one review, the most common symptoms at presentation of CUP were general deterioration (73%), digestive symptoms (58%), liver

Table 45-1 Favorable- Versus Poor-Prognosis Carcinoma of Unknown Primary

Favorable Prognosis	Poor Prognosis
Extragenital germ cell syndrome	Liver metastases (nonneuroendocrine)
Isolated single small metastasis	Pleural or lung metastases
Papillary peritoneal adenocarcinoma (women)	Adrenal metastases
Isolated axillary adenocarcinoma (women)	Multiple brain metastases
Cervical adenopathy (squamous cell)	
Isolated inguinal adenopathy	
Neuroendocrine histology	

enlargement (58%), abdominal pain (56%), respiratory symptoms (45%), ascites (26%), and node enlargement (16%) (²⁰). Most patients with CUP present with multiple metastases, with three or more organs involved. In patients with a dominant (or single) site of metastasis, the most common reported sites were liver (25%), bone (22%), lungs (20%), lymph nodes (15%), pleural space (10%), and brain (5%).

DIAGNOSTIC EVALUATION

In the past, minimalist diagnostic strategies had been advocated, limiting the scope of initial evaluations to differentiate only between treatable and untreatable disease. Others have supported a more aggressive approach, wherein a complete assessment of the extent of the disease and detection of the primary tumor site are attempted. In our experience, a more pragmatic approach is better. Extensive evaluation of all patients presenting with metastases is an expensive and wasteful extreme that does not benefit patients. In one study, the average cost of evaluating a patient with CUP was \$17,973 and much higher with recent testing (^{21,22}). In that study, mean survival was 8.1 months, representative of the natural history of CUP, with only 18% of patients surviving 1 year. However, a strictly minimalist approach may result in the oversight of treatable and potentially curable neoplasms.

An important determinant of the appropriate extent of evaluation for any patient with CUP is whether the data obtained by a diagnostic test will influence treatment decisions. If a treatable or potentially curable cancer is strongly suspected (eg, a germ cell tumor or

lymphoma or oligometastatic disease treated with surgery or multimodality therapy), further investigation should proceed until a precise clinical diagnosis can be made, provided that therapy is not unreasonably delayed. The recommended general approach at the present time is thus one of a directed evaluation based on clinical presentation and pathologic findings; predictions of tumor origin or mutations from molecular profiling techniques may also play a role in streamlining the scope of evaluation.

Physical Examination and Laboratory Tests

A thorough medical history should be obtained, and a physical examination, including a digital prostate examination in men and a breast and pelvic examination in women, should be performed. Determination of the patient's performance status, nutrition, and the presence or absence of concomitant medical illnesses and malignancy-related complications (eg, paraneoplastic syndromes or painful metastases) that may affect patient care is required.

Laboratory tests should include routine biochemical and hematologic surveys. The role of tumor markers in the evaluation of patients with CUP is often not diagnostic. Most tumor markers are nonspecific and are not useful for identifying a primary site or for prognostic purposes. Adenocarcinoma markers (eg, carcinoembryonic antigen [CEA], cancer antigen 125 [CA 125], CA 15-3, and CA 19-9) are often elevated in patients with CUP and cannot be reliably used to identify a specific primary site or to predict either OS or the exact burden of metastatic disease (²³⁻²⁵). Serum tumor markers may play a role in helping to evaluate patients for responses to therapy, although levels are not always predictive of response to chemotherapy.

Their selective use in a directed approach is more helpful than ordering a large battery of tumor markers on all patients who present with CUP. Men who present with metastatic adenocarcinoma and osteoblastic bone metastases CUP should have PSA and prostatic acid phosphatase levels measured. In all men with undifferentiated (or poorly differentiated) midline carcinomas, beta-human chorionic gonadotropin and alpha-fetoprotein levels should be measured, especially if the clinical presentation suggests an extragonadal germ cell tumor. In patients with hepatic tumors, alpha-fetoprotein levels should also be measured if there are risk factors or pathologic characteristics that suggest a possibility of primary hepatocellular carcinoma.

Diagnostic Imaging and Invasive Studies

In the absence of contraindications, a baseline intravenous contrast CT scan of the chest, abdomen, and pelvis is the standard of care, as supported by the National

Comprehensive Cancer Network and National Institute for Health and Clinical Excellence CUP radiology guidelines (^{26, 27}). Patients with CUP should then be approached in a "directed" fashion. Endoscopy of the upper and lower gastrointestinal (GI) tract is indicated for patients with abdominal complaints, ascites, liver metastases, or other findings in the initial workup and pathology that are indicative of a possible GI primary tumor.

All women with CUP and adenocarcinoma should undergo mammography. In cases of suspicious findings on a breast examination and negative mammography findings, patients should have breast sonography and a biopsy as indicated. Because both the sensitivity (23%-29%) and specificity (71%-73%) of mammography in detecting an occult carcinoma are low, breast magnetic resonance imaging (MRI) has been evaluated as an alternative in patients with a high suspicion for breast primary cancer. In the setting of isolated axillary adenopathy, MRI is sensitive in detecting occult primary breast cancers (>75%) and should be performed in women with isolated axillary adenopathy and negative mammography findings (²⁸⁻³³). Women with adenocarcinoma presenting with metastatic sites other than cervical or axillary adenopathy that are compatible with breast cancer (ie, bone, liver, or lungs) may also undergo breast MRI if the mammography findings are negative (^{32, 33}).

Patients with upper or midcervical adenopathy with a squamous cell carcinoma on pathology should undergo a thorough head and neck evaluation, including panendoscopy (ie, laryngoscopy, bronchoscopy, and esophagoscopy) with random biopsies. Ipsilateral or (more often) bilateral tonsillectomy has also been recommended as part of the staging process because this has been shown to identify an occult primary lesion deep in the tonsillar crypts in up to 30% of patients with this presentation of CUP (³⁴⁻³⁶). Computed tomography of the head and neck region is routinely done as part of the initial workup. In addition, the utility of 18-fluorodeoxyglucose positron emission tomography (FDG-PET) has been well documented in patients with squamous carcinoma and cervical adenopathy; small prospective and retrospective studies suggest that a primary head and neck tumor is identified in 25% to 30% of these patients (³⁶⁻⁴²). A recent retrospective review found that the primary tumor site was identified in 44% of these patients undergoing PET-CT fusion scans, and this modality appears to be emerging as a superior alternative to either PET or CT alone (^{38, 39}).

Outside the indication given previously, the role of PET-CT is unclear. Several small studies have evaluated the utility of PET in CUP patients (^{43, 44}). Moller et al reviewed (¹⁸) FDG-PET as a diagnostic tool for patients with extracervical CUP (⁴⁴). They identified four publications (152 patients); these studies were retrospective

and heterogeneous in their inclusion criteria, study design, and diagnostic workup prior to FDG PET-CT. The primary tumor was detected by FDG PET-CT in 39% of patients with extracervical CUP. Lung was the most commonly detected primary tumor site ($\approx 50\%$). Pooled estimates of sensitivity, specificity, and accuracy of FDG PET-CT in the detection of the primary tumor site were 87%, 88%, and 87.5%, respectively. They concluded that FDG PET-CT may have a role in identification of the primary tumor in extracervical CUP; however, prospective studies with more uniform inclusion criteria are warranted. Although not studied prospectively, PET-CT scans may be useful in selected patients with solitary metastases prior to definitive locoregional therapies and in follow-up of patients with predominant bone disease (²).

Histopathologic Evaluation

All pathologic material obtained at biopsy from a patient with CUP should be evaluated by an experienced pathologist who is familiar with CUP workup. The pathologist should also be informed of the patient's pertinent history and clinical findings so that he or she can recommend further analysis on the basis of this information. In the CUP world, pathology trumps radiology. Collaboration between the pathologist and treating oncologist is critical. Adequate tissue sampling is essential.

The CUP cancers include adenocarcinoma, poorly differentiated adenocarcinoma (60%); poorly differentiated carcinoma (PDC), undifferentiated carcinoma, or undifferentiated neoplasm (30%); squamous cell carcinoma (5%); and neuroendocrine cancer (2%). Rarely (2%), CUP can present as mixed tumors, including sarcomatoid, basaloid, and adenosquamous carcinomas (Table 45-2).

Adequacy of tissue is essential, especially when the pathologist has to make a diagnosis on deep fine-needle aspirations and there is insufficient tissue for IHC staining. The diagnosis of a poorly differentiated

neoplasm implies that the pathologist is unable to classify it into any of the general neoplastic categories (carcinoma, lymphoma, melanoma, or sarcoma). Subsequent evaluation of this group of poorly differentiated lesions by means of special IHC techniques is warranted because some of these patients will have tumors that are potentially curable and very responsive to treatment. Many IHC reagents are at the disposal of the pathologist, making the histologic classification of the tumor easier (Table 45-3).

Especially useful are the antibodies to common leukocyte antigens present in lymphoma and the antibodies to PSA present in most prostate cancers. Other useful IHC markers include cytokeratin CK7, CK20, and thyroid transcription factor (TTF-1). Thyroid transcription factor is a nuclear transcription factor that is normally expressed in lung and thyroid tissues and

Table 45-3 Commonly Utilized Immunoperoxidase Stains to Assist in the Differential Diagnosis of Poorly Differentiated Neoplasms

Stain	Likely Primary Site
Estrogen/progesterone receptor, gross cystic disease fluid protein-15 (GCDFFP-15), low molecular weight cytokeratin (CK)	Breast cancer
Thyroid transcription factor (TTF-1), CK7, CK20, surfactant protein A precursor (SP-A1)	Lung cancer
Prostate-specific antigen (PSA), epithelial membrane antigen (EMA), alpha-methylacyl coenzyme A racemase/P504S (AMACR/P504S)	Prostate cancer
Leukocyte common antigen (LCA), CD3, CD4, CD5, CD20, CD45	Lymphoma
Vimentin, desmin, ^a factor VIII ^b	Sarcoma
Chromogranin/synaptophysin, neuron-specific enolase, cytokeratin	Neuroendocrine tumor
EMA, β -hCG, AFP, placental alkaline phosphatase (PLAP)	Germ cell tumor
CK7, CK20, ^c uroplakin III	Urothelial malignancies
S100, vimentin, HMB-45, neuron-specific enolase	Melanoma
CK7, CK20, ^c CDX-2, carcinoembryonic antigen (CEA)	Colorectal cancer

Abbreviations: AFP, alpha-fetoprotein; β -hCG, beta-human chorionic gonadotrophin; CDX-2, Caudal type homeobox-2; HMB-45, Human melanomablack-45.

^aPositive in desmoid tumors, rhabdomyosarcomas, and leiomyosarcomas.

^bPositive in angiosarcomas.

^cWhereas a CK7⁺/CK20⁻ staining pattern is typical of lung neoplasms, CK7⁺/CK20⁺ is suggestive of a colorectal primary. Dual CK7⁺/CK20⁺, however, is suggestive of urothelial primary.

Table 45-2 Major Histologies in Carcinoma of Unknown Primary

Histology	Proportion (%)
Well to moderately differentiated adenocarcinoma	55
Poorly differentiated adenocarcinoma	30
Squamous	6
Neuroendocrine	4
Undifferentiated malignancy	5

in their neoplasms. Staining for TTF-1 is frequently positive in lung cancer, especially in adenocarcinomas (60%-75%) and small cell lung cancers (66%-87%); however, it is inconsistently expressed in squamous cell carcinoma. Among the various monoclonal antibodies against various cytokeratins, CK7 and CK20 can help differentiate between different solid tumors. (For instance, CK7 is more commonly associated with pulmonary or gynecologic malignancies, whereas CK20 is frequently seen in GI adenocarcinomas.) The CK7⁺/CK20⁻ immunophenotype, in conjunction with TTF-1 staining, is suggestive of a lung primary and is a highly sensitive and specific method for differentiating primary pulmonary adenocarcinomas from metastatic extrapulmonary adenocarcinomas (Fig. 45-1) ⁽⁴⁵⁻⁴⁹⁾. In contrast, the CK7-/CK20⁺ immunophenotype is suggestive of a colorectal primary site. CK7⁺ and CK20⁺ dual staining suggest a malignancy of urothelial origin. Using light microscopy and IHC, a putative primary tumor may be assigned in up to a third of CUP cases. Immunohistochemistry can also suggest biomarker studies with potential therapeutic impact (eg, Kras, epidermal growth factor receptor [EGFR], Her2, and ALK mutations).

Hep par 1 is an antigen whose expression is confined to benign and malignant hepatocytes and aids in the diagnosis of hepatocellular carcinoma in patients with CUP presenting with liver lesions. In women, depending on the pathology and pattern of metastasis, estrogen receptor and progesterone receptor staining is done to look for a breast primary. Another marker for a breast primary is gross cystic disease fluid protein 15 (GCDFP-15), which is present in 62% to 72% of breast cancers.

Dennis and colleagues ⁽⁵⁰⁾ have identified other novel molecular markers using a bioinformatics approach. All publicly available gene expression data from various adenocarcinomas were pooled together, and four novel proteins not previously recognized as tumor markers were found to be significantly upregulated. This was confirmed by reverse transcription-polymerase chain reaction. One example was lipophilin B, which was found to be restricted to breast, ovarian, and prostate cancers.

The use of cytogenetic analysis in the diagnosis of CUPs is limited. Specific chromosomal abnormalities have been identified in several types of lymphoma (8; 14 translocation in small non-cleaved-cell non-Hodgkin lymphoma), germ cell tumors (12p), and Ewing sarcoma (t11; 22 or t21; 22). In the cytogenetic study by Pantou et al ⁽¹¹⁾, lymphoma was diagnosed in four patients with CUP on the basis of the presence of immunoglobulin (Ig) H/Alk-1 rearrangement, which was identified by fluorescence in situ hybridization. In addition, one patient was diagnosed with Ewing sarcoma due to detection of characteristic

FIGURE 45-1 Immunohistochemical stains performed on the biopsy specimen from a patient with primary metastatic adenocarcinoma to a supraclavicular lymph node. Immunoperoxidase stains were positive for CK-7 (A) and TTF-1 (B) but negative for CK-20, (C), thus suggestive of metastatic non-small cell lung cancer. (Used with permission from Dr. Nelson Ordoñez, Department of Pathology, MDACC.)

rearrangement of chromosomes 11 and 22. In the era of novel and sophisticated IHC, cytogenetics is rarely ordered to help with therapy decisions. Most useful are patterns and groups of IHC used in an effective algorithm that can prove to be clinically appropriate and cost effective, although the approach to this is not uniform in the community ^(51, 52).

Molecular Profiling of Carcinomas of Unknown Primary

Tissue of origin molecular profiling using DNA microarray and reverse transcription–polymerase chain reaction (RT-PCR) is a promising technique to establish the putative primary diagnosis in patients with CUP^(53, 54). The performance of these assays in known cancers has been validated using independent blinded sets of tumor samples, with an accuracy of approximately 90%⁽⁵⁵⁻⁵⁷⁾. The feasibility of using formalin-fixed small biopsy or fine-needle aspiration samples makes this practical for use in the clinic setting.

Messenger RNA- or microRNA-based ToO assays have been studied in prospective and retrospective CUP trials. In CUP, these assays suggest a specific primary tumor in about 70% of patients studied⁽⁵⁸⁻⁶⁴⁾. Because, by definition, the primary tumor site is not known in CUP, validation of site prediction in CUP remains a challenge. Results from multiple small studies suggest that ToO predictions are likely accurate. Indicators include (1) concordant results of ToO testing and the appearance of a latent primary during the course of the patient's illness (or many years later); (2) strong correlation between ToO assay results and diagnostic IHC (both suggesting a single putative primary); (3) a prospective study demonstrating that patients treated with ToO-based site-directed therapy had survival similar to those with the corresponding known primary⁽⁶⁵⁾.

In the United States, there are currently three commercially available Medicare-approved tests. They differ in the platform used, number of potential cancers identified, the size and histologic samples of the training set, and the reporting format. All three assays report on identifying a putative primary in about 75%-85% of patients with CUP. No comparative studies have been conducted, although in our personal experience when IHC is diagnostic, all three tests usually give similar results.

At present, the only *outcomes*-based study is a prospective single-arm study evaluating the role of the 92-gene assay to predict the ToO and assay-directed site-specific therapy in patients with CUP⁽⁶⁵⁾. The authors concluded that the median OS of 12.5 months (95% CI, 9.1 to 15.4 months) for patients who received assay-directed site-specific therapy compares favorably with previous studies using empiric therapy. Biliary and urothelial profiles were 33% of the predictions. Unfortunately, firm conclusions of therapeutic impact cannot be drawn from this study given the nonrandomized design; statistical biases; confounding variables, including use of subsequent lines of (empiric) therapy; and the heterogeneity of the CUP cancers.

At this time, we lack randomized controlled trials to gauge the therapeutic impact of ToO molecular

profiling assays. Creative trial designs are urgently needed to study CUP subsets and impact of these assays on survival and quality of life of patients with CUP.

Two prospectively defined blinded studies of difficult-to-diagnose primary cancers (several poorly differentiated) have reported on the cost effectiveness of ToO molecular profiling over IHC. Samples were evaluated by IHC/morphology analysis or the ToO molecular profiling test⁽⁶⁶⁾. Accuracy was defined based on comparison with pathology of known primary. In one, the assay demonstrated overall accuracy of 79% for tumor classification versus 69% for IHC/morphology analysis ($P = .019$). Mean IHC use was 7.9 stains per case (range 2 to 15). The other study also confirmed similar findings⁽⁶⁷⁾; the assay accurately identified 89% of specimens, compared with 83% accuracy using IHC ($P = .013$). In the subset of poorly differentiated and undifferentiated carcinomas, assay accuracy exceeded that of IHC (91% to 71%, $P = .023$). These results have important implications for management of CUP cancers and warrant a study of an integrated algorithm evaluating ToO molecular profiling complementing IHC in select patients. At this time, we lack randomized controlled trials to gauge the therapeutic impact of ToO molecular profiling assays. Creative trial designs are urgently needed to study CUP subsets and impact of these assays on survival and quality of life of patients with CUP.

MANAGEMENT OF SPECIFIC CLINICOPATHOLOGIC SUBGROUPS

Carcinomas of Unknown Primary Presenting as Isolated Brain Metastases

In up to 15% of patients presenting with brain metastases, the primary site remains unknown^(68, 69). The important factor in treating patients with brain lesions is to distinguish patients with metastatic disease from those with primary brain tumors. Once this distinction has been made, patients with single metastatic lesions should be considered for surgery, and those with multiple lesions should receive radiotherapy. In a recent small prospective study, patients with CUP who had single brain metastases treated with gross total resection and subsequent whole-brain radiotherapy (WBRT) had a median survival of 13 months. Patients with CUP who had multiple brain metastases and who underwent either WBRT alone or gross resection of symptomatic lesions followed by adjuvant WBRT had a median survival of only 6 to 8 months⁽⁶⁹⁾. Stereotactic brain radiation is often used in the CUP setting using the same principles as for brain metastases from known primary cancers.

Carcinomas of Unknown Primary Presenting as Metastatic Cervical Adenopathy

In this subgroup, patients present with high-to-midcervical or -supraclavicular adenopathy; on histopathology, these tumors are squamous cell or PDCs. For squamous cell carcinoma, the primary site is eventually identified during follow-up in approximately 20% of patients, with the tonsil being the most common site, followed by the pyriform sinus and base of the tongue.

Adenocarcinoma is much less common and is generally from either metastatic nonpapillary thyroid carcinoma or advanced malignant disease from a distant site (GI, lung, or breast carcinoma presenting as a metastatic supraclavicular node). Of all malignancies of the head and neck, only 5% to 10% are classified as unknown primary after imaging and panendoscopy. The prognosis for patients with cervical CUP overall is better than that for other CUP clinical subgroups, but even within this group, significant heterogeneity exists. Yalin et al (⁷⁰), in a retrospective study of 107 patients with cervical CUP (62% PDC, 24% squamous carcinoma, and 14% adenocarcinoma), reported a 5-year OS rate of 35.5%. In another retrospective study by Issing et al (⁷¹), 5- and 10-year OS rates were 42.7% and 30.6%, respectively. The prognosis is significantly worse in the presence of any of the following: adenocarcinoma, level III/IV lymphadenopathy, multiple lymph nodes, and bulky disease.

Patients with supraclavicular adenopathy have a far worse prognosis than those with adenopathy in other lymph node-bearing areas. Carcinoma affecting supraclavicular lymph nodes on the right most commonly arises from occult primary tumors of the lungs and breast. When disease affects the lymph nodes on the left side, spread from intra-abdominal malignancies by way of the thoracic duct (Virchow node) is an additional possibility.

The management of patients with cervical CUP has become increasingly controversial, primarily because of the question of postoperative radiation therapy. The notion of adjuvant irradiation of all potential mucosal sites has been questioned because of the absence of any demonstrated survival benefit in randomized studies. To date, postoperative radiation therapy in cervical CUP significantly improves locoregional control, but this does not translate into improved OS. This being said, combined-modality therapy (surgery and radiation therapy) is better than either modality alone (⁷²). Most patients with only cervical or supraclavicular involvement should have regional therapy consisting of surgery, postoperative radiation therapy, and close follow-up. Patients who undergo an excisional biopsy

for diagnosis usually do not need additional surgery if no gross disease is left behind, only a single lymph node measuring less than 6 cm is involved, and no extracapsular extension is noted on pathologic review. If any of these features is present, a neck dissection is indicated. In addition, for patients with squamous cell carcinoma, unilateral tonsillectomy ipsilateral to the presenting neck mass is commonly advocated as part of the surgical treatment because occult tonsillar carcinomas are usually found in 18% to 39% of patients who undergo tonsillectomy (^{71, 72}). Identification of the primary site would thereby reduce morbidity by limiting the field of radiation and would improve surveillance.

In patients with N1 or N2a disease (squamous cell), it is unclear whether postoperative radiation improves local control because studies have been contradictory. In this case, close surveillance would also be an acceptable option after surgery. All other patients should receive postoperative radiation to the bilateral neck covering all potential occult primary sites (ie, nasopharynx, oropharynx, and hypopharynx). The 3-year survival rate after radical neck dissection or radical neck irradiation ranges from 35% to 60%. Within this group, patients with N1 disease have a better prognosis; patients with N3 disease, regardless of the local treatment modality used (surgery, radiotherapy, or both), fail to achieve complete remission in 65% of cases.

Although the role of chemotherapy in patients with cervical CUP remains poorly defined, extrapolation of phase II/III data in head and neck cancer indicates a role in patients with advanced nodal disease (N3). A recent large meta-analysis of more than 10,000 patients in 63 trials with head and neck squamous cell carcinoma demonstrated a small but significant absolute survival benefit of 4% at 5 years for chemotherapy (⁷³). Intensive concurrent chemoradiotherapy in unresectable squamous cell head and neck cancers with cisplatin/5-fluorouracil-based and cetuximab-based regimens has resulted in improved complete response rates, locoregional control, and preservation of organ function, albeit at the cost of significant toxicities.

Women With Carcinomas of Unknown Primary and Isolated Axillary Adenopathy

Women who present with adenocarcinoma in the axillary lymph nodes compose another subset with a more favorable prognosis. These patients are often managed as women with stage II breast cancer. Isolated axillary adenopathy is an uncommon presentation of breast cancer, accounting for only 1 to 3 of every 1,000 diagnosed breast cancers. Mammography and ultrasound should be performed, and biopsies should be performed on any identified lesions. If

mammography findings are normal, additional imaging of the breast with MRI is indicated because of its greater ability to detect small primary breast tumors (70%-95% sensitivity). Magnetic resonance imaging has a very low false-negative rate. Of approximately 40 women reported in the literature with isolated axillary adenocarcinoma and negative breast MRI findings, only 4 were found to have breast cancer at surgery or during follow-up (⁷⁴).

The present recommended management of women with CUP of the axilla includes axillary dissection, axillary radiotherapy for those at high risk of local recurrence (eg, extracapsular invasion or more than four positive lymph nodes), and appropriate systemic therapy for breast cancer, depending on age and menopausal status. If breast MRI findings are negative, neither mastectomy nor breast irradiation is recommended (⁷⁵⁻⁷⁷). If the breast MRI is positive or suspicious, radiation to the breast is usually recommended. The prognosis is not as favorable in men who present with axillary adenopathy only (⁷⁵).

This management paradigm is changing as molecular profiling complements pathology as a diagnostic tool in this subset of patients. All women with axillary adenopathy do not have occult breast cancer. Profiling for ToO can help with treatment decisions especially if the IHC does not correlate with breast cancer and ER, PR, and Her-2 status is negative.

Carcinomas of Unknown Primary Presenting as Isolated Inguinal Adenopathy

A few patients with CUP present with inguinal adenopathy. Undifferentiated (anaplastic) carcinoma is identified in at least half of these cases. Some of these anaplastic “carcinomas” appear to be melanomas with no obvious primary skin lesion. The remaining patients have squamous cell carcinomas arising from the skin, genitourinary tract, anus, or pelvis. A detailed investigation for primary lesions in these areas is important because curative therapy is available for carcinomas of the anus, vulva, vagina, and cervix even with spread to regional lymph nodes. In patients with carcinomas and PDCs confined to the groin nodes, where no primary site was identified, a superficial groin dissection should be performed with or without radiation therapy. Bimodality therapy with surgery and radiation may increase the risk of significant lymph edema and requires careful planning. Chemotherapy, before definitive therapy and in the context of a clinical trial, may be offered to patients with bulky locoregional adenopathy and is not an uncommon practice in the clinic.

Carcinomas of Unknown Primary and Isolated Pleural Effusions

Most patients with isolated pleural effusions have adenocarcinomas, which may sometimes be difficult to differentiate from mesotheliomas. Newer IHC markers (eg, calretinin, CK 5/6, and WT1 [Wilms Tumor-1]) that are more sensitive in differentiating epithelioid malignant mesothelioma from pulmonary adenocarcinoma can assist in the diagnosis (⁷⁸). Additional IHC markers, including TTF-1, CK 7/20, and breast markers, should routinely be done as first- and second-tier diagnostics to aid in treatment. If the effusion reaccumulates quickly, pleurodesis may be attempted to slow the rate of fluid reaccumulation, or as done more often currently, a pleural catheter with daily aspirations is preferred (this can be removed after chemotherapy response is noted and the flow decreases). Chemotherapy is initiated in most patients based on their IHC profile and taxane plus carboplatin versus gemcitabine plus cisplatin are commonly used doublets.

Carcinomas of Unknown Primary Presenting as Malignant Ascites

Patients with malignant ascites usually belong to one of two subsets, each with a very different natural history of disease. The first group consists of patients with mucin-producing adenocarcinoma, who may present with ascitic fluid that contains signet-ring cells. These patients often have multiple peritoneal implants, with the primary site most likely being the GI tract (ie, stomach, small bowel, appendix, colon, or pancreaticobiliary). Given the current armamentarium of drugs available for treatment of metastatic colon cancer and the improved survival, it is important to consider those combinations for patients with IHC suggestive of colon profile (CK20+, CK 7-, and CDX-2+). The second subset is composed of women patients with primary serous papillary peritoneal carcinomatosis. This disease is often also associated with pelvic adenopathy or masses. These patients may have elevated CA 125 levels but do not have detectable ovarian cancer. Some investigators consider these patients to have true unknown primary ovarian tumors or primary serous carcinomas of the peritoneum (^{79, 80}). Disease management should be the same as for women with ovarian carcinoma. A prolonged median survival of 13 months, with 25% of patients having a progression-free survival lasting more than 2 years, was reported for paclitaxel/carboplatin-based chemotherapy in patients with peritoneal carcinomatosis. In this study, a high overall response rate (ORR) and number of complete responses were reported for this subgroup of patients with CUP (68.4% and 20%, respectively).

Carcinomas of Unknown Primary Presenting as Isolated Bony Metastases

When bone metastases are detected, men should be evaluated for prostate cancer and women for breast cancer given that they may be candidates for hormonal therapy, which is relatively easier compared to cytotoxic therapies. Other cancer profiles include lung, cholangiocarcinoma, renal, and rarely melanoma. Patients with a single bony metastasis may be candidates for surgery or radiation and then monitored. Patients with disease at multiple sites and good performance status and whose tumors progress after radiation therapy should be offered a trial of chemotherapy. Many experimental agents are currently available in ongoing clinical trials. Therapy with bone-seeking radioisotopes (eg, strontium 89) may be useful in the treatment of disseminated painful bone metastases in a few patients. Bisphosphonates are routinely used as in other malignancies, such as multiple myeloma, breast cancer, and prostate cancer. Often, PET-CT is the imaging modality of choice to follow response to therapy for disseminated osseous metastatic disease.

Carcinomas of Unknown Primary Presenting as Hepatic Metastases

Patients with hepatic metastases constitute 30% to 40% of people with CUPs; they compose a clinical subgroup with a relatively poor prognosis, with reported median OS between 49 days and 7 months. The most important diagnostic considerations in this class are to distinguish primary liver and biliary tumors (hepatocellular carcinoma and cholangiocarcinoma) from cancers that have metastasized to the liver and to identify patients with neoplasms of a more indolent nature (eg, neuroendocrine tumors). A careful pathologic review with IHC of liver biopsy specimens is therefore essential. The two most common histologies in primary CUP of the liver are adenocarcinoma (55%) and poorly differentiated/undifferentiated carcinoma (30%). The recommended initial therapy for unresectable disease is systemic chemotherapy, and surgery may be considered an option for those with resectable disease.

Neuroendocrine Tumors of Unknown Primary Site

Neuroendocrine tumors compose about 4% of all CUPs and commonly present with diffuse liver or bone metastases. Histologically, neuroendocrine tumors can be well differentiated or low grade, with features that are typical of carcinoid or islet cell tumors exhibiting a more indolent behavior. Management of these tumors should be similar to established guidelines for metastatic low-grade neuroendocrine tumors from a known

primary site. In patients with limited disease, surgical resection or chemoembolization may be appropriate. If not amenable to local therapy, then targeted therapy is considered with (anti-vascular endothelial growth factor [anti-VEGF] agents, including sunitinib, or mammalian target of rapamycin [mTOR] inhibitors, including everolimus.

A second group involves high-grade neuroendocrine tumors that may present as PDC by light microscopy but have strong neuroendocrine features revealed by IHC (ie, neuron-specific enolase, chromogranin A, and synaptophysin positive). These high-grade neuroendocrine tumors are treated like small cell lung carcinoma with etoposide plus platinum or irinotecan plus platinum combinations, with high reported response rates.

Carcinomas of Unknown Primary and Extragenadal Germ Cell Syndrome

As a group, patients who have undifferentiated carcinoma or PDC are younger than 50 years and present with rapidly growing midline tumors involving the lymph nodes, mediastinum, or retroperitoneum; their tumors have been found to be very responsive to chemotherapy, particularly to platinum-containing regimens. It is believed that these patients have poorly differentiated extragonadal germ cell tumors. They have response rates to chemotherapy of 35% to 50%, and those who achieve a complete response often enjoy a durable remission. In a prospective study by Hainsworth and colleagues of 220 patients with PDC or poorly differentiated adenocarcinoma (PDAC) treated between 1978 and 1989 with cisplatin-based chemotherapy regimens, approximately half of the patients had a predominant tumor location in the mediastinum, retroperitoneum, or peripheral lymph nodes. The ORR was 63%, with 26% complete responses and an actuarial 10-year disease-free survival rate of 16%.

However, this was not found to be true by Lenzi and colleagues⁽⁴⁾, who retrospectively reviewed the clinical outcomes of 337 patients with PDC/PDAC. No prolonged survival was observed in this cohort of patients, and no significant survival advantage resulted from cisplatin-based chemotherapy. Moreover, elevated serum levels of alpha-fetoprotein or beta-human chorionic gonadotropin, contrary to other reports in the literature, were not found to be predictive of an improved median OS. This discrepancy may have resulted from several confounding factors.

First, older studies of extragonadal germ cell syndrome included patients with PDCs who in actuality did not have CUP but had other highly treatable malignancies⁽⁴⁾. In a study by Hainsworth et al⁽⁸¹⁾, of the 36 long-term survivors, 20% were subsequently found to have either lymphoma⁽⁸⁾, testicular cancer⁽¹⁾, or

leiomyosarcoma⁽¹⁾. Conversely, in the study by Lenzi, patients in whom the primary site was identified were excluded from the analysis. Most of these patients were found to have highly treatable malignancies, such as lymphoma (6%), breast cancer (8%), ovarian cancer (3%), germ cell tumors (2%), and prostate cancer (1%). Exclusion of these patients would significantly reduce response and median survival rates.

Second, even among patients with PDC/PDAC of unknown primary, significant heterogeneity exists. In the study by Lenzi, CART analysis of 337 patients revealed different groups with widely discrepant survival times. The group with the longest median OS (40 months) included patients with PDC, lymph node involvement, and only one or two metastatic sites. By contrast, patients with non-lymph node metastases had a very poor prognosis, with a median OS of only 7 months⁽⁴⁾.

Carcinomas of Unknown Primary and Single Sites Discovered Incidentally on Resection

Carcinomas of unknown primary are notorious for unusual, isolated presentations. Such lesions may appear on the skin, in single isolated lymph nodes removed during surgery for benign unrelated conditions, and at other, even more unusual sites. Patients should be examined for primary tumors and other sites of metastasis, as described previously. If no primary tumor and no additional sites of metastasis are found, complete removal of the lesion must be ensured; this often requires additional excision with wider margins (if skin or subcutaneous). The patient may then be monitored without therapy and in selected cases are candidates for radiation. Many such patients may enjoy prolonged survival. Patients with isolated skin lesions may have an undifferentiated primary integumentary tumor with a potential for cure after adequate local surgical treatment.

CHEMOTHERAPEUTIC STRATEGIES FOR CARCINOMAS OF UNKNOWN PRIMARY

Combination regimens using newer chemotherapeutic agents have demonstrated greater benefit than did older single-agent therapies for CUP cancers. Several difficulties arise when survival and response rates reported in different chemotherapy trials are compared. For example, histologic criteria for patient selection often varied from study to study. Moreover, in older studies, IHC methods were not used to evaluate pathologic specimens. Despite these difficulties, no study has firmly established any chemotherapy regimen as the “gold standard”

in CUP. The median survival in most studies, regardless of regimen, has ranged between 5 and 13 months, with response rates of less than 30% and without a significant improvement in survival (Table 45-4).

Nevertheless, patients with certain clinical subtypes (eg, peritoneal carcinomatosis and lymph node–predominant disease) do benefit from chemotherapy. Historically, cisplatin-based combination chemotherapy regimens were frequently used to treat patients with CUP. Response rates in the literature range from 12% to 26% and median survival from 5 to 7 months. Combining paclitaxel with carboplatin has modestly improved both survival and response rates. In patients with widespread metastases and poor performance status, however, systemic chemotherapy is unlikely to be beneficial, and only supportive therapy is usually indicated.

In a phase II study by Hainsworth and colleagues, patients with CUP ($n = 55$) received paclitaxel (200 mg/m² day 1), carboplatin (AUC = 6 day 1), and oral etoposide (50 mg alternating with 100 mg days 1-10) every 21 days⁽⁸²⁾. Most were previously untreated, with only four having received prior chemotherapy. Most patients had moderately to well-differentiated adenocarcinoma (55%) or PDC/PDAC (38%), with squamous (2%) and neuroendocrine (5%) histologies less prevalent. The dominant sites of disease were lymph nodes (25%), liver (16%), and lungs (16%). Approximately 24% of patients in the study had multiple sites of disease, with 42% of patients having more than two metastatic sites. Response rates were equivalent in all histologic subgroups, with a reported ORR of 47% and a median OS of 13.4 months. This regimen was well tolerated, with myelosuppression the most common grade 3/4 toxicity. No treatment-related deaths were reported.

Briasoulis and colleagues⁽⁸³⁾ found equivalent response rates and median OS in CUP with carboplatin (AUC = 6) and paclitaxel (200 mg/m²) without oral etoposide. In this phase II trial, patients ($n = 77$) were given a maximum of eight cycles of chemotherapy. In addition, granulocyte colony-stimulating factor was administered on days 5 to 12. The proportions of differing histologic subtypes were comparable to those in the Hainsworth study: adenocarcinoma (61%), undifferentiated (35%), and squamous (4%). Three distinct clinical subsets were present in this study: peritoneal carcinomatosis (25%, mostly women); visceral or bony metastases (43%); and predominant nodal or pleural disease (30%). The reported ORR, median response duration, and median OS were 38.7%, 6 months, and 13 months, respectively. Although response rates were equivalent for adenocarcinoma and undifferentiated carcinoma, significant differences were seen among the three clinical subsets: liver/bone or disseminated metastases (ORR, 15.1%; median OS, 10 months); nodal/pleural disease (ORR, 47.8%; median OS, 13 months); and peritoneal (ORR, 68.4% [75% for women]; median

^aStatistically significant difference $P = .05$.

OS, 15 months), $P = .01$. Three patients with nodal-pre-dominant disease had durable responses lasting longer than 2 years. Grade 3/4 neutropenia was only 4%, with two reported septic deaths.

The results of docetaxel in combination with carboplatin in one small phase II study appear to be inferior to those of paclitaxel/carboplatin in the trials mentioned. The ORR was 22%, the median OS was 8 months, and the 1-year OS rate was 29%. Differences in sites of disease and histology among these three studies may account for the discrepancy. Severe grade 3/4 myelosuppression was more frequent with docetaxel (50%) than with paclitaxel, with two reported septic deaths⁽⁸⁴⁾.

Patients with undifferentiated or PDCs not fitting into the extragonadal germ cell or neuroendocrine clinical subgroups have traditionally been given a trial of a cisplatin-based regimen. Patients with squamous cell carcinomas who require chemotherapy are also often treated effectively using a cisplatin-based regimen.

The role of salvage chemotherapy in CUP is poorly defined. Gemcitabine has been published as second-line therapy in patients with previously treated CUP. In a phase II study by Hainsworth and colleagues⁽⁸⁵⁾, gemcitabine was administered weekly at 1,000 mg/m² (on days 1, 8, and 15 of a 28-day cycle). All patients ($n = 39$) received two cycles and were then evaluated for response. Chemotherapy was continued for a maximum of six cycles for either an objective response or stable disease. Approximately 90% of patients had failed a prior regimen containing platinum and a taxane. Most patients had either adenocarcinoma (59%) or PDC/PDAC (31%). Median time to progression was 5 months. Gemcitabine was well tolerated, with 92% of patients receiving two or more cycles. The most common grades 3 to 4 toxicities were fatigue/weakness and mucositis/esophagitis.

Hainsworth et al⁽⁸⁶⁾ reported on a combination-targeted therapy trial of bevacizumab and erlotinib in 51 patients; 25% were chemotherapy naïve with advanced bone or liver metastases, and 75% had been treated with one or two chemotherapy regimens. Responses were noted in 4 patients (8%), and 30 patients (59%) experienced stable disease or a minor response. The median OS duration was 8.9 months, with 42% of patients alive at 1 year.

These combination therapy trials have been a significant contribution in the post 5-fluorouracil and cisplatin era of second-generation chemotherapeutic agents. They have certainly served their function in allowing the access to several broad-spectrum chemotherapies in patients with CUP and helped us understand the responses to these therapies. Although evaluation of empiric regimens was the preferred approach in the past, with the emergence of modern molecular diagnostic trials that help define CUP subtypes, our

focus has shifted from empiric combinations to more tailored regimens, especially as directed by IHC and where helpful ToO or mutational profiles. Further, as therapies for known cancers improve and become more selective based on evolving predictive markers, the newer therapeutic approaches should be evaluated in the appropriate CUP subtypes as well.

SUMMARY AND FUTURE TRENDS

All patients with CUP should undergo a directed diagnostic evaluation for the primary tumor and a detailed pathologic evaluation of the metastatic specimen. A subset of patients defined by clinicopathologic criteria and considered to have favorable prognosis benefit significantly from selective or aggressive treatments. For most patients who present with advanced disseminated CUP, the prognosis remains poor, and no unique empiric combination therapy of established efficacy is available. We have moved away from the paradigm of one treatment fits all to a more focused approach that integrates clinical presentation, pathologic evaluation, and the evolving diagnostic tools. Our current focus is to study the impact of molecular profiling and next-generation sequencing-based studies that help individualize CUP treatments. More broadly, there is an extensive push toward personalizing cancer care through the use of genomic tools to identify driver mutations in an individual tumor. For this approach to be successful, it will require both additional molecular insights and novel drugs that are effective against specific mutations.

INTRODUCTION

Fortunately, pediatric cancers are rare, with only 1 in 300 children being diagnosed before 18 years of age. And, with overall survival (OS) approaching 80%, there is hope for most of these children and for their families. However, just as in adults, if their cancer is metastatic at diagnosis, if the cancer does not respond to standard therapies, or if they suffer a relapse, the prognosis is universally grim. Despite intensified therapies, the survival for most children with relapsed cancer has not improved in decades. In large part, this is due to the toxicities of such regimens as we have likely reached the tolerable limit with most chemotherapeutic agents. Thus, as is the case for adults with cancer, there has been a focus on understanding the underlying biology of the disease to find targetable lesions and to develop novel agents and treatment regimens to improve survival in children with relapse. However, there are multiple challenges we face. First, the spectrum of pediatric cancers is distinctly different from adults (Fig. 46-1), with acute lymphoblastic leukemia (ALL), medulloblastoma and gliomas, neuroblastoma, Hodgkin and non-Hodgkin lymphomas, and sarcomas the most common cancers in children as opposed to the most common carcinomas of the prostate, breast, lung, colon, and so on in adults. Second, the relative rarity of these cancers results in less preclinical research to find and develop potential therapeutic targets and limited patient numbers to enroll and test novel therapeutic strategies.

One of our approaches has been to study the pediatric cancers in parallel with similar adult tumors and

to enroll patients on early adult trials to give children access to promising agents and to provide some data on safety and efficacy to support the development of pediatric-specific trials. In this chapter, we present a few examples of tumor types seen commonly in children and describe some of the therapeutic advances and promising strategies for treating children with relapsed cancers.

SALVAGE STRATEGIES

Acute Lymphoblastic Leukemia

Acute lymphoblastic leukemia is the most common cancer diagnosis in children, accounting for 25% of cancer diagnoses in children 15 years old or less. An estimated 3,000 new cases of childhood ALL are diagnosed yearly in the United States. After a peak incidence of 90 cases per million per year at age 2 to 3 years, ALL incidence rates decrease steadily into adolescence. Initial complete remission (CR) rates are 95%, and survival in childhood ALL is approaching 90% through the application of reliable prognostic factors that permit use of risk-oriented treatment protocols. However, relapse occurs in approximately 20%, with higher rates of relapse in adolescents and young adults as well as children less than 1 year of age (ie, “infants”). Despite excellent outcomes overall, relapsed patients with ALL outnumber nearly all other childhood malignancies. With traditional intensive combination chemotherapy and allogeneic hematopoietic stem cell transplantation, 30% to 40% of all children with relapsed ALL can be cured. The factors that effect

FIGURE 46-1 Spectrum of Pediatric and Adult Cancers.

salvage rate are timing of relapse (18-36 months from diagnosis), site of relapse (bone marrow, central nervous system [CNS]/testicular, combined), and immunophenotype (T cell vs B cell). Unfortunately, most children still die from relapsed ALL despite aggressive chemoradiotherapy approaches, including transplantation, and novel salvage regimens are needed (¹).

For children with first relapse of childhood ALL, the mitoxantrone-based Medical Research Council (MRC) ALL R3 relapsed protocol has relatively better outcomes than other common regimens and is currently our standard reinduction regimen (²). Promising CR2 rates have also been seen with the addition of the proteasome inhibitor bortezomib to the MRC ALL R3 backbone, with 80% (16/20) CR/CRi in B-ALL patients (³), as well as the addition of bortezomib to the more traditional four-drug reinduction regimen in COG AALL07P1, with 64% (63/99) of B-ALL patients achieving CR2. Surprisingly, AALL07P1 showed similar CR2 rates of 68% (15/22) in T-ALL patients (⁴). The current first relapse regimen under study in the COG is testing the substitution of the CD19-targeting bispecific engaging antibody blinatumomab to the MRC ALL R3 relapsed protocol.

With attainment of CR2 in 70% to 85% (<1% minimal residual disease by flow cytometry), we offer transplant to most children with relapsed ALL, with very late relapses and isolated CNS relapses as

typical exceptions. We offer a variety of transplant trials, including cord blood and haploidentical, as well as addition of anti-CD19 chimeric antigen receptor (CAR) T cells, natural killer (NK) cells, and so on. Failure to respond adequately to first-relapse regimens leads to a variety of second-line regimens. We commonly offer clofarabine/cyclophosphamide/etoposide (CR2 rates of 44% [⁵]), mitoxantrone/cytarabine (CR2 rate of 57% [⁶]) or one of several targeted agents with the institutional adult ALL regimen hyper-CVAD (⁷), or promising single agents when available. With recently published complete responses in children (⁸), we are testing the combination of anti-CD22 immunotoxin inotuzumab with hyper-CVAD (without anthracycline), with some dramatic responses in children. In addition, the combination of the mTOR inhibitor everolimus and Hyper-CVAD is being tested. For T-cell ALL specifically, we have used nelarabine in combination with hyper-CVAD (⁹), a trial testing a 5-day continuous infusion of nelarabine (NCT01094860), and a single agent Notch-inhibiting gamma secretase inhibitor BMS-906024 phase I trial (NCT01363817), based on multiple responses in adults (¹⁰).

Targeting ALL blasts with antibodies, both unconjugated and conjugated to toxins, has been shown to be an effective therapeutic strategy. Monoclonal antibodies to surface antigens such as CD19, CD20, CD22,

and CD52 have been used in unconjugated form (eg, rituximab and epratuzumab), conjugated to immunotoxins or chemotherapeutic drugs (eg, moxetumomab, inotuzumab ozogamicin), or in the form of bispecific antibodies (eg, blinatumomab). The incorporation of rituximab (CD20) into the hyper-CVAD regimen showed improved outcome in adults younger than 60 years with more than 5% CD20-positive, *BCR-ABL1*-negative B lymphoblastic leukemia (¹¹). Recent significant success with the anti-CD19-anti-CD3 bispecific T-cell engaging (BiTE) antibody blinatumomab has led to responses in about 50% of patients with relapsed pediatric B-ALL.

Recent therapeutic advances in ALL have also included the use of adoptive immunotherapies. Anti-CD19 CAR-expressing T cells have shown dramatic success in patients with relapsed B-ALL, with up to 90% remission rates reported (¹²). We have developed a unique nonretroviral approach utilizing the Sleeping Beauty transposon system to transfect T cells with CAR constructs, opening this technology to rapid translation of targetable tumor markers (¹³).

Patients with *BCR-ABL1*-positive ALL had poor prognoses. When tyrosine kinase inhibitors targeting *ABL1* are added to multidrug chemotherapy, CR rates are more than 90%, and event-free survival (EFS) is superior to that in historical controls. Recent work has discovered that a subset (~10%) of children with *BCR-ABL1*-negative ALL have gene expression patterns similar to those with *BCR-ABL1*-positive ALL. Most children and adults with this “Ph-like” ALL harbor a range of novel kinase translocations (including *ABL1*, *ABL2*, *PDGFRB*, *EPOR*, *JAK2*, *JAK1*, etc.), some of which are targetable clinically. Thus, we and others have begun to screen for these lesions and to target these cases with appropriate kinase inhibitors (dasatinib, ruxolitinib) and chemotherapy in the clinical trial setting (^{14, 15}).

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is one of the first malignancies cured by a combination of chemotherapy and radiation therapy (RT). With appropriate staging and evaluation of treatment response using positron emission tomographic (PET) scanning, current treatment for HL achieves a 5-year EFS of 80% and 5-year OS of more than 90% (¹⁶). The standard of care for patients with relapsed or refractory HL is salvage chemotherapy followed by autologous stem cell transplantation (SCT), which can induce long-term remissions in approximately 50% of patients. The malignant Hodgkin's Reed-Sternberg cells of classical HL are characterized by the expression of CD30, a member of the tumor necrosis factor T cells, and eosinophils; it represents an ideal target for monoclonal antibody therapy.

Brentuximab vedotin (SGN-35) is an antibody-drug conjugate (ADC) comprising an anti-CD30 antibody conjugated by a protease-cleavable linker to the potent antimicrotubule agent monomethyl auristatin E (MMAE). Binding of the ADC to CD30 on the cell surface initiates internalization of the ADC-CD30 complex, which then disrupts the microtubule network, induces cell cycle arrest, and results in apoptotic death of the CD30-expressing tumor cell. Brentuximab vedotin is currently approved by the Food and Drug Administration (FDA) for HL after failure of autologous SCT or failure of two chemotherapy regimens with patients who are not candidates for autologous SCT (¹⁷). Use of brentuximab vedotin at an earlier treatment time is under investigation with multiple clinical trials. Phase I study of brentuximab vedotin with standard chemotherapy of doxorubicin, bleomycin, vincristine, and decarbazine (ABVD) and modified standard chemotherapy with doxorubicin, vincristine, and decarbazine (AVD) as first-line treatment for advanced-stage HL showed significantly increased pulmonary toxicity associated with the combination of brentuximab vedotin and bleomycin. This study confirmed the dose of brentuximab vedotin was safely escalated to 1.2 mg/kg and showed a remarkable response rate of 95% to 96% to the therapy (¹⁸).

Osteosarcoma

Osteosarcoma is the most common malignant bone tumor of childhood. Osteosarcoma typically affects pubertal adolescents, with a peak incidence in childhood of 12 years. Risk stratification can be made using tumor stage, location, and response to therapy. Survival of patients with nonmetastatic disease at the time of diagnosis has improved dramatically over the past 30 years due to advances in chemotherapy and surgery, with 60% to 65% of patients surviving more than 10 years. However, patients who present with metastatic disease at the diagnosis or those who have recurrent disease have a poor prognosis, with OS rates of less than 20% (¹⁹).

Treatment of metastatic or relapsed osteosarcoma is challenging, although multiple novel approaches are being tested. One approach under investigation is targeting the bone-forming behavior of this tumor through treatment with radioactive samarium 153-EDTMP or more recently radium 223 dichloride, which concentrated in bone-producing osteosarcoma (²⁰). As another approach, we have introduced immunomodulators into osteosarcoma therapy. Based on its potent immunostimulatory properties, liposomal muramyl tripeptide phosphatidylethanolamine (L-MTP-PE) was added to standard osteosarcoma chemotherapy. Although the statistical benefit to survival was not clear in the largest US trial, the European Medicines Evaluation Agency

approved this therapy for patients with pulmonary metastases of osteosarcoma; however, it is not currently available in the United States. More recently, we have used aerosolized interleukin (IL) 2 to enhance local immune responses against pulmonary metastases. Preclinical evidence demonstrates that aerosolized gemcitabine upregulates *Fas* expression in pulmonary metastases, leading to immune sensitivity ⁽²¹⁾.

Desmoplastic Small Round Cell Tumor

Desmoplastic small round cell tumor (DSRCT) is an extremely rare undifferentiated mesenchymal tumor that affects about 100 children, adolescents, and young adults annually in the United States. It is an aggressive tumor that may show a response to multimodal front-line therapy, although OS rates remain below 30%. The t(11;22) *EWS-WT1* translocation is seen in the majority of cases, confirming the unique pathobiology of this disease.

For patients with relapsed DSRCT, few chemotherapeutics have shown activity, and targeted agents have had limited success as well. However, the insulin-like growth factor (IGF) 1R-inhibiting antibody ganitumab showed one partial response, and there were 3 patients with prolonged stable disease (>24 weeks) of 16 patients with DSRCT. Individual partial responses have been seen with other agents (eg, the multikinase inhibitor pazopanib, the novel agent tasisulam, etc.). Unfortunately, DSRCT frequently disseminates throughout the peritoneal cavity. For these cases, we have used the approach of combining extensive surgical resection followed by hyperthermic intraperitoneal chemotherapy (HIPEC), which has shown promise ⁽²²⁾.

Medulloblastoma

Medulloblastoma is the most common pediatric malignant CNS tumor, with a peak age of incidence at 5 years and with 80% of medulloblastomas occurring before the age of 15 years. Medulloblastoma is known to be associated with familial cancer syndrome in less than 1% of patients; Gorlin (*PTCH* mutation, SHH receptor) and Turcot (mismatch repair genes) syndromes are the most common. Age less than 3 years at diagnosis, residual tumor after resection, anaplastic histology, *MYC* amplification, 17p loss, and metastatic disease may predict poor outcome. Children with localized disease have a greater than 80% 5-year EFS comparing to those with disseminated disease, who have less than 40% EFS. Treatment typically is multidisciplinary, including surgery, chemotherapy, and RT in newly diagnosed children more than 3 years old.

Recent genomic studies have identified four subtypes of medulloblastoma with distinct cellular origins, namely, WNT, SHH, group 3, and group 4, with

the WNT and group 3 subtypes having the best and worst prognosis, respectively. Recurrent mutations in *CTNNB1*, *PTCH1*, *MLL2*, *SMARCA4*, *DDX3X*, *CTD-NEP1*, *KDM6A*, and *TBR1* have been identified ⁽²³⁾. The pathways of current clinical interest for medulloblastoma include *VEGF*, *SHH*, *WNT*, *Notch*, and *ERBB* with therapeutic implications ⁽²⁴⁾.

For standard-risk medulloblastoma, Packer et al reported that 421 patients between 3 and 21 years of age with nondisseminated medulloblastoma were prospectively randomly assigned to treatment with 23.4 Gy of craniospinal RT, 55.8 Gy of posterior fossa RT, plus one of two adjuvant chemotherapy regimens: lomustine (CCNU), cisplatin, and vincristine or cyclophosphamide, cisplatin, and vincristine. The results of this study disclosed an 81% 5-year EFS rate for children older than 3 years of age with nondisseminated disease ⁽²⁵⁾. Proton beam-based radiation is currently being investigated as an alternative to conventional irradiation (NCT01063114).

For high-risk medulloblastoma in children under the age of 3, a German group conducted a study for new diagnoses of medulloblastoma treated with postoperative chemotherapy alone, consisting of cyclophosphamide, methotrexate, vincristine, carboplatin, and etoposide. Forty-three children were treated according to the protocol. In children who had complete resection (17 patients), residual tumor (14), and macroscopic metastases (12), the 5-year progression-free survival (PFS) and OS rates (+/- SE) were 82% +/- 9% and 93% +/- 6%, 50% +/- 13% and 56 +/- 14 %, and 33% +/- 14% and 38% +/- 15%, respectively ⁽²⁶⁾.

An alternate treatment approach for patients less than 3 years old is to avoid radiation and use high-dose chemotherapy and autologous stem cell rescue. Dhall et al reported the result for 21 patients with nonmetastatic disease. The 5-year EFS and OS rates (+/- SE) for all patients, patients with gross total resection, and patients with residual tumor were 52% +/- 11% and 70% +/- 10%, 64% +/- 13% and 79% +/- 11%, and 29% +/- 17% and 57% +/- 19%, respectively. The 5-year EFS and OS (+/-SE) for patients with desmoplastic and classical medulloblastoma were 67% +/- 16% and 78% +/- 14%, and 42% +/- 14% and 67% +/- 14%, respectively ⁽²⁷⁾. There were four treatment-related deaths. The majority of survivors (71%) avoided irradiation completely. Mean intellectual functioning and quality of life for children surviving without irradiation was within average range for a majority of survivors tested.

For relapsed medulloblastoma, the combination of irinotecan and temozolomide showed some efficacy, with an objective response rate 33.3%; 68.3% experienced clinical benefit, and median survival was 16.7 months ⁽²⁸⁾.

In MD Anderson, our focus is to profile novel therapy for relapsed brain tumors. Focusing on locoregional

and immunotherapy, we have begun to infuse methotrexate into a catheter placed in the fourth ventricle to target posterior fossa tumors (medulloblastoma, ependymoma, and ATRT; NCT02458339) ⁽²⁹⁾. Extending this approach of targeting the posterior fossa tumors, we now infuse autologous ex vivo expanded NK cells (NCT02271711). Another area of interest is target therapy; we are testing an SHH inhibitor for relapsed medulloblastoma.

Low-Grade Gliomas

Approximately half of pediatric CNS tumors are gliomas and are associated with two cancer predisposition syndromes: neurofibromatosis 1 (*NF1* mutations) and tuberous sclerosis syndrome (*TSC* mutations). Gliomas occur in both children and adults; however, the majority of pediatric gliomas are low-grade gliomas (LGGs), with indolent pilocytic astrocytomas the most common subtype. Surgical resection, if feasible, is the most effective therapeutic option, with complete resection of an LGG leading to greater than 90% survival, while less than total resection leads to an about 60% survival. The management of pediatric LGGs that cannot be completely resected has evolved considerably during the last two decades. Although radiation used to be the standard treatment for incompletely resected or unresectable LGGs, chemotherapy and observation have now progressively become the most commonly used options after initial diagnosis, depending on several factors, including tumor location, amount of residual tumor, age, or association with *NF1*.

The most widely used first-line chemotherapy is a combination of vincristine and carboplatin. In a study of children with newly diagnosed LGGs with evidence of progression, 56% had an objective response to vincristine/carboplatin, and PFS was 68% \pm 7% at 3 years ⁽³⁰⁾. Multiple chemotherapies are proven to be effective as treatment of LGGs, including vinblastine, temozolomide, irinotecan, and bevacizumab ⁽³¹⁾. However, some of the short-term and long-term adverse effects are not negligible: severe myelosuppression that requires transfusion and growth factors, hearing loss, or infertility. The COG study showed that a procarbazine, thioguanine, lomustine, and vincristine combination had similar EFS as a combination of vincristine and carboplatin ⁽³²⁾. Any of the chemotherapies mentioned can be used as relapse treatment if not used as frontline treatment. Although there is no single standard of care, tolerability and long-term adverse effects are considered to be major factors to determine the treatment plan.

Importantly, translocations of *BRAF* occur in 70% of pilocytic astrocytomas ⁽³³⁾, and the *BRAF* V600E-activating mutation occurs in 5% to 10% of pediatric pilocytic astrocytomas. Although the *BRAF* V600E

mutation is not frequently seen with pediatric gliomas, there are case reports that gliomas with *BRAF* V600E mutation showed a dramatic response to vemurafenib ⁽³⁴⁾. We offer screening of the mutation and have been experiencing cases with great responses. Because adult melanoma studies showed that most of the patients develop resistance to vemurafenib after a certain period, development of resistance to vemurafenib is also concerning with pediatric gliomas. To overcome this resistance, mTOR inhibitor (everolimus) has been combined with vemurafenib in a phase I trial at MD Anderson (NCT01596140). Alternatively, MEK1 inhibitor, when combined with *BRAF* inhibitor in melanoma patients, showed improvement of EFS and overcame single-drug resistance ⁽³⁵⁾.

Diffuse Intrinsic Pontine Glioma

Diffuse intrinsic pontine glioma (DIPG) comprises 70% to 80% of brainstem tumors in children, with an annual incidence of nearly 300 in the United States. Despite the collaborative efforts and advancement in the multimodality management of brain tumors, the prognosis of these tumors has remained dismal over the last two decades and poses therapeutic challenges. The median OS has remained 9 to 12 months. These tumors occur commonly between the ages of 5 and 10 years, arising from the pons and causing its diffuse enlargement. Stereotactic biopsy of these tumors was first reported in 1978. There have been arguments against biopsy as this is thought to have poor yield and biology of the limited sample would not be truly representative of the entire tumor. Treatment strategies based on clinical trials in adults with high-grade gliomas (HGGs) did not translate into increased OS of DIPG. Today, focal RT given over 6 weeks remains the standard of care for newly diagnosed DIPG ⁽³⁶⁾.

Recently, whole-genome, whole-exome, or transcriptome sequencing identified recurrent somatic mutations in *ACVR1* exclusively in DIPGs (32%), in addition to previously reported frequent somatic mutations in histone H3 genes *TP53* and *ATRX* ⁽³⁷⁾. Structural variants generating fusion genes were found in 47% of DIPGs, with recurrent fusions involving the neurotrophin receptor genes *NTRK1* and *NTRK2*. Mutations targeting receptor tyrosine kinase–RAS–PI3K signaling, histone modification or chromatin remodeling, and cell cycle regulation were found in 68%, 73%, and 59% of pediatric HGGs, respectively, including in DIPGs. There have been multiple trials with target therapies, imatinib, sunitinib; however, none of them showed increased OS. There is also always concern of drug penetration to the tumor in the pons area. Currently, a COG phase I/II study is investigating use of suberoylanilide hydroxamic acid (SAHA) along with RT and maintenance therapy with SAHA for newly

diagnosed DIPG. For relapsed DIPG, the tumors that respond to radiation once and show progression after a certain period, multiple target therapies such as SAHA and everolimus are under consideration for clinical trials. Re-irradiation is also an option for patients who maintain stable disease for a certain period.

High-Grade Gliomas

The outcome for children with HGGs remains poor despite the use of multimodal therapy with surgery, RT, and chemotherapy. Although RT does prolong time to progression slightly, adjuvant chemotherapy has had little impact on survival in children with HGGs. In the first study by the Children’s Cancer Group (CCG 943), RT with chemotherapy consisting of chloroethyl-cyclohexyl nitrosourea (CCNU), vincristine, and prednisone following surgical therapy showed a 5-year EFS of 46%, compared to 18% in patients with RT only. Then, the CCG 945 study showed no improvement in survival for patients treated with the 8-in-1drug regimen compared to the CCNU/vincristine/prednisone regimen. Five-year PFS was 19% +/- 3%, while those who did not have a GTR had a 5-year PFS of 11% +/- 4% (38). The COG ACNS0126 study used temozolomide as a radiosensitizer followed by 10 cycles of temozolomide at 200 mg/m²/d for 5 days of every 28-day cycle. The 3-year EFS and OS were 11% +/- 3% and 22% +/- 5%, respectively (39). The results with temozolomide given during RT and as an adjuvant therapy were similar to CCG 945 (P = .98). ACNS0126 demonstrated comparable survival with less toxicity than in studies utilizing prior nitrosourea-based regimens, which made temozolomide a de facto standard treatment.

Recently, the COG study conducted a randomized “pick-the-winner” approach to determine if either of the two experimental treatment arms (bevacizumab or vorinostat during chemoradiotherapy) had a higher nominal 1-year EFS than the standard treatment arm (temozolomide during chemoradiotherapy). A preliminary report showed that there was no significant benefit from choosing bevacizumab or vorinostat over temozolomide (40). From adult studies and small pediatric studies, using bevacizumab along with temozolomide as adjuvant therapy is tolerable therapy, and this was used as a backbone neoadjuvant therapy in this study (41).

For relapse HGGs, adult studies for glioblastoma multiforme (GBM) suggest bevacizumab and protracted temozolomide for recurrent/progressive disease even after prior temozolomide exposure (42). Multiple adult studies with recurrent HGGs showed activity of bevacizumab with or without irinotecan (43). Bevacizumab in patients with recurrent GBM is approved by the FDA. To date, robust identification and correlation of dysfunctional genes with the tumorigenesis

have not been performed—a likely reason for continuing therapeutic failure. There is a dire need to treat these patients as they come for therapy after having exhausted treatment options. To understand the genetic landscape of relapsed brain tumors, we enroll our patients in the CM50 study, which is a sequencing study of 50 genes commonly altered in cancers, with at least 50% of those genes pertinent to pediatric brain cancers. We are currently opening a phase I targeted therapy trial for pediatric HGG. The trial is using a combination of dasatinib (PDGFR and SRC inhibitor) and temsirolimus (mTOR inhibitor) and metronomic cyclophosphamide (antiangiogenesis) for targeting the most common driving pathways in pediatric HGG: AKT and angiogenesis (NCT02389309) (61).

FINAL WORD

Although OS for children with cancer is excellent, children with relapsed disease still face dismal outcomes. Several recent successes (Table 46-1) have allowed us to make significant progress for specific subsets of patients, although much more work must be done. We

Table 46-1 Current Successful Treatments

Cancer Type	Salvage Therapy	Targeted Therapy
Acute lymphoblastic leukemia	MRC R3 protocol	Blinatumomab, CAR19 T cell
Hodgkin lymphoma	High-dose chemo with autologous SCT	Brentuximab
Osteosarcoma	Ifosfamide, etoposide	Radium 223, aerosolized IL-2
Desmoplastic small round cell tumor	HIPEC	Ganitumab, pazopanib
Medulloblastoma	Irinotecan + temozolomide, fourth-ventricle methotrexate, IT: intrathecal lipo-AraC	Fourth ventricle NK cell
Low-grade glioma	Vinblastine, irinotecan, temozolomide	Vemurafenib
Diffuse intrinsic pontine glioma	Reradiation	Vorinostat, everolimus
High-grade glioma	Temzolomide, bevacizumab, Irinotecan	Vemurafenib

still face the challenges of increasing knowledge of the biology of these tumors, and through increasing access to novel therapeutic agents, we are hopeful that we will be able to make a brighter future for our young patients.

CANCER GENES

Over the past 50 years, multiple discoveries have had an impact on our understanding of key genomic events that influence the development of malignant growth. After many large-scale sequencing projects of cancer genomes, we now understand that many genetic alterations in specific cancer genes are responsible for the development and progression of the disease. These alterations may occur at the level of the patient's germline, predisposing to inherited forms of cancer that may develop in many tissues throughout the body. Genetic alterations may also be somatic, or newly acquired changes within the genes of an individual cell or group of cells over time and due to environmental stresses. Somatic alterations may come in many forms, including single-base substitutions; insertions or deletions of DNA fragments; rearrangements and rejoining of DNA from alternative locations in the genome; and copy number increases and reductions. Should these alterations affect key cancer genes, malignancy may develop.

In the early 1970s, when studying retroviruses that reverse transcribe RNA into DNA, it was found that (1) certain retroviruses, when incorporated into host cells, have the ability to transform normal cells into rapidly dividing tumors. Rous sarcoma virus (RSV), isolated by Peyton Rous, was the first retrovirus found to cause sarcoma in chickens (2). Later, hybridization studies proved that the RSV gene, termed *v-src*, was homologous to a highly conserved eukaryotic gene, *c-src*. *Src* became the first known viral oncogene (3). In contrast to highly transforming retroviruses, weakly transforming viruses can insert into the genome near proto-oncogenes,

normal genes that when mutated give rise to an oncogene, and induce cancer. Activation of proto-oncogenes to oncogenes, through activating point mutations, gene amplification, or chromosomal translocation events, can occur independent of retroviral transformation and cause cancer.

In 1981, Shih and colleagues showed that normal NIH3T3 mouse fibroblast cells could be made cancerous by introduction of total genomic DNA from human cancers (4). Isolation of the specific DNA segment responsible for this transforming activity led to the identification of the first naturally occurring, human cancer-causing sequence change—the single-base G > T substitution that causes a glycine-to-valine substitution in codon 12 of the *HRAS* gene (5). These experiments demonstrated the causal relationship between oncogenic mutations and cancer. The discovery of *HRAS* and many other oncogenes altered our understanding of cancer and expanded our knowledge of driver mutations that can be targeted to treat disease.

Another commonly referred to class of cancer genes is tumor suppressor genes. These genes are frequently involved in cell cycle regulation, inhibition of cellular proliferation, and DNA repair. When functioning normally, they act as barriers to unregulated tumor growth. However, dysfunction of both copies of the gene are usually required to initiate tumor development as only one functioning copy is needed to regulate the cell. Alfred Knudson, in 1971, was the first to theorize about the role of tumor suppressor genes in cancer development (6). He described the two-hit hypothesis: The development of cancer was due to the

loss of inherited regulatory genes that functioned to suppress tumor formation, subsequently followed by the somatic loss of the normal homologous allele. In non-hereditary forms, both alleles would be somatically affected (^{6,7}).

The first tumor suppressor gene to be identified was the retinoblastoma (*RB*) gene, found to cause childhood cancers of the retina. In the hereditary form, one copy of the *RB* gene is usually defective, with a second mutation or deletion of the normal gene leading to early cancer development. Hereditary forms frequently affect the bilateral eyes. Sporadic retinoblastoma is much rarer and occurs when there is homozygous deletion or somatic mutation of both normal copies of the gene. Sporadic retinoblastoma usually presents later in life than the hereditary form and usually affects only one eye.

In the mid-1980s, Webster Cavanee localized the retinoblastoma gene to a small region on chromosome 13 and found that both the inherited and sporadic varieties had the same secondary abnormalities leading to homozygosity of mutations in the *RB* region (⁸). In 1986, Stephen Friend isolated human complementary DNA mapping to the *RB* gene (⁹). The following year, Wen-Hwa Lee and Yuen-Kai Fung both cloned *RB* using chromosome walking (^{10,11}). Huei-Jen Su Huang and colleagues later proved a causative relationship between the defective *RB* gene and cancer by performing rescue experiments of the neoplastic phenotype in *RB*-mutated retinoblastoma cells with wild-type *RB* (¹²). Aside from retinoblastoma, many tumors have subsequently been found to have defects in the *RB* gene, which may play a role in the establishment of these cancers.

NEXT-GENERATION SEQUENCING

Completion of the Human Genome Project in April 2003 and subsequent publication of a human reference genome provided new opportunities for analyzing cancer. Early on, many groups conducted these studies by sequencing large segments of polymerase chain reaction (PCR) products to detect substitutions and small insertions and deletions. More recently, second-generation sequencing, or next-generation sequencing, has revolutionized the field of oncology by allowing for the entire sequencing of whole genomes in a relatively timely and economic manner (¹³). Commonly used next-generation platforms include the Illumina and Ion Torrent systems. In just over a week, a solitary run on an Illumina HiSeq 2000 sequencer can generate 200 gigabases of data. Over the past decade, there has been a dramatic decrease in sequencing cost with an increase in sequencing capacity that has outpaced Moore's

law of technology (¹⁴). Deep sequencing and single-cell sequencing has allowed us to identify mutations in highly admixed samples. In addition, next-generation sequencing has allowed us to query multiple genomic alterations at a time, such as somatic mutations, copy number variations, as well as some structural information common to cancer (¹⁵).

MUTATIONAL BURDEN OF CANCER

Some cancers may be driven by a single mutation alone; however, other tumors may contain alterations in multiple driver genes, leading to overproliferation. On the low end of the range, leukemias and liquid malignancies harbor far fewer coding single mutations, about 9.6 per tumor that would alter protein-coding sequence, on average (^{16,17}). Some more common solid tumors, such as colon, breast, brain, or pancreas, contain 33 to 66 genes, on average, with coding somatic mutations (¹⁶). The large majority, about 95% of mutations, are single-base substitutions (90.7% missense, 7.6% nonsense, and 1.7% alterations of splice sites or untranslated regions), the minority being insertions or deletions of one or more bases (¹⁶).

Toxic environmental factors may cause some tumors to have markedly more mutations than others with distinct mutational signatures. In addition, defects in DNA repair proteins such as dysfunction in the Fanconi pathway, the DNA mismatch repair pathway (Lynch syndrome), or the proofreading domains of DNA polymerases *POLE* or *POLD1* may increase mutational burden (^{18,19}). Recently, it was also found that the median frequency of mutations varies within cancer types as well. In 2013, Lawrence et al published a study examining 27 different cancer types. This study showed a wide variance in the frequency of nonsynonymous mutations that ranged more than 1,000-fold across cancers within a given subtype (Fig. 47-1) (²⁰). As previously described, this study showed a high frequency of mutations in melanoma and lung cancer, thought to be caused by UV radiation and tobacco carcinogen exposure, respectively, with over 100 mutations/Mb. The frequency of mutations in melanoma and lung cancers was also quite variable, however, ranging from 0.1 to 100 mutations/Mb. Although less extreme than the latter cancers, acute myelogenous leukemia's (AML's) frequency of mutations also ranged widely from 0.01 to 10 mutations/Mb. This was despite the overall low number of mutations (0.37/Mb) (²⁰). Alexandrov and colleagues analyzed the sequencing data from 7,042 cancers and demonstrated that these tumors exhibited greater than 20 discrete mutational signatures. Some signatures could be found across cancer types (ie, APOBEC cytidine deaminase signature),

FIGURE 47-1 Whole-exome somatic mutation frequencies in 3,083 tumor-normal pairs. Each dot represents a tumor-normal pair. The y axis is the total somatic mutation frequency. Tumor types are ordered on the x axis (lowest to highest) by their median somatic mutation frequency. (Reproduced with permission from Lawrence MS, Stojanov P, Polak P, et al: Mutational heterogeneity in cancer and the search for new cancer-associated genes, *Nature*. 2013 Jul 11;499(7457):214-218.)

and other signatures were found in a single cancer class. Kataegis, or regional hypermutation, was also found in many cancers ⁽²¹⁾.

Despite the number of mutations present, not all mutations contribute to the production and growth of tumor cells. Identifying the background mutation rates for tumors as described previously was integral to our understanding of those genes that play a key role in the development of the tumor and confer a selective growth advantage. These alterations in genes are termed *driver* mutations. Those genes that are present within the tumor but do not contribute to tumor formation are deemed *passenger* mutations ⁽²²⁾. Driver mutations may not all contribute to tumor growth in the same manner, and some driver mutations may be integral to certain steps of tumor development (proliferation vs invasion). Common driver mutations that occur in cancer genes include *PTEN*, *EGFR*, *TP53*, *IDH1*, *RB1*, *KRAS*, and *BRAF* ⁽²³⁾. In addition, some mutations originally deemed passenger mutations may become drivers once treatment leads to eradication of sensitive clones and provides a niche for already present, resistant, clones to develop ⁽²⁴⁾. Work is currently under way to target these genes for treatment options.

CHROMOSOMAL GAINS, LOSSES, AND TRANSLOCATIONS

Chromosomal gains, losses, and translocations are some commonly observed hallmarks of cancer alterations. Somatic copy number alterations may span the entire chromosome or one arm of a chromosome, although they may be limited to particular regions of the genome ⁽²⁵⁾. It has been reported that an average cancer cell may have gains or losses involving a quarter of its chromosomes, with smaller, local events affecting about 10% of the genome ⁽²⁶⁾. Many of these focal events occur in “peak” regions, affecting a median of 6 to 7 genes (although up to 150-200 genes in some cases). Due to the broader effect of amplification and deletion events, it is difficult to interpret which genetic alterations contribute to carcinogenesis ^(15, 27).

Chromosomal translocations are associated with both liquid and solid malignancies, particularly leukemias, lymphomas, and sarcomas. In some tumors, translocations can result in the fusion of genes normally found at a distance from each other or bring genes closer to enhancer or promoter elements, resulting in alteration in their normal expression patterns. The number of translocations may differ between cancers depending on their degree of genomic instability ⁽²⁸⁾.

As discussed further in the chapter, translocations can become targets for cancer treatment.

TUMOR HETEROGENEITY

Not only have tumors been found to have a varied number of mutations, but also tumors display intratumoral heterogeneity, with diverse mutations within a given tumor type. In melanoma, for example, *BRAF* mutations are present in about 50% to 60% of patients, allowing for the majority, but not all, patients to benefit from *BRAF* inhibitors^(29,30). Intertumoral heterogeneity therefore may have an impact on treatment of patients as each individual patient's tumor may respond to a drug differently. Currently, sequencing is used to correlate mutation status with disease response in individual patients and may be used as a biomarker to stratify patients in a clinical trial. Large-scale sequencing projects by groups such as The Cancer Genome Atlas and the International Cancer Genome Consortium have set out to characterize the mutational landscape of various tumors to obtain a better understanding for the degree of tumor diversity^(31,32).

As mutations may vary among individuals with the same type of cancer, individual tumors or their metastatic lesions may also have cells with distinct mutations and, by extension, phenotypes. This is termed *intratumoral heterogeneity*⁽³³⁾. This added complexity may account for partial responses to treatment and therapeutic resistance within an individual when

treated with chemotherapy or targeted agents. Two classically described theories regarding the development of intratumoral heterogeneity include the cancer stem cell hypothesis and the clonal evolution model. In the cancer stem cell hypothesis, it is suggested that a small, distinct population of cells retain the ability to grow and divide. These cells are responsible for the maintenance of the tumor. As is seen with noncancerous stem cells throughout the body, epigenetic modifications can cause these cells to differentiate into their biologically diverse nonrenewable constituents. These diverse, differentiated cancer cells compose the bulk of tumor, yet do not necessarily contribute to its expansion and tumorigenic potential⁽³⁴⁾. In the clonal evolution model, with time, genetic and epigenetic events accumulate in cells; if these changes confer a competitive advantage, they will allow selective growth of distinct clones that survive over others⁽³⁴⁾. It is possible that both phenomena can occur in the same tumor. Figure 47-2 depicts the two models⁽³⁵⁾.

The expansion of subclones may occur in a linear or branched fashion⁽³⁶⁾. In 2012, Gerlinger and colleagues published a paper in the *New England Journal of Medicine* using multiregional whole-exome sequencing of four renal cell carcinoma samples to elucidate the subclonal architecture and branched evolution of the disease. They found that the majority of driver alterations were subclonal, which acted as a confounder when identifying pertinent driver mutations. This study also demonstrated the unconventional pattern of mutations with regional patterns of heterogeneity.

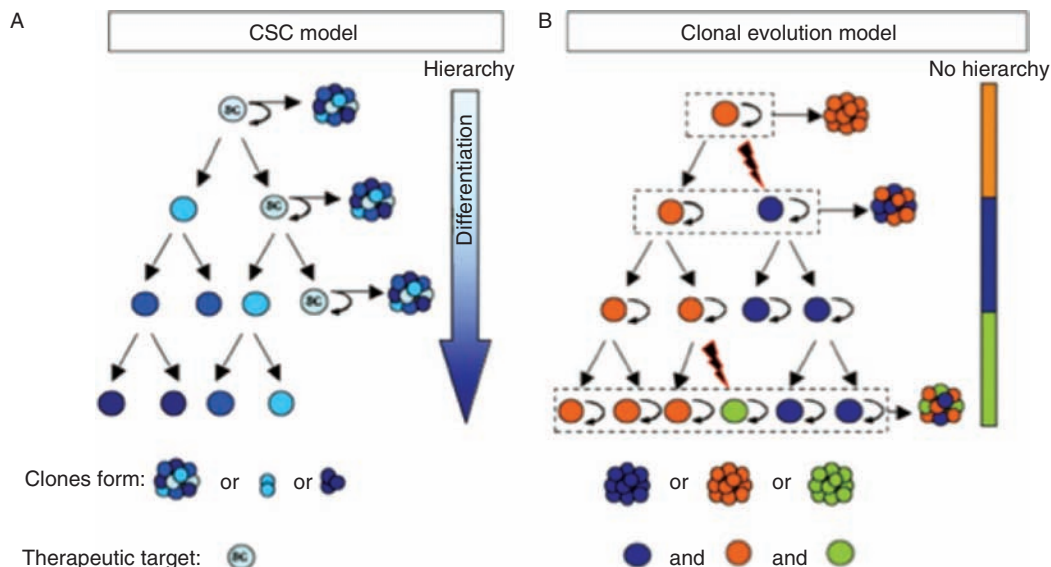

FIGURE 47-2 Models of intratumoral heterogeneity: **A.** The cancer stem cell model: a specialized subpopulation of cancer cells possesses the capacity of self-renewal and differentiation. This leads to formation of a hierarchical lineage system of subclones (**B**). The clonal evolution model: genetic mutations lead to multiple cell populations without distinct cellular hierarchy. Most cells are assumed to retain self-renewing capacity. CSC: Cancer Stem Cell. (Adapted with permission from Laks DR, Visnyei K, Kornblum HI: Brain tumor stem cells as therapeutic targets in models of glioma, *Yonsei Med J.* 2010 Sep;51(5):633-640.)

Mutational convergence was also seen with multiple subclonal mutations found in the same driver genes, however at different loci⁽³³⁾.

In stark contrast to the former study, in 2015, Zhang and colleagues and Bruin and colleagues published two studies concurrently in *Science* examining multi-regional samples from lung cancer specimens^(37, 38). Unlike renal cell carcinoma, mutational architecture showed more limited branching of subclones with the majority of driver mutations being truncal. Patients who relapsed also had a higher degree of subclonal mutations than those who did not. Smoking-related mutations decreased over time, despite an increase in APOBEC-associated mutations. This may speak to an etiology of treatment resistance due to increased diversity of alterations⁽³⁸⁾. These studies show the vast differences between the patterns of intratumoral heterogeneity between cancer subtypes and the need for greater understanding of heterogeneity to personalize cancer therapy.

MULTISTEP CANCER PROGRESSION

There are multiple theories on how the development and progression of cancer occurs. Some have explained this process with the use of a multistep cancer progression model. Cancer growth occurs due the acquisition and subsequent selection of mutations that give a

selective advantage to the cells in which they occur. In Fig. 47-3, we show how this model has been used to describe the acquisition of mutations during progression of myeloproliferative neoplasia and how this has an impact on clinical outcomes⁽³⁹⁾. Here, for example, myeloproliferative neoplasms have been classified as *JAK2* or *TET2* mutation positive or negative. Those positive for both mutations can then be further examined to assess whether the order of mutation acquisition has an impact on phenotype, clinical presentation, and outcomes. The *TET2*-first tumors gain a self-renewal advantage but do not overdivide. Secondary *JAK2* mutants then compete with the *TET2*-alone clones, leading to overpopulation of terminal cells. When *JAK2* homozygosity occurs as a last event, this clone has limited space to expand. This may account for the slower clinical presentation of *TET2*-first mutants. The *JAK2*-first mutants produce excess differentiated cells. After secondary *TET2* mutation acquisition, stem cells obtain a self-renewal advantage, and *JAK2*-*TET2*-mutant cells expand.

Loss of heterozygosity of *JAK2* V617F (either before or after *TET2* mutation) leads to expansion and resultant excess of differentiated cells. Subsequently, *JAK2*-first patients present more frequently as having polycythemia vera and have an elevated risk of thrombotic events. The understanding of the sequence of mutational events has allowed us to build more reliable tumor models that recapitulate the evolution of

FIGURE 47-3 Multistep cancer progression of myeloproliferative neoplasia: order of mutation acquisition influences the evolution of disease. This model depicts single hematopoietic units acquiring mutations over time.

the disease from benign to malignant. Also, knowing what are the initial mutational events dictating a cancer's history will help with development of screening efforts against early disease. Further studies of disease biology have shown that this model may be too simplified, and that tumor progression and acquisition of mutations may be happening concomitantly.

CIRCULATING DNA

Although serum-based biomarkers are commonly used to diagnose and track cancer progression, these indicators are often not elevated or are nonspecific. In addition, they are often prognostic rather than predictive of response to therapy. DNA sequencing has allowed for the discovery of multiple cancer-associated genes that may be correlated to cancer development and metastasis. Depending on tumor location and the patient's clinical status, however, it is often difficult to serially biopsy or surgically remove tumor specimens for sequencing. This is particularly a problem with solid tumors. Circulating tumor cells or cell-free DNA have been found in blood specimens as a noninvasive source for sequencing⁽⁴⁰⁾. This information can then be used as a surrogate for analysis of the tumor itself⁽⁴¹⁾. In 2008, Maheswaran et al demonstrated the ability to detect epidermal growth factor receptor (EGFR) mutations in circulating lung cancer cells⁽⁴²⁾. They showed that deleterious EGFR activating mutations could be detected in circulating tumor cells from 92% of patients and in 33% of matched free-plasma DNA. In more recent years, circulating tumor cells and cell-free DNA have become surrogate markers in clinical trials⁽⁴³⁾.

CURRENT TARGETED THERAPIES

With the advent of second-generation sequencing, as well as improvements in molecular biology (immunohistochemistry, fluorescent in situ hybridization, PCR), our ability to characterize tumors has improved. This expansion in our knowledge base has led to many breakthroughs in drug development of targeted agents. One of the first breakthroughs for targeted therapy was the discovery of the BCR-ABL translocation as the main driver for a majority of chronic myelogenous leukemia (CML) cases and a smaller subset of acute lymphoblastic leukemia^(44, 45). In the 1990s, while performing a high-throughput screen for tyrosine kinase inhibitors, Novartis developed the compound STI-571 (imatinib). In collaboration with Moshe Talpaz and Charles Sawyers, Brian Druker conducted the first clinical trial of STI-571, demonstrating its ability to inhibit proliferation of BCR-ABL-positive CML⁽⁴⁶⁾. This trial

paved the way for imatinib's approval by the Food and Drug Administration (FDA) in 2001 for CML.

After the success of imatinib, many more targeted therapies were presented to the FDA for approval. In 1998, the targeted monoclonal antibody trastuzumab was approved to treat metastatic breast cancer⁽⁴⁷⁾. In 2011, the small molecule inhibitor vemurafenib was approved by the FDA to treat metastatic melanoma⁽⁴⁸⁾. These agents, and many more, are discussed in detail throughout the manual; they are highlighted here in [Table 47-1](#), which includes a list of the current FDA-approved targeted cancer therapies. Note that this table does not include targeted immunotherapies, hormonal agents, or cell cycle inhibitors discussed in other chapters.

BASKET CLINICAL TRIALS

At MD Anderson, we routinely send gene panels to assess the mutational profile of individual patients. These panels include commonly mutated, validated cancer driver genes. A patient's tumor samples are sequenced using next-generation sequencing technology, and then results undergo an analytic process to determine which of these mutations are deemed actionable. The results of these studies can then be used to direct physicians on treatment decision making or for referral to clinical trial based on the aberrations. Recently, the FDA required biomarker testing in conjunction with efficacy results for targeted therapy approval. One way to develop trials in line with new FDA standards is the creation of basket clinical trials.

Basket trials are a relatively new clinical trial design theory; recruitment is based on the molecular aberration rather than the underlying tumor histology. In these trials, patients with multiple different tumor types may be receiving the same treatment. The MD Anderson Battle Umbrella trials have been conducted with a similar principle; patients with late-stage lung cancer are assigned to an arm of therapy based on their biomarker profile. This has allowed for testing of multiple targeted therapies in a more timely fashion. In the phase I department of MD Anderson, there are basket trials under way currently that are sponsored by a pharmaceutical company.

In 2015, the National Cancer Institute (NCI) launched the NCI-MATCH (Molecular Analysis for Therapy Choice) trial, with plans to enroll 1,000 patients on targeted drug combination therapies, based on molecular alterations by pathway rather than on tumor histology. Patients will be randomly assigned to receive a drug specific for that genetic alteration or a treatment unknown to be particularly effective on that pathway⁽⁴⁹⁾.

Table 47-1 Current FDA-Approved Targeted Therapies

Agent	Target(s)	FDA-Approved Indication(s)
Ado-trastuzumab emtansine (Kadcyla)	HER2 (ERBB2/neu)	Breast cancer (HER2+)
Afatinib (Gilotrif)	EGFR (HER1/ERBB1), HER2 (ERBB2/neu)	Non-small cell lung cancer (EGFR exon 19 deletions or exon 21 substitution [L858R] mutations)
Axitinib (Inlyta)	KIT, PDGFR β , VEGFR1/2/3	Renal cell carcinoma
Bevacizumab (Avastin)	VEGF ligand	Cervical cancer Colorectal cancer Ovarian and fallopian cancer Glioblastoma Non-small cell lung cancer Peritoneal cancer Renal cell carcinoma
Bosutinib (Bosulif)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome positive)
Cabozantinib (Cometriq)	FLT3, KIT, MET, RET, VEGFR2	Medullary thyroid cancer
Ceritinib (Zykadia)	ALK	Non-small cell lung cancer (ALK fusion)
Cetuximab (Erbix)	EGFR (HER1/ERBB1)	Colorectal cancer (KRAS wild type) Squamous cell cancer of the head and neck
Crizotinib (Xalkori)	ALK, MET	Non-small cell lung cancer (ALK fusion)
Dabrafenib (Tafinlar)	BRAF	Melanoma (<i>BRAF</i> V600 mutation)
Dasatinib (Sprycel)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome positive) Acute lymphoblastic leukemia (Philadelphia chromosome positive)
Erlotinib (Tarceva)	EGFR (HER1/ERBB1)	Non-small cell lung cancer Pancreatic cancer
Everolimus (Afinitor)	mTOR	Pancreatic neuroendocrine tumor Renal cell carcinoma Nonresectable subependymal giant cell astrocytoma associated with tuberous sclerosis Breast cancer (HR ⁺ , HER2 ⁻)
Gefitinib (Iressa)	EGFR (HER1/ERBB1)	Non-small cell lung cancer with known prior benefit from gefitinib (limited approval)
Ibrutinib (Imbruvica)	BTK	Mantle cell lymphoma Chronic lymphocytic leukemia Waldenstrom's macroglobulinemia
Idelalisib (Zydelig)	PI3K δ	Chronic lymphocytic leukemia Follicular B-cell non-Hodgkin lymphoma Small lymphocytic lymphoma
Imatinib (Gleevec)	KIT, PDGFR, ABL	Gastrointestinal stromal tumor (KIT ⁺) Dermatofibrosarcoma protuberans Multiple hematologic malignancies, including Philadelphia chromosome-positive ALL and CML
Lapatinib (Tykerb)	HER2 (ERBB2/neu), EGFR (HER1/ERBB1)	Breast cancer (HER2 ⁺)
Lenvatinib (Lenvima)	VEGFR2	Thyroid cancer
Nilotinib (Tasigna)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome positive)
Olaparib (Lynparza)	PARP	Ovarian cancer (BRCA mutation)
Panitumumab (Vectibix)	EGFR (HER1/ERBB1)	Colorectal cancer (KRAS wild type)
Pazopanib (Votrient)	VEGFR, PDGFR, KIT	Renal cell carcinoma
Pertuzumab (Perjeta)	HER2 (ERBB2/neu)	Breast cancer (HER2 ⁺)

(Continued)

Table 47-1 Current FDA-Approved Targeted Therapies (Continued)

Agent	Target(s)	FDA-Approved Indication(s)
Ponatinib (Iclusig)	ABL, FGFR1-3, FLT3, VEGFR2	Chronic myelogenous leukemia Acute lymphoblastic leukemia (Philadelphia chromosome positive)
Ramucirumab (Cyramza)	VEGFR2	Gastric cancer or gastroesophageal junction (GEJ) adenocarcinoma Non-small cell lung cancer
Regorafenib (Stivarga)	KIT, PDGFR β , RAF, RET, VEGFR1/2/3	Colorectal cancer Gastrointestinal stromal tumors
Ruxolitinib (Jakafi)	JAK1/2	Myelofibrosis
Sorafenib (Nexavar)	VEGFR, PDGFR, KIT, RAF	Hepatocellular carcinoma Renal cell carcinoma Thyroid carcinoma
Temsirolimus (Torisel)	mTOR	Renal cell carcinoma
Trametinib (Mekinist)	MEK	Melanoma (BRAF V600 mutation)
Trastuzumab (Herceptin)	HER2 (ERBB2/neu)	Breast cancer (HER2 ⁺) Gastric cancer (HER2 ⁺)
Vandetanib (Caprelsa)	EGFR (HER1/ERBB1), RET, VEGFR2	Medullary thyroid cancer
Vemurafenib (Zelboraf)	BRAF	Melanoma (BRAF V600 mutation)
Vismodegib (Erivedge)	PTCH, Smoothened	Basal cell carcinoma
Ziv-aflibercept (Zaltrap)	PIGF, VEGFA/B	Colorectal cancer
Axitinib (Inlyta)	KIT, PDGFR β , VEGFR1/2/3	Renal cell carcinoma

FUTURE DIRECTIONS

In the future, we hope to use our knowledge of mutational alterations to find novel therapeutic targets. Through our understanding of altered driver pathways and their inherent sensitivities, we may be able to build on rational combination therapies already in existence. With the decreasing cost of sequencing, there will be an expansion in genetic testing of tumors to characterize their mutational profiles and to better understand their underlying biology. Deep sequencing as well as single-cell sequencing has enabled us to understand the evolution of cancer and the complexity of intra-tumoral heterogeneity and mechanisms of tumor resistance. Currently, the majority of targeted therapies are being developed and tested in the metastatic setting. Understanding the developmental process may allow us to screen for cancers earlier in the disease process. In addition, better understanding of the interplay between genomics and the immune system will allow us to design trials that are synergistic with our body's own defenses. In conclusion, our expanded understanding of the mutational landscape of cancer has greatly affected our ability to treat and even cure malignancy. It is important to continue to develop this knowledge and translate genomics research to improve patient care.

PROMISE OF IMMUNOTHERAPY

The ability of the immune system to recognize and eradicate cancer was first postulated in the 19th century; however, proof of principle remained elusive until the 20th century. The effect of infection on tumor regression was observed as early as 1884 by Anton Chekov (¹); following this, William Coley developed a mixture of killed bacteria that were used to treat various types of cancer between the 1890s and 1960s with mixed clinical benefit. In addition, the concept of using bacterial elements was validated with Food and Drug Administration (FDA) approval of intravesical administration of BCG, which is an FDA-approved therapy that leads to nonspecific inflammatory immune responses and clinical benefit for patients with superficial bladder cancer (²). The discovery of the major histocompatibility complex (MHC) and T-cell receptor (TCR) in the 1980s provided insight into T-cell function that led to a number of clinical trials (^{3,4}). Unfortunately, many of the early clinical trials failed due to incomplete understanding of T-cell function. Further research led to understanding of costimulatory and coinhibitory molecules, which led to improved strategies in the field of cancer immunotherapy, including chimeric antigen receptor (CAR) T cells and immune checkpoint therapies, resulting in clinical success that turned the tide in favor of immunotherapy.

The basic principles that guide cancer immunology are (a) immune surveillance, (b) immune editing, and (c) immune tolerance (⁵). Immune surveillance involves scanning and eliminating the transformed nascent cells by the immune system. This theory was bolstered

by the finding of tumor-specific antigen that could be identified by cytotoxic T cells (⁶). Immune editing is a process that involves elimination in which the immune system acts as an extrinsic tumor suppressor (similar to the original concept of immunosurveillance); second, *equilibrium* occurs, in which tumor cells survive but are held in check by the immune system; and third, in *escape*, tumor cell variants with either reduced immunogenicity or the capacity to attenuate or subvert immune responses grow into clinically apparent cancers. Escape theory also gave credence to the concept of immune tolerance by which cancer cells exploit the body's immune system and use it for their continuous immune evasion and subsequent growth and proliferation.

The immune compartments that aid in tumor elimination and promote tumor evasion are listed in [Table 48-1](#). The guiding theory for development of immunotherapy is to promote antitumor immune factors and attenuate protumor factors.

CELL-BASED THERAPY

Immune cells, such as cytotoxic T cells, are one of the main effector mechanisms of tumor killing and elimination. Cell-based therapy involves increasing the number and efficiency of immune cells that are capable of recognizing and killing the tumor cells

Adoptive T-Cell Therapy

Adoptive T-cell therapy (ACT) involves adoptive transfer of autologous tumor-infiltrating lymphocytes (TILs)

Table 48-1 Anti and Protumor Arms of the Immune System

	Antitumor	Protumor
	Innate: Mature dendritic cell Tumor-associated macrophage (M1 phenotype) Tumor-associated neutrophil (N1)	Innate: Immature dendritic cell Tumor-associated macrophage (M2 phenotype) Tumor-associated neutrophil (N2)
Cellular compartment	NK cells Adaptive: CD8+ T cells CD4+ T cells: Th-1, Th-9, Th-17	Adaptive: CD4+ T cells: Th-9, Th-17 T - regulatory cells
Soluble factors (cytokines)	Granzyme B, IL-1 a,b, IL-2, IL-6, IFN-g, IL-12, IL-17	TGF-b, IL-2, IL-4, IL-6, IL-10, IL-17, IL-23

to the tumor-bearing host ^(7,8). It involves isolation and ex vivo rapid expansion of TILs from tumor, followed by infusion of large numbers of expanded autologous TILs as depicted in Fig. 48-1. Therapy with TILs has been especially promising for patients with stage III and IV unresectable melanoma, and its efficacy has been further increased with combined interleukin (IL) 2 therapy and preconditioning of the host with chemotherapy agents such as Cytosan and fludaribine. Objective response has been reported in more than 50% of patients ^(8,9). The transition of ACT into the clinical setting, however, has not been without difficulties. These can be considered in two groups: factors relating to difficulties in generating appropriate products for adoptive transfer and factors relating to host or tumor resistance to transferred populations.

Recent advances in development of artificial antigen-presenting cells (aAPCs) have helped to overcome many technical issues with rapid TIL expansion ⁽¹⁰⁾. Further, TIL therapy has been shown to be particularly beneficial in patients pretreated with other immunotherapy agents such as IL-2 or checkpoint blockade like anti-CTLA4 (anti-cytotoxic T lymphocyte-associated antigen 4) ⁽⁸⁾.

Chimeric Antigen Receptor T Cell

In an effort to increase the affinity of T cells to tumor antigen, CAR T cells are engineered that contain a synthetic antigen receptor with specificity to a tumor cell marker coupled with T-cell signaling domain, resulting in high-affinity recognition of the tumor antigen ⁽¹¹⁾.

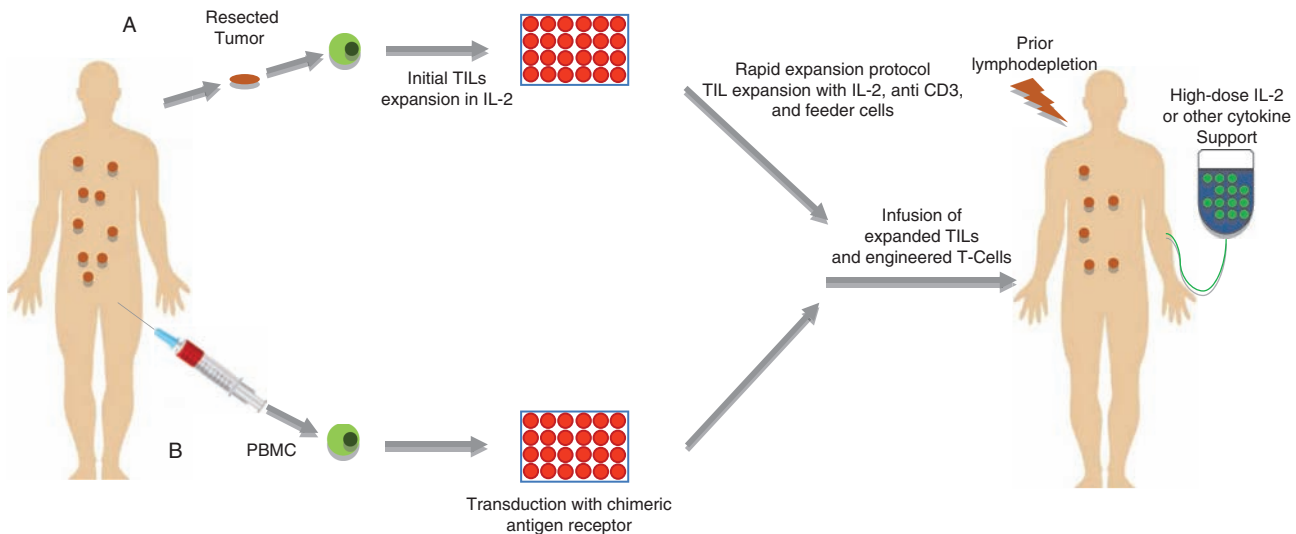

FIGURE 48-1 Adoptive T-cell therapy. There are currently two major sources of T cells used in adoptive cell therapy for melanoma and other cancers. A. The first form of therapy uses tumor-infiltrating lymphocytes (TILs) expanded ex vivo from surgically resected metastatic tumors. The TILs are initially expanded ex vivo using anti-CD3 activation in the presence of irradiated PBMC feeder cells and IL-2. The final product is infused into the patient. B. The second major approach for adoptive T-cell therapy uses T cells expanded from autologous PBMCs that undergo one of three possible manipulations to enrich the cells for tumor antigen-specific T cells.

The CAR T cells are particularly effective against cancer with known tumor antigen. The CAR T cells with specificity for CD19 have shown activity in chronic lymphocytic lymphoma ⁽¹²⁾. Recently, a phase III study demonstrated the CD19-coupled CAR T cells were particularly effective against relapsed refractory acute lymphoblastic leukemia (ALL) ^(13, 14). Autologous T cells transduced with lentiviral vector expressing a chimeric antigen receptor with specificity for the B-cell antigen CD19, coupled with CD137/4-1 BB (a costimulatory receptor in T cells) and CD3-zeta (a signal transduction component of the T-cell antigen receptor) signaling domains were infused in patients with relapsed or refractory ALL and resulted in complete remission in 90% of cases. A potential drawback of CAR T-cell therapy is exaggerated immune response against normal tissue expressing the antigen; therefore, careful dose escalation studies are necessary to predict the therapeutic window. Further, in many cancers the tumor antigen is not known, making CAR T-cell therapy ineffective against undefined tumor antigens.

CANCER VACCINE

Tumors express a vast array of antigens. Cancer vaccines typically consist of a known tumor antigen with an immunostimulatory formulation that could activate the tumor antigen-specific lymphocyte population, leading to eradication of cells expressing this antigen.

Although therapeutic cancer vaccines have impressive antitumor activity in various animal models, their clinical benefit in cancer patients has to date been minimal ⁽¹⁵⁾. However, optimization of a cancer vaccine with

a combinatorial strategy resulted in significant success of the cancer vaccine, most notably two prostate cancer vaccines: Provenge and Prostavac ^(16, 17). Provenge (sipuleucel-T) is a cancer vaccine based on dendritic cells (DCs) that was approved in 2010. Provenge is prepared from patient's peripheral blood mononuclear cells (PBMCs) pulsed with a fusion protein of granulocyte-macrophage colony-stimulating factor (GM-CSF) and the prostate cancer antigen prostatic acid phosphatase (PAP), with the rationale that on injection GM-CSF-activated DCs will present the antigen (PAP) to T cells in a more efficient manner. Provenge increased the median survival by 4.1 months compared to placebo in metastatic prostate cancer. Prostavac is another prostate cancer vaccine that is composed of vaccinia and fowlpox vector that contain the transgenes for prostate-specific antigen (PSA) and multiple T-cell costimulatory molecules (TRICOM) ⁽¹⁸⁾. The TRICOM consists of costimulatory molecules B7.1, leukocyte function-associated antigen 3 (LFA-3), and intercellular adhesion molecule 1 (ICAM-1). The PSA-TRICOM vaccines infect antigen-presenting cells (APCs) and generate proteins that are expressed on the surface of APCs that present antigen to T cells, resulting in antigen-specific tumor killing. E75 (nelipepimut-S) is a human leukocyte antigen (HLA) A2/A3-restricted immunogenic peptide derived from the HER2 protein, which was used in a phase I/II trial involving patients with node-positive or high-risk node-negative breast cancer expressing any level of Her-2 to prevent recurrence ⁽¹⁹⁾.

Although there remains significant room for improvement in the design and delivery of cancer vaccines, these clinical successes have led to the proof of principle that cancer vaccines are effective. Few of the cancer vaccines that are approved or are currently in clinical trials are listed in [Table 48-2](#).

Table 48-2 List of Cancer Vaccines

Types of Cancer	Target Antigen	Formulation
Breast	Her-2/Neu	E75, a human leukocyte antigen (HLA) A2/A3-restricted HER-2/neu (HER2) peptide and granulocyte-macrophage colony-stimulating factor.
Breast	Mammoglobin-A	A plasmid encoding the mammaglobin-A gene with potential immunostimulating and antineoplastic activities
Prostate	PAP	Autologous PBMC loaded with GM-CSF+PAP fusion protein
Prostate	PSA	Vaccinia and fowlpox virus encoding PSA and CD86, ICAM-1, and LFA3
Follicular B cell Lymphoma	Idiotypic	Autologous tumor Ig Idiotypic conjugated to KLH, given with GM-CSF
Vulvar neoplasia: HPV16 E6/E7 Melanoma	gp100	Overlapping long peptides of HPV E6/E7 proteins emulsified in IFA gp100.209-217(210M) peptide emulsified in IFA

ANTIBODY-/RECEPTOR-BASED THERAPY

Immunostimulatory Agents

Dendritic cells are professional APCs that are critical for effective T-cell stimulation. Both DCs and T cells possess an array of stimulatory molecules that are necessary for sustained and durable immune response, making them potential therapeutic targets.

Dendritic Cell–Based Immunostimulatory Agents

Toll-like receptors (TLRs) are a group of 13 receptors present in DCs that have distinct ligands, and the receptor-ligand interaction leads to the activation of DCs, inducing the expression of type I interferons, cytokines (eg, IL-12), and costimulatory molecules (eg, CD80, CD86, and CD40) that are critical for T-cell activation^(20, 21). Clinical trials with TLR agonists have shown promise, particularly in combination with other therapeutic modalities. The imidazoquinolone Imiquimod ligates TLR7; in several clinical trials, topical application resulted in an 80% to 90% clearance rate for superficial basal cell carcinoma^(22, 23). Systemic administration of TLR7 and TLR9 agonist as monotherapy in melanoma and renal cell carcinoma had a strong immune response but failed to demonstrate objective clinical response^(24, 25). Although they failed as monotherapy, their capacity to boost the immune system makes them a suitable adjuvant therapy. Both CpG and imiquimod induced increased levels of tumor antigen-specific T cells in patients with melanoma and prostate cancer vaccinated with recombinant protein tumor antigen NY-ESO1 showing promise in combination therapy^(26, 27).

Another attractive target for enhancing DC function is CD40, which is present on APCs, including DCs, and ligation of CD40 with its ligand CD40L present on T cells is critical for T-cell priming⁽²⁸⁾. CD40 targeting agents as monotherapy showed modest clinical benefit in non-Hodgkins lymphoma and melanoma⁽²⁹⁾. To increase its efficacy, a novel approach utilized electroporation to introduce messenger RNA encoding CD40 ligand, constitutively active TLR4, CD70, and multiple melanoma tumor antigens into autologous DCs (TriMix-DC). Tumor regressions were observed in 6 of 17 patients who had received interferon- α -2b in combination with TriMix-DC⁽³⁰⁾. Further, combination of anti-CD40 antibody and the chemotherapy agent gemcitabine showed tumor regression in both humans and mice⁽³¹⁾.

T-Cell Based Immunostimulatory Agents

Engagement of the TCR on T cells with MHC serves as a first signal for T-cell activation; the second signal

is mediated by the binding of costimulatory molecules on the T-cell surface to B7 proteins (such as CD80 or CD86) on APCs. Both signals are critical for effective T-cell activation, proliferation, and migration, making costimulatory molecules an interesting therapeutic target for sustained immune response^(32, 33).

Greater attention has been focused on 41BB (CD137) and OX40 (CD134). Preclinical studies with antimouse anti-CD137 have shown promising activity in combination with antitumor antibody. Most recently, it was shown that targeting anti-CD137 increases the efficacy of cetuximab (anti-epidermal growth factor receptor monoclonal antibody [mAb]) in murine xenograft models, making it another suitable target for combination therapy⁽³⁴⁾. Clinical studies with PF-05082566 (Pfizer, anti-CD-137) in combination with rituximab in B-cell Lymphoma and MK-3475 (anti-programmed cell death 1 [PD-1]) in solid tumor are ongoing. Further, a phase I clinical trial using a mouse mAb that agonizes human OX40 signaling in patients with advanced cancer showed that patients treated with one course of the anti-OX40 mAb (9B12) had an acceptable toxicity profile and regression of at least one metastatic lesion in 12 of 30 patients⁽³⁵⁾.

Immune Checkpoint Blockade

T-cell activation is tightly controlled by immune-suppressive cells and cytokines as well as by the coinhibitory molecules present in T cells, such as CTLA-4 or PD-1 (see Fig. 48-2)⁽³⁶⁾. The CTLA-4 is expressed by activated CD4 and CD8 T cells, and it competes with costimulator CD28 for binding to its ligands (B7 proteins). Binding of CTLA-4 to B7 proteins interrupts CD28 costimulatory signals and serves as a negative regulator of T-cell responses.

For many years, it was widely accepted that T-cell responses can be turned “on” via T-cell receptor and CD28 costimulation, but the concept of turning “off” T-cell responses did not exist until the discovery of CTLA-4. It was a paradigm shift in cancer immunotherapy to move away from vaccine strategies aimed at turning on T-cell responses to immunotherapy strategies aimed at turning off T-cell inhibitory pathways⁽³⁷⁾. Preclinical studies with anti-CTLA-4 antibodies demonstrated rejection of syngeneic transplanted tumors in mice.

These preclinical studies led to the eventual development of an antibody to block human CTLA-4 (ipilimumab), which was subsequently shown in a phase III randomized, controlled trial in patients with metastatic melanoma to improve the median overall survival⁽³⁸⁾. Importantly, additional studies have shown that a subset of patients treated with anti-CTLA-4 had durable clinical responses lasting 10 or more years⁽³⁹⁾. This trial led to the approval of ipilimumab by the FDA in March 2011 for the treatment of patients with metastatic melanoma.

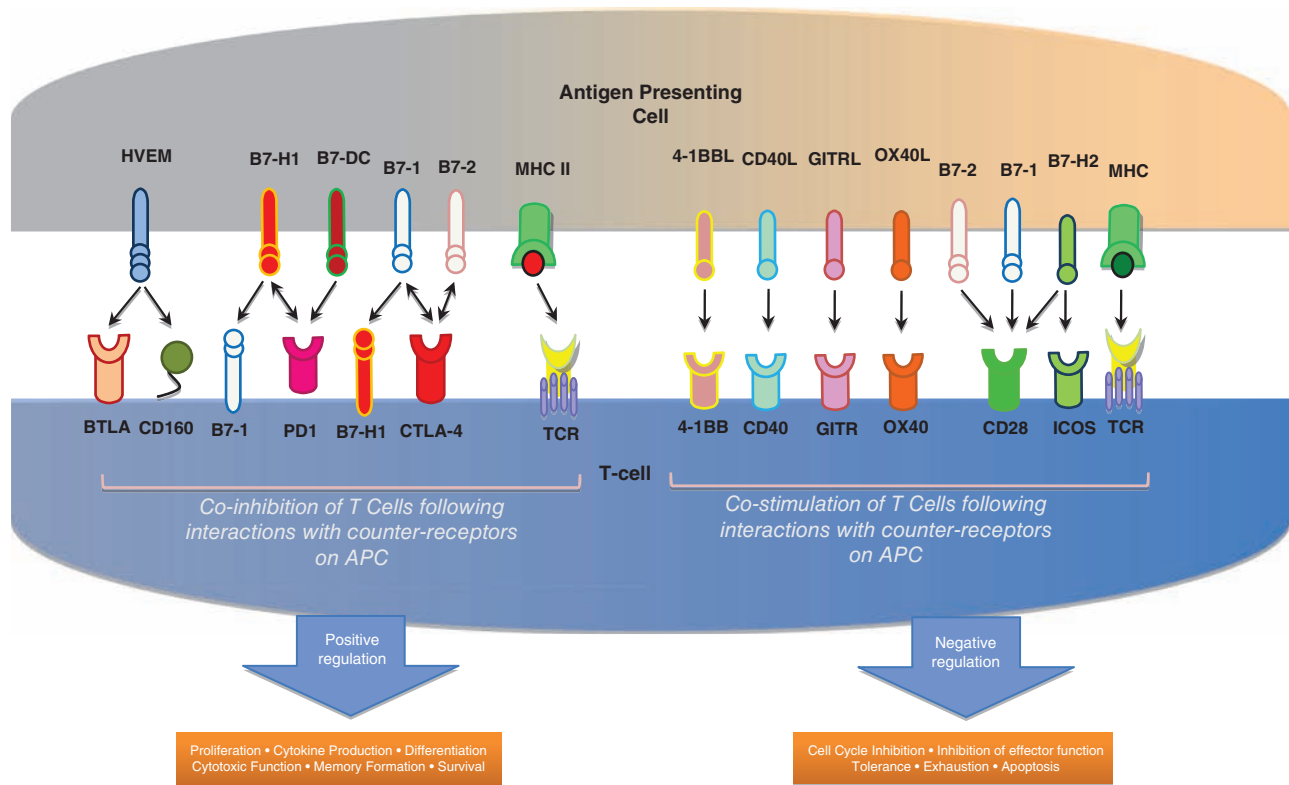

FIGURE 48-2 T-cell activation begins with interaction of the T-cell receptor (TCR) on a T cell with major histocompatibility complex (MHC) bound to antigen on an antigen-presenting cell (APC) (signal 1); activation of the T cell requires additional signals that are provided by the interaction between CD28 and other costimulatory molecules (signal 2). T-cell activation is inhibited by coinhibitory molecules such as CTLA4, PD-1.

A number of factors have been proposed to potentially serve as biomarkers for response to ipilimumab therapy. Recent studies suggest that an increase in TILs correlates with clinical response of anti-CTLA-4 therapy⁽⁴⁰⁾. In addition, sustained Inducible T-cell COStimulator (ICOS) expression on CD4 T cells has also been observed to correlate with survival of patients with melanoma treated with anti-CTLA-4 therapy⁽⁴¹⁾.

Consistent with this observation, increased frequency of ICOS⁺ CD4 T cells can also serve as a pharmacodynamic biomarker for anti-CTLA-4 therapy⁽⁴²⁾. ICOS is one of the costimulatory receptors of T cells. A preclinical study showed that engagement of the ICOS pathway markedly enhanced efficacy of CTLA-4 blockade in cancer immunotherapy⁽⁴³⁾. This finding provides a potential mechanism for future clinical studies with agonistic signaling through ICOS in combination with blockade of CTLA-4.

Programmed cell death 1 is another negative regulator of T-cell response that is mainly expressed by activated CD4 and CD8 T cells as well as APCs⁽⁴⁴⁾. In preclinical studies, blocking antibodies against PD-1 resulted in reduction of tumor metastasis and growth in a number of experimental tumor models^(45,46). These preclinical results led to many clinical trials. In a phase

I clinical trial, a fully human immunoglobulin (Ig) G4 anti-PD-1 mAb (nivolumab) was evaluated in patients with relapsed or refractory Hodgkin's lymphoma and demonstrated objective responses in 20 patients (87%), including 17% with a complete response⁽⁴⁷⁾.

A randomized, controlled, phase III clinical study compared nivolumab versus dacarbazine (chemotherapy) in patients with previously untreated melanoma (without the *BRAF* mutation), and the overall response rate favored nivolumab (40% vs 14%)⁽⁴⁸⁾. Another phase III clinical trial compared nivolumab versus chemotherapy (dacarbazine or carboplatin plus paclitaxel) in patients with ipilimumab-refractory advanced melanoma induced an overall response rate of 32% versus 11%, respectively, leading to the accelerated FDA approval of nivolumab for patients with unresectable or metastatic melanoma no longer responding to other drugs⁽⁴⁹⁾.

Pembrolizumab is another humanized IgG4 mAb targeting PD-1 that demonstrated an overall response rate of 26% in patients with ipilimumab-refractory advanced melanoma in a phase I clinical trial, which prompted its accelerated FDA approval⁽⁵⁰⁾. Nivolumab also had an overall response rate of 87% in patients with Hodgkin's lymphoma who had failed brentuximab vedotin⁽⁴⁷⁾.

These studies show that nivolumab and pembrolizumab have significant clinical activity in a variety of heavily pretreated patients with solid tumor malignancies as well as patients with hematological malignancies.

Programmed cell death 1 has two ligands, PD-L1 and PD-L2, with distinct expression profiles. The PD-L1 ligand is expressed not only on APCs but also on T cells, B cells, and nonhematopoietic cells, including tumor cells. Expression of PD-L2 is largely restricted to APCs, including macrophages and myeloid DCs, as well as mast cells. Promising clinical results were observed with drugs targeting PD-L1. A phase I trial with anti-PD-L1 (human IgG4 mAb; BMS-936559) demonstrated an objective response rate of 6% to 17% in patients with advanced non-small cell lung cancer (NSCLC), melanoma, and Renal Cell Carcinoma (RCC) ⁽⁵¹⁾. Another agent targeting PD-L1, MPDL3280A (human IgG1), was engineered with a modification in the Fc domain that eradicates antibody-dependent cellular cytotoxicity. MPDL3280A showed objective response rates of 13% to 26% in multiple solid tumor malignancies, including NSCLC, melanoma, RCC, colorectal cancer, gastric cancer, and head and neck squamous cell carcinoma ⁽⁵²⁾. Remarkably, MPDL3280A also had a 26% objective response rate in bladder cancer ⁽⁵³⁾.

Because anti-CTLA-4 and anti-PD-1 target distinct inhibitory pathways in T cells, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to the monotherapies ⁽⁵⁴⁾. A phase I clinical trial evaluated the concurrent treatment of advanced melanoma with ipilimumab plus nivolumab using various doses of both drugs (four cohorts). The objective response rate was 40% when all four cohorts were included and 53% in the cohort representing the maximum dose that was associated with an acceptable level of toxicities. This latter cohort was also associated with unprecedented 1- and 2-year overall survival rates of 94% and 88%, respectively ⁽⁵⁵⁾. These results show that drugs targeting the immune checkpoints, CTLA-4, PD-1, and PD-L1 as monotherapy or in combinations, are likely to become the standard of care in various solid as well as hematologic malignancies.

FUTURE DIRECTION

Recent success with immunotherapy in the management of cancer has given credence to the long-held belief that the immune system can be used to treat cancer. Most immunotherapies currently approved or in clinical trials are being used in the metastatic setting. More clinical trials are warranted to test the efficacy of immunotherapy in the presurgical or neoadjuvant setting. The potential for immunotherapies augmenting the effects

of conventional chemotherapy or radiotherapy also requires further exploration. Combinational immunotherapy and the combination of immunotherapy with conventional therapy will be the theme of future cancer treatment. The identification of multiple other immune pathways that can be targeted has led to the development of numerous immunotherapy agents that will require testing as monotherapy and combination therapy in the clinic. Furthermore, this new class of cancer treatment also brings a unique set of side effects, which will require close monitoring of patients and additional work to understand predictive biomarkers of toxicities, as well as studies to guide rational development of combination strategies for optimal patient benefit.

INTRODUCTION

The Human Genome Project has enabled sequencing of human DNA and led to advancements in technologies that detect genomic, transcriptional, proteomic, and epigenetic changes. These technologies, combined with novel drug development, have accelerated the implementation of personalized medicine. Personalized medicine uses concepts of the genetic and environmental bases of disease to individualize prevention, diagnosis, and treatment ^(1,2). Optimization of treatment using targeted therapy—molecules targeting specific enzymes, growth factor receptors, and signal transducers, thereby interfering with a variety of oncogenic cellular processes—and other strategies made possible by advances in translational medicine holds the promise of improving patient care ⁽³⁾.

This chapter focuses on targeted therapy in cancer therapeutics. The material is organized according to the key drivers of carcinogenesis in humans and summarizes the current state-of-the-art applications of personalized medicine.

RAS-RAF-MEK PATHWAY

Upregulation of the mitogen-activated protein kinase (MAPK) cascades RAF (rapidly accelerated fibrosarcoma) and MEK (MAPK/extracellular signal-regulated kinase [ERK]) contributes to carcinogenesis. Several cell surface molecules activate RAS (KRAS, NRAS, and HRAS), a family of guanine triphosphatases (GTPases) that activate downstream RAF protein kinases (BRAF,

CRAF, and ARAF). The most important substrates of RAF kinases are MEK1 and MEK2 (MAPK/ERK kinases). The MEK kinases have one main substrate, ERK ⁽⁴⁾. Activation of ERK leads to modifications in gene expression mediated by transcription factors that control cell cycle progression, differentiation, metabolism, survival, migration, and invasion. This pathway regulates apoptosis by the posttranslational phosphorylation of apoptotic regulatory molecules (Bad, Bim, Mcl-1, and caspase 9). RAS is a downstream effector of the epidermal growth factor receptor (EGFR). Activation of ERK promotes upregulated expression of EGFR ligands and an autocrine loop critical for tumor growth ⁽⁵⁾. The frequency of molecular alterations in major pathway components is shown in the COSMIC (Catalogue of Somatic Mutations in Cancer) database (<http://www.sanger.ac.uk/genetics/CGP/cosmic/>).

Melanoma

Mutations in *BRAF* are found in 62% to 72% of patients with metastatic melanoma ⁽⁶⁾ and are less frequent in the radial growth phase (10%) and in situ (5.6%) melanomas ⁽⁷⁾. Mutations of *NRAS* occur in 5.2% of melanomas ⁽⁷⁾. In conjunctival melanoma, *BRAF* and *NRAS* mutations were identified in 29% and 18% of patients, respectively ⁽⁸⁾. Alterations of *KIT* were found in 36% and 39% of patients with acral and mucosal melanoma, respectively ⁽⁹⁾. Alterations of *GNAQ* and *GNA11* were found in 45% and 32% of patients with uveal melanoma, respectively ⁽¹⁰⁾.

Inhibitors of BRAF and MEK have been approved by the US Food and Drug Administration (FDA) based

on their significant antitumor activity and tolerability in patients with melanoma. The FDA-approved drugs and selected investigational agents by molecular target/pathway are listed in [Table 49-1](#).

Vemurafenib and Dabrafenib

Vemurafenib was the first BRAF FDA-approved inhibitor for metastatic melanoma with a *BRAF* V600E mutation. A phase III trial demonstrated a 3.7-month improvement in progression-free survival (PFS) in the vemurafenib arm compared to the dacarbazine arm (median PFS 5.3 months and 1.6 months, respectively). The median overall survival (OS) was not reached in the vemurafenib arm and was 7.9 months in the control arm ⁽¹¹⁾. Dabrafenib is also FDA approved for patients with unresectable or metastatic melanoma with a *BRAF* V600E mutation, based on the results of a phase III study that compared dabrafenib with dacarbazine. The median PFS was 5.1 months and 2.7 months in the dabrafenib and the dacarbazine arms, respectively ⁽¹²⁾. Vemurafenib ⁽¹³⁾ and dabrafenib ⁽¹⁴⁾ have antitumor activity in patients with melanoma and brain metastases.

Trametinib

Trametinib is a MEK1/MEK2 kinase inhibitor that was approved by the FDA as a single agent or combined with dabrafenib for unresectable or metastatic melanoma with a *BRAF* V600E or V600K mutation. Approval was based on the results of a randomized trial, which demonstrated longer PFS with trametinib than with chemotherapy consisting of either dacarbazine or paclitaxel in patients with stage IIIc or IV melanoma and a *BRAF* V600E or V600K mutation ⁽¹⁵⁾. The median PFS durations were 4.8 and 1.5 months in the trametinib and chemotherapy arms, respectively (hazard ratio [HR], 0.47; $P < .0001$). The 6-month OS rates were 81% and 67%, respectively ⁽¹⁵⁾.

In a phase I and II study of dabrafenib plus trametinib or dabrafenib monotherapy in patients with melanoma and a *BRAF* V600E or V600K mutation, the objective response (complete response [CR] and partial response [PR]) rates were 76% and 54%, respectively ($P = .03$) ⁽¹⁶⁾. Cutaneous squamous cell carcinoma (SCC), an adverse event associated with BRAF inhibitors, was less common in the dabrafenib plus trametinib group than in the dabrafenib group (7% vs 19%, respectively) ⁽¹⁶⁾.

Other MEK inhibitors are in clinical trials. In a randomized phase II study in patients with BRAF-mutated advanced melanoma, selumetinib (MAP2K1/MAP2K2 inhibitor) plus dacarbazine was associated with longer PFS compared to dacarbazine (5.6 vs 3 months), but no improvement in OS was noted ⁽¹⁷⁾.

Lung Cancer

Mutations in *BRAF* occur in 1% to 4% of patients with non-small cell lung cancer (NSCLC). Molecular alterations in *EGFR*, *ALK*, *ROS1*, *NRAS*, and *KRAS* are also involved in the pathogenesis of lung cancer. We have noted responses in patients with NSCLC and *BRAF* V600E mutation treated with vemurafenib. A study of dabrafenib with or without trametinib in *BRAF* V600E-mutant NSCLC is ongoing.

Mutations of *KRAS* are more common in smokers. In metastatic NSCLC, mutated *KRAS* is associated with a worse prognosis than mutated *EGFR*. Mutation of *KRAS* was associated with shorter PFS in patients receiving maintenance erlotinib. No difference was noted in OS between mutated and wild-type *KRAS* ⁽¹⁸⁾. In colorectal cancer (CRC), *KRAS* mutations are associated with resistance to cetuximab. In a phase II study, selumetinib combined with docetaxel was associated with a higher response rate (37%, all PRs) in patients with *KRAS*-mutant NSCLC compared to docetaxel plus placebo (0%) ⁽¹⁹⁾. Other clinical trials evaluating MEK inhibitors combined with chemotherapy in *KRAS*-mutant NSCLC have been completed (NCT01192165, NCT01362296). In a phase II randomized study of trametinib compared to docetaxel in patients with *KRAS*-mutant NSCLC ⁽²⁰⁾, the rates of response and PFS were similar in the two arms (response, 12% [all PR]; median PFS, trametinib: 12 weeks; docetaxel: 11 weeks). Other studies of RAS-RAF-MEK inhibitors are ongoing.

PI3K-AKT-mTOR PATHWAY

The phosphatidylinositol 3-kinase (PI3K) signaling pathway is involved in the survival, growth, metabolism, motility, and progression of cancer and is a critical pathway in cancer ⁽²¹⁾. The PI3K family of proteins catalyzes the phosphorylation of phosphatidylinositols (PtdIns) at their 3' position and consists of classes I, II, and III. Only class IA signaling aberrations are involved in human cancers ⁽²²⁾. The class IA PI3Ks are composed of heterodimers of regulatory subunits (p85 α , p85 β , p50 α , p55 α , and p55 γ) and catalytic subunits (p110 α , p110 β , p110 δ). Three genes encode the regulatory subunits: PIK3R1 encodes p85 α ⁽²²⁾, and PIK3R2 and PIK3R3 encode the p85 β and p55 γ isoforms of the p85 regulatory subunit, respectively. Three genes, PIK3CA, PIK3CB, and PIK3CD, encode the highly homologous p110 catalytic subunit isoforms p110 α , p110 β , and p110 δ and share a similar five-domain structure. At the amino terminus, there is an adapter-binding domain that interacts with the p85 regulatory subunit, followed by a RAS-binding domain that mediates interaction with RAS.

The class I PI3Ks can phosphorylate the 3' position of PtdIns, PI-4-P, and PI-4,5-P₂ though PI-4,5-P₂. This phosphorylation generates the second-messenger phosphatidylinositol (3,4,5) triphosphate (PIP₃). Cytosolic proteins, such as the AKT family of protein-serine/threonine kinases, bind to PIP₃ and localize to the plasma membrane in response to PI3K activation⁽²³⁾. In the absence of stimulated growth conditions, baseline levels of PIP₃ are undetectable in mammals. The PIP₃ levels at the plasma membrane are regulated by the tumor suppressor phosphatase and tensin (PTEN) homolog, whose lipid phosphatase activity converts PIP₃ to PI-4,5-P₂. Loss of PTEN function through inactivating mutations, deletion, chromosomal translocation, or epigenetic silencing is the second most common initiating event in cancer after p53 mutations.

Mutations or amplifications of the PI3K catalytic subunits p110α (*PIK3CA*) and p110β (*PIK3CB*), the PI3K regulatory subunits p85α (*PIK3R1*) and p85β (*PIK3R2*), and AKT (*AKT1*) can activate the PI3K pathway. Mutations, deletions, or epigenetic changes in negative regulators of the PI3K axis (PTEN and inositol polyphosphate-4-phosphatase, type II) may modify tumor cell sensitivity to chemotherapy or targeted therapies⁽²⁴⁾. AKT is the main effector of PI3K activation and has three isoforms: AKT1, AKT2, and AKT3. AKT signaling plays a significant role in cell hypertrophy, survival, hyperplasia, and metabolism. Mammalian target of rapamycin (mTOR) is the catalytic subunit of mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2), which are distinguished by

their accessory proteins, regulatory-associated protein of mTOR (RAPTOR) and rapamycin-insensitive companion of mTOR (RICTOR)⁽²⁵⁾.

Several studies focused on targeting the PI3K-AKT-mTOR pathway. Rapamycin analogues (rapalogs) have antitumor activity in various tumors and are frequently combined with other anticancer agents⁽²⁶⁾. Everolimus is approved for the treatment of subependymal giant cell astrocytoma; hormone receptor (HR)-positive, HER2 (human epidermal growth factor receptor 2)-negative breast cancer (in combination with exemestane); neuroendocrine pancreatic tumors; tuberous sclerosis-associated subependymal giant cell astrocytoma; and renal cell carcinoma (sunitinib or sorafenib refractory). Temsirolimus is approved for renal cell carcinoma. The efficacy of rapalogs combined with endocrine therapy for advanced breast cancer was evident in the BOLERO-2 trial, which showed a median PFS of 6.9 months for everolimus and exemestane versus 2.8 months for exemestane alone⁽²⁷⁾.

PI3K Inhibitors

The first generation of class I pan-PI3K inhibitors targeted PI3Kα, PI3Kβ, PI3Kγ, and PI3Kδ. Wortmannin and LY294002 had limited activity. Ongoing studies are evaluating new pan-PI3K inhibitors with improved pharmacokinetic profiles and target specificity. Their antitumor activity is primarily cytostatic. Novel agents that inhibit both PI3K and mTOR may improve the antitumor activity of either agent.

GDC-0941

GDC-0941 is a selective oral class I PI3K inhibitor and at high concentrations also an mTOR inhibitor. It is being investigated in clinical trials in patients with metastatic breast cancer (NCT00960960, NCT01437566) and advanced NSCLC. Initial studies of GDC-0941 demonstrated PRs in patients with melanoma and ovarian, cervical, and estrogen receptor (ER)-positive/HER-negative breast cancer (²⁸⁻³⁰). At the maximum tolerated dose (MTD), dose-limiting toxicities (DLTs) included grade 3 macular rash and asymptomatic T-wave inversion on electrocardiograms, grade 3 thrombocytopenia, and grade 4 hyperglycemia (^{29, 30}). Ongoing studies evaluating GDC-0941 include a phase II study in patients with untreated advanced or recurrent NSCLC treated with carboplatin/paclitaxel or carboplatin/paclitaxel/bevacizumab with or without GDC-0941 (NCT01493843). In a phase I/II study, GDC-0941 and cisplatin are being studied in patients with androgen receptor (AR)-negative, triple-negative, metastatic breast cancer, and in a phase II study, patients with advanced/metastatic breast cancer resistant to aromatase inhibitor therapy are being treated with GDC-0941 or GDC-0980 with fulvestrant versus fulvestrant alone (NCT01437566). Clinical trials are also investigating combinations of PI3K inhibitors taselisib (GDC-0032) or pictilisib (GDC-0941) with other targeted agents (eg, palbociclib, a cyclin-dependent kinase 4 and 6 [CDK4/6] inhibitor) in advanced solid tumors or breast cancer (NCT02389842).

BKM120

BKM120 is an oral pyrimidine-derived pan-PI3K inhibitor with activity against all class I PI3K isoforms. A phase I study demonstrated that BKM120 was well tolerated, with a dose-dependent safety profile (³¹). Adverse events included hyperglycemia, rash, nausea, fatigue, and mood alterations. Hyperglycemia is a typical adverse event associated with the use of PI3K/AKT/mTOR pathway inhibitors. Another study demonstrated that in colorectal, breast, lung, and endometrial cancers treated with BKM120, two of 77 patients had a PR (triple-negative breast cancer with *KRAS* and *p53* mutations, *n* = 1; and ER-positive/HER-negative metastatic breast cancer, *n* = 1; both had tumor *PIK3CA* mutations), and 58% of patients had stable disease (SD).

BAY 80-6946

BAY 80-6946 is a pan-class I PI3K inhibitor with activity against PI3K α , PI3K β , PI3K δ , and PI3K γ . A phase I study demonstrated that the MTD of BAY 80-6946 was 0.8 mg/kg intravenously weekly (3 weeks on, 1 week off). Adverse events included hyperglycemia,

fatigue, nausea, diarrhea, and mucositis. Clinical benefit was reported in patients with advanced breast, endometrial, and gastric cancers.

BEZ235

BEZ235 is an oral, reversible, and selective inhibitor of PI3K and TORC1/2. Preclinical data demonstrated antitumor activity in melanoma, breast, CRC and sarcoma. BEZ235 suppresses cell proliferation, induces G1 cell cycle arrest, and promotes autophagy by inhibiting the activity of AKT, S6K, S6, and 4EBP1 target proteins. BEZ235 has been investigated in phase I/II clinical trials in patients with advanced cancer alone (³²) or in combination with paclitaxel, trastuzumab, everolimus, or MEK162. In a phase IB study, BEZ235 combined with trastuzumab in 15 patients with HER2-positive metastatic breast cancer with altered PI3K/PTEN status was tolerable. Stable disease and PR were reported in four and one patients, respectively (³³). An improved formulation of BEZ235 was used as a monotherapy or combined with trastuzumab, and SD was noted in 40% of patients with advanced cancer. The most common adverse events were nausea, diarrhea, elevated transaminases, and headache. The DLTs were fatigue, asthenia, grade 3 thrombocytopenia, and grade 3 mucositis (³²). A clinical trial of BEZ235 and everolimus in advanced cancer is ongoing (NCT01628913).

In prostate cancer, PTEN loss may be associated with resistance to castration (^{34, 35}). BEZ235 causes growth arrest in PTEN-negative prostate cancers, but inhibition of the PI3K pathway leads to activation of AR signaling (inhibition of AR appears to result in promotion of PI3K activity) (³⁵).

Other p110 α Isoform-Specific Inhibitors

Other p110 α isoform-specific inhibitors, such as BYL719, GDC-0032, and INK1117, are being investigated in various solid tumors. BYL719 was associated with less hyperglycemia than the pan-PI3K inhibitor BKM120 (³⁶). In a phase I study, BYL719 induced tumor reduction in 33% of patients with ER-positive, metastatic breast cancer and a *PIK3CA* mutation (³⁷). Multiple studies are investigating the role of BYL719 in solid tumors as a single agent or in combination with targeted agents and cytotoxics. Although preclinical data demonstrated that *PIK3CA* alterations are the best biomarkers for predicting sensitivity to BYL719, p110 α inhibitors are not effective in *PIK3CA*-mutated cells that also have a PTEN deletion (³⁷).

AKT Inhibitors

The AKT inhibitors may induce the PI3K-stimulating receptor tyrosine kinase HER3 in breast cancer cell

lines and may increase IGF-1R and the insulin receptor, thereby leading to the development of escape pathways and resistance mechanisms. Combination therapies that block the feedback response may overcome resistance to AKT inhibitors. Several studies have investigated or are investigating AKT inhibitors (such as MK2206, GSK2141795, and BAY1125976) as single agents or in combination with targeted therapies or chemotherapy in specific tumor types (examples are NCT01333475, NCT01902173, NCT01979523, and NCT01915576). Other drugs, such as MSC2363318A, a dual p70S6K/AKT inhibitor, are in clinical trials (NCT01971515).

Based on the increase in tumor inhibition with combined MEK/PI3K targeting and the tolerability of drugs targeting each pathway individually, early-phase trials combining GDC-0941 (PI3K inhibitor) with GDC-0973 (MEK inhibitor) and combining BKM120 (PI3K inhibitor) with GSK1120212 (MEK inhibitor) have been completed^(38, 39). The latter study demonstrated promising antitumor activity in patients with *KRAS*-mutant ovarian cancer.

Conclusions

In summary, molecular alterations in the PI3K/AKT/mTOR pathway have been identified in multiple tumor types, emphasizing the critical role of this pathway in tumorigenesis and disease progression. The PI3K inhibitors, as single agents, have mostly cytostatic activity. Several escape mechanisms are involved in resistance to PI3K/AKT/mTOR inhibitors. Clinical trials are exploring the role of PI3K, AKT, or mTOR inhibitors in combination with other targeted or cytotoxic agents. In our experience, patients with molecular alterations in the PI3K/AKT/mTOR pathway treated with targeted therapies have shorter survival compared to patients with alterations in the RAS/RAF/MEK or EGFR/HER/other pathways treated with the matched targeted agents, perhaps due to less-effective therapies than those for other pathways or intrinsic resistance (unpublished data). Carefully designed clinical trials, patient selection, and the elucidation of mechanisms of response and resistance to PI3K/AKT/mTOR pathway inhibitors, including protein and phosphoprotein expression with signatures of sensitivity/resistance, may improve clinical outcomes.

EPIDERMAL GROWTH FACTOR RECEPTOR

Epidermal growth factor receptor (ErbB1, HER1) is a cell surface transmembrane receptor that belongs to the EGF family of extracellular protein ligands. It is a

member of the ErbB receptor family, which consists of four receptor tyrosine kinases: EGFR, HER2 (ErbB2), HER3 (ErbB3), and HER4 (ErbB4). The EGF binds to EGFR, stimulating ligand-induced dimerization, receptor dimerization, and signaling through tyrosine kinase activity, leading to activation of multiple pathways involved in cell proliferation, survival, metastases, and neoangiogenesis⁽⁴⁰⁾.

Epidermal Growth Factor Receptor–Targeted Therapies

Therapies that target EGFR include tyrosine kinase inhibitors (TKIs) and monoclonal antibodies. Gefitinib was the first selective EGFR inhibitor and was approved by the FDA in 2003 for NSCLC, but in 2005 the FDA withdrew this approval for use in new patients because gefitinib did not improve survival compared to placebo in previously treated patients⁽⁴¹⁾.

Erlotinib

Erlotinib targets the EGFR tyrosine kinase and is approved by the FDA for first-line treatment of patients with metastatic NSCLC with tumor *EGFR* exon 19 deletions or exon 21 (L858R) substitution mutations; maintenance therapy of patients with NSCLC and no evidence of disease progression after four cycles of platinum-based first-line chemotherapy; and treatment of NSCLC after failure of one or more prior chemotherapy regimens. It is approved as first-line treatment, in combination with gemcitabine, of patients with locally advanced/metastatic pancreatic cancer. In NSCLC, erlotinib demonstrated a significant improvement in median PFS and OS compared to placebo⁽⁴²⁾. Mutations in the *EGFR* kinase domain predicted response to EGFR TKIs^(43, 44). In patients with *EFGR* alterations, the response rate to EGFR TKIs ranged from 48% to 90%^(45, 46). Randomized trials demonstrated that the use of gefitinib or erlotinib is associated with longer PFS compared to platinum doublets in patients with lung adenocarcinoma and activating EGFR mutations. However, no OS benefit was noted⁽⁴⁷⁻⁵¹⁾, perhaps partially due to crossover after disease progression.

In a randomized study of erlotinib versus placebo as maintenance therapy in patients with advanced NSCLC who had an objective response or SD after four cycles of a platinum-based doublet, erlotinib was associated with superior PFS in patients with adenocarcinoma or SCC. Survival benefit was noted only in patients with SCC⁽⁵²⁾. The role of EGFR TKIs in patients with wild-type EGFR is unclear⁽⁵³⁾.

The role of adjuvant erlotinib in patients with resected NSCLC and EGFR molecular alterations was investigated in a phase III trial (comparing placebo vs erlotinib) (NCT00373425)⁽⁵⁴⁾. In 973 randomized

patients, there was no difference in disease-free survival between the two arms (HR, 0.90; $P = .32$). In a subset analysis of 161 patients with deletion 19 or L858R EGFR mutations, the median disease-free survival was 46.4 months in the erlotinib arm versus 28.5 months in the placebo arm (HR, 0.61; $P = .04$)^(55, 56). In a phase II study (RTOG 1306, NCT01822496), patients with stage III EGFR-mutant lung cancer or ALK-positive NSCLC were randomized to erlotinib followed by concurrent chemoradiation, crizotinib followed by concurrent chemoradiation, or chemoradiation alone.

Afatinib

Newer agents irreversibly inhibit EGFR and target additional EGFR members, such as HER2 and HER4. Afatinib is a selective, oral inhibitor of EGFR/ErbB1, HER2, and HER4. In a phase III study of afatinib or cisplatin plus pemetrexed in patients with metastatic lung adenocarcinoma with EGFR mutations, afatinib was associated with longer PFS compared to standard doublet chemotherapy (11.1 months vs 6.9 months, respectively; $P = .001$)⁽⁵⁷⁾. In patients with exon 19 deletions or L858R mutations, the median PFS was 13.6 months. Development of resistance is attributed to additional *EGFR* mutations (T790M on exon 20, 50% of patients)⁽⁵⁸⁾ or *PIK3CA* mutations; *MET* or *HER2* amplification; epithelial-to-mesenchymal transformation; or transformation to small cell lung cancer. Novel third-generation EGFR TKIs that target T790M mutations such as CO-1686 (rocicetinib) are being investigated.

Cetuximab

Cetuximab is a chimeric mouse-human immunoglobulin 1 monoclonal antibody against EGFR. It is indicated for the treatment of advanced SCC of the head and neck (combined with radiation therapy); recurrent or metastatic SCC of the head and neck (combined with platinum-based therapy with 5-fluorouracil); and recurrent or metastatic SCC of the head and neck that progresses after platinum-based therapy. Cetuximab with FOLFIRI (irinotecan, fluorouracil, and leucovorin) is indicated for the first-line treatment of K-RAS wild-type, EGFR-positive metastatic CRC and cetuximab with irinotecan for irinotecan-refractory patients; cetuximab monotherapy is indicated for patients with oxaliplatin- and irinotecan-refractory CRC or patients with irinotecan intolerance.

The role of cetuximab in lung cancer has not been determined. In a phase III study, the addition of cetuximab to taxane/carboplatin did not significantly improve PFS or OS⁽⁵⁹⁾. In another phase III study in patients with advanced EGFR-expressing NSCLC, the

addition of cetuximab to cisplatin and vinorelbine was associated with improved OS compared to the cisplatin and vinorelbine arm (median OS, 11.3 months vs 10.1 months, respectively; $P = .04$)⁽⁶⁰⁾. The SWOG 0819 trial comparing carboplatin/paclitaxel with and without bevacizumab (in eligible patients) and/or cetuximab in stage IV or recurrent NSCLC has been suspended (NCT00946712).

Mutations and overexpression of EGFR are frequent in patients with CRC⁽⁶¹⁾. In patients with irinotecan-refractory CRC, cetuximab demonstrated significant antitumor activity as monotherapy (overall response rate [ORR], 10.8%; median time to progression, 1.5 months; median OS, 6.9 months) or combined with irinotecan (22.9%; 4.1 months and 8.6 months, respectively)⁽⁶¹⁾. In a phase III study, cetuximab was associated with improved survival compared to best supportive care in patients with refractory metastatic CRC (6.1 months vs 4.6 months)⁽⁶²⁾. In another phase III study, first-line treatment with cetuximab plus FOLFIRI reduced the risk of progression compared to FOLFIRI alone in patients with metastatic CRC, but the benefit of cetuximab was limited to patients with KRAS wild-type tumors⁽⁶³⁾.

In patients with previously untreated metastatic CRC, cetuximab plus FOLFOX-4 (oxaliplatin, leucovorin, and fluorouracil) was associated with a higher ORR (43% vs 36%) compared to FOLFOX-4 alone⁽⁶⁴⁾. In patients with KRAS wild-type CRC, cetuximab plus FOLFOX-4 compared to FOLFOX-4 alone was associated with a higher ORR (61% vs 37%; $P = .01$) and a lower risk of disease progression (HR, 0.57; $P = .02$). This study demonstrated that KRAS mutational status is a highly predictive selection criterion for the addition of cetuximab to FOLFOX-4 in this setting⁽⁶⁴⁾.

Panitumumab

Panitumumab is a fully humanized IgG2 anti-hEGFR antibody indicated for the treatment of patients with wild-type *KRAS* (exon 2 in codons 12 or 13) metastatic CRC as first-line therapy in combination with FOLFOX and monotherapy in fluoropyrimidine-, oxaliplatin-, and irinotecan-refractory patients. In a phase III study of panitumumab with FOLFOX4 versus FOLFOX4 alone as first-line therapy in patients with wild-type *KRAS* metastatic CRC, the addition of panitumumab to FOLFOX4 resulted in higher rates of overall response (57% vs 48%; $P = .02$), PFS (10 vs 8.6 months; $P = .01$), and OS (HR, 0.83; $P = .03$)⁽⁶⁵⁾. In a randomized study of panitumumab versus cetuximab in patients with chemotherapy-refractory wild-type *KRAS* exon 2 metastatic CRC, panitumumab was not inferior to cetuximab, and the OS benefit was similar (median OS, 10.4 vs 10 months, respectively; HR, 0.97)⁽⁶⁶⁾.

KIT

The tyrosine-protein kinase KIT (c-Kit or CD117) is a receptor tyrosine kinase protein that is encoded by the *KIT* gene. KIT regulates cell differentiation and proliferation, resists cell apoptosis, and plays an important role in tumorigenesis and migration by activating downstream signaling molecules following interaction with stem cell factor (SCF). Complete loss of KIT activity results in in utero or perinatal death; “loss of function” leads to failure of particular stem cell populations to migrate and survive. Activating mutations of *KIT* occur in almost all patients with systemic mastocytosis. In gastrointestinal stromal tumors (GISTs), activating mutations of *KIT* occur in more than 80% of patients; two-thirds of *KIT* mutations occur in exon 11, resulting in dysfunction of the intracellular autoinhibitory juxtamembrane domain. The majority of these mutations are indels. Deletion of exon 11 is associated with shorter PFS and OS in patients with GIST (⁶⁷). Approximately 10% to 15% of *KIT* mutations in GIST occur in the extracellular region encoded by exon 9 (primarily in intestinal GIST). Mutations in *KIT* occur in core binding factor leukemias (17% of acute myeloid leukemia [AML]), in up to 26% of patients with testicular seminomas, and in 30% of patients with unilateral ovarian dysgerminomas (⁶⁸). Activating *KIT* mutations and amplifications have been reported in 5% of patients with melanoma. In melanoma, *KIT* mutations occur as follows: exon 9 (5%), exon 11 (45%), exon 13 (25%), exon 17 (10%), and exon 18 (15%); more than 90% of these mutations are missense mutations. Therefore, KIT inhibition is an attractive therapeutic strategy in patients with tumor aberrations of the SCF/c-KIT signaling pathway.

Gastrointestinal Stromal Tumor

Imatinib binds directly to the ATP-binding site within KIT, competitively inhibiting ATP binding and stabilizing the kinase in the inactive conformation. In the preimatinib era, the median survival of patients with advanced GIST was less than 1.5 years. The use of imatinib in advanced GIST is associated with a median survival of approximately 5 years (⁶⁹). In the adjuvant setting, imatinib was associated with decreased risk of relapse after surgery with curative intent. The reintroduction of imatinib after disease relapse is associated with results inferior to those for continued imatinib therapy, suggesting that imatinib should not be interrupted (⁶⁹). Primary resistance to imatinib is noted in 10% of patients with GIST and is attributed to the type of *KIT* mutation (exon 9 mutations have a threefold higher risk of resistance than exon 11 mutations) or to suboptimal dose in patients with *KIT* exon 9 mutations (⁷⁰). Secondary resistance is attributed to acquired mutations in the

ATP-binding site (exons 13/14) that interfere with imatinib binding or in the activation loop (exons 17/18) that stabilize the active conformation of KIT (⁷¹). In patients with imatinib-resistant GIST tumors, sunitinib (TKI/anti-VEGF agent) demonstrated significant improvement in the median time to progression compared to placebo, leading to FDA approval for this indication (⁷²). The efficacy of sunitinib in imatinib-secondary resistance is attributed to structural and enzymatic characteristics of sunitinib. Other tyrosine kinases targeted by sunitinib may play a role in its efficacy.

Regorafenib is FDA approved for TKI-resistant GIST. In a phase III study, regorafenib was associated with longer PFS than placebo (median PFS, 4.8 months vs 0.9 months, respectively; $P < .0001$) (⁷³). Although antitumor activity was noted with dasatinib and sorafenib, the use of nilotinib has not shown significant antitumor activity in the third-line setting (⁷⁴).

Inhibitors of *KIT* combined with other targeted agents may improve the outcomes of patients with *KIT* alterations and overcome resistance. A phase I study of dasatinib and ipilimumab for unresectable or metastatic GIST or other sarcomas is ongoing (NCT01643278).

Melanoma

In patients with melanoma and a *KIT* alteration, the use of imatinib was associated with an ORR of 23.3% (⁷⁵). Patients whose disease responds to imatinib typically have activating mutations in exons 11 (L576p; response, 64%) and 13 (K462E; response, 43%). Other mutations in exon 11 (eg, V559X, V560D) are also sensitive to imatinib. Wild-type *KIT* amplification is not sensitive to imatinib. In smaller studies, sunitinib or nilotinib also had antitumor activity (^{76,77}).

Mastocytosis

One of the indications of imatinib is the treatment of adults with systemic mastocytosis and a non-*KIT* D816V mutation (or unknown *KIT* mutation status). A *KIT* D816V mutation, which occurs in most patients with mastocytosis, is resistant to imatinib. In a phase II clinical trial, dasatinib was associated with symptomatic benefit in patients with mastocytosis harboring a *KIT* D816V mutation (⁷⁸). In this setting, responses have been reported with midostaurin (NCT00782067).

HUMAN EPIDERMAL GROWTH FACTOR RECEPTOR 2

As previously discussed, the HER family includes four receptors: HER1, HER2, HER3, and HER4. HER2 is involved in the regulation of proliferation and survival

of epithelial cells and is considered an orphan receptor because it has no known ligand. HER1, HER3, and HER4 receptors have ligands and form homodimers or heterodimers on ligand binding. HER2 can heterodimerize with any of the other receptors and is the preferred dimerization partner, leading to autophosphorylation of tyrosine residues within the cytoplasmic domain of the receptors and initiating signal transduction via the PI3K/AKT and RAS/MAPK pathways ⁽⁷⁹⁾. In breast cancer, amplification and overexpression of the *HER2* oncogene is a poor prognostic factor ⁽⁸⁰⁾. Overexpression of HER2 occurs in approximately 15% to 20% of early-stage breast cancer and was historically associated with poor clinical outcomes.

Studies combining HER2-targeted therapies with other agents (PI3K, mTOR inhibitors) or immunotherapy and combinations of two or more HER2-targeted therapies (trastuzumab and TDM1; trastuzumab and pertuzumab followed by TDM1) have been completed or are ongoing (examples are NCT02073487, NCT02073916, NCT01835236, and NCT02252887).

Trastuzumab

Trastuzumab is a recombinant DNA-derived humanized monoclonal antibody that selectively binds with high affinity to the extracellular domain of HER2 protein. The antibody is an IgG1 kappa that contains human framework regions with the complementarity-determining regions of a murine antibody that binds to HER2. Trastuzumab is indicated as monotherapy for patients with metastatic breast cancer whose tumors overexpress HER2 protein and had one or more chemotherapy regimen(s) and combined with paclitaxel for patients with metastatic breast cancer whose tumors overexpress HER2 protein and who have not received chemotherapy for their metastatic disease. Approximately 15% of patients develop disease recurrence after trastuzumab therapy. Resistance to trastuzumab has been attributed to altered receptor-antibody interaction, activation of the downstream pathways by increased signaling from other members of the HER family or other receptors, or constitutive activation of downstream elements. Prospective studies are assessing the role of trastuzumab in patients whose breast cancers do not overexpress HER2.

Lapatinib

Lapatinib, a dual TKI of EGFR and HER2, has anti-tumor activity in trastuzumab-refractory breast cancer. Lapatinib is FDA approved in combination with capecitabine for patients with advanced or metastatic

breast cancer whose tumors overexpress HER2 and who have received prior therapy, including anthracycline, taxane, and trastuzumab therapy, and letrozole for postmenopausal women with hormone receptor-positive metastatic breast cancer that overexpresses the HER2 receptor and for whom hormonal therapy is indicated.

Trastuzumab Emtansine

Trastuzumab emtansine (ado-trastuzumab emtansine, T-DM1) is an antibody-drug conjugate consisting of trastuzumab linked to the cytotoxic agent mertansine (DM1). Trastuzumab inhibits the growth of cancer cells by binding to HER2, and mertansine enters and destroys cells by binding to tubulin. T-DM1 is specifically toxic to tumor cells because it targets HER2, which is overexpressed in cancer cells. In patients with HER2-positive, trastuzumab-resistant breast cancer, T-DM1 improved survival by 5.8 months compared to lapatinib and capecitabine combination therapy ⁽⁸¹⁾. This study led to the FDA approval of T-DM1, which is indicated as monotherapy for patients with HER2-positive, metastatic breast cancer previously treated with trastuzumab with or without a taxane. Patients receiving T-DM1 should have received prior therapy for metastatic disease or developed disease recurrence during or within 6 months of completing adjuvant therapy.

Pertuzumab

Pertuzumab is a humanized monoclonal antibody that binds to the HER2 receptor and inhibits the interaction between HER2 and other HER family members (HER1, HER3, and HER4) on the surface of cancer cells. Pertuzumab is FDA approved in combination with trastuzumab and docetaxel as a neoadjuvant treatment for patients with HER2-positive breast cancer and as a treatment for patients with HER2-positive metastatic breast cancer. Clinical trials are evaluating the role of pertuzumab or T-DM1, combined with standard chemotherapy and trastuzumab, for early-stage breast cancer in the adjuvant setting.

CDK4/6 INHIBITORS

In many cancer cells, CDK4 and CDK6 mediate cell cycle control. Randomized phase II trials in patients with ER-positive metastatic breast cancer demonstrated that CDK4/6 inhibition combined with first-line endocrine treatment can improve PFS. Clinical trials with CDK4/6 inhibitors as single agents or combined with other drugs are ongoing.

ANDROGEN RECEPTOR INHIBITION

The AR is expressed in the vast majority of ER-positive breast cancers. Interestingly, a subset of ER-negative tumors also expresses AR. Ongoing clinical trials will define the role of androgen deprivation and AR blockade in ER-positive and ER-negative tumors.

BRCA1 AND BRCA2

Hereditary *BRCA1* and *BRCA2* mutations are associated with an increased risk of developing breast and ovarian cancer. *BRCA1/2* mutations lead to impaired double-strand DNA repair. PARP1 plays an important role in repairing single-strand breaks, and PARP1 inhibitors result in the formation of multiple double-strand breaks. Thus, the use of PARP inhibitors in tumors with *BRCA1*, *BRCA2*, or *PALB2* mutations renders the cells unable to efficiently repair DNA and makes them vulnerable to apoptosis. In phase II studies in *BRCA*-associated breast cancer, the use of PARP inhibitors was associated with clinical responses⁽⁸²⁾. Ongoing studies are comparing PARP inhibitors with standard chemotherapy in women with *BRCA1/2*-mutated advanced breast cancer. Clinical trials of PARP inhibitors in patients with deleterious *BRCA1/2* mutations have been completed or are ongoing in breast and ovarian cancer and in other tumor types (examples are NCT01989546, NCT02326844). The PARP inhibitors in clinical testing include olaparib (as a single agent or in combination with the PI3K inhibitors BKM120 or BYL713), veliparib, rucaparib, and talazoparib as single agents or in combination with cytotoxics.

C-MET

c-MET (or MET) is a receptor tyrosine kinase with specificity for a single ligand, the hepatocyte growth factor (HGF). Binding of HGF to MET leads to receptor dimerization and autophosphorylation of MET on its intracellular kinase domain and subsequent phosphorylation of its C-terminal docking site and juxtamembrane domain. These phosphorylation events enable activation of multiple downstream effector proteins, such as the adaptor proteins Grb2 and Gab1, leading to activation of the PI3K, Ras/RAF/MEK/ERK, PLC- γ , STATs, and FAK signaling pathways. c-MET plays a role in promoting the proliferation, survival, motility, and invasion of normal and tumor cells. It is thought c-MET promotes metastasis through increased production of HGF by hepatocytes, leading to enhanced paracrine signaling and clonal selection of metastatic cells with high MET expression^(83,84). c-MET promotes

angiogenesis, and it is involved in the development of resistance to cytotoxic chemotherapy and VEGF or EGF receptor inhibitors. c-MET and phospho-c-MET have been associated with poor clinical outcomes in patients with CRC and lung cancer and with disease progression in patients with breast cancer and melanoma. The intracellular pathways activated by c-MET interact with receptors such as EGFR, HER2, WNT, and the insulinlike growth factor receptor 1 (IGFR1). Activation of EGFR leads to c-MET phosphorylation and activation. Activation of the WNT- β -catenin pathway results in *MET* transcription⁽⁸⁵⁾. c-MET activation can promote other growth receptor pathways, including the HER3-PI3K-AKT signaling pathway⁽⁸⁶⁾. The c-MET mutations are usually a result of sporadic somatic alterations acquired during cancer development^(83,84,86,87). Germline *MET* mutations are found in papillary renal cell carcinoma, familial gastric cancer, and CRC. Development of resistance to sunitinib⁽⁸⁸⁾, gefitinib⁽⁸⁶⁾, and erlotinib⁽⁸⁷⁾ has been in part attributed to c-MET activation. Paired analysis of tumors from patients with lung cancer whose disease stopped responding to gefitinib or erlotinib identified MET amplification as an acquired resistance mechanism in selected patients⁽⁸⁶⁾.

Targeted therapy against the HGF/MET pathway includes small-molecule inhibitors and antibodies against either HGF or MET. Cabozantinib is a small-molecule inhibitor that inhibits c-Met and VEGFR2 and is FDA approved for medullary thyroid cancer. Monoclonal antibodies include rilotumumab and ficlatuzumab. Rilotumumab was in development, but all clinical trials in advanced gastric cancer (including two phase III studies) were closed after a randomized trial demonstrated an increased death rate in the rilotumumab and chemotherapy combination arm compared to the chemotherapy arm. A phase II randomized, double-blind study is comparing ficlatuzumab plus erlotinib with placebo plus erlotinib in patients with previously untreated, metastatic, EGFR-mutated NSCLC and “BDX004-positive label” (NCT02318368). Onartuzumab is a monovalent humanized monoclonal antibody produced in *Escherichia coli* that binds to the Sema domain on the extracellular part of MET to block HGF binding. A phase III study that compared onartuzumab plus erlotinib versus erlotinib plus placebo in patients with MET-positive advanced NSCLC was discontinued owing to the lack of clinically meaningful efficacy in an interim analysis.

Clinical trials have been completed or are in development for the monoclonal antibodies against c-MET, such as LY-2875358, h224G11A, and DN30. Synthetic small-molecule unselective (crizotinib, foretinib, cabozantinib, MGCD-265) and selective (tivantinib, JNJ-38877605, AMG337, AMG208, PF-04217903, EMD-1214063, LY-2801653, and INC-280) c-MET

TKIs are being investigated. A phase III trial of tivantinib plus erlotinib for the treatment of patients with locally advanced or metastatic, nonsquamous NSCLC was discontinued because it did not meet its primary end point of prolonging OS.

ANAPLASTIC LYMPHOMA KINASE

Gene rearrangements of ALK occur in 2% to 7% of patients with NSCLC. In these patients, the use of the ALK inhibitor crizotinib as first-line therapy was associated with longer PFS and less toxicity compared to chemotherapy^(89,90). Crizotinib is a small-molecule inhibitor initially developed to target c-MET (and is highly specific in this targeting) that is FDA approved for the treatment of ALK-positive NSCLC. A phase II trial is evaluating the role of crizotinib in predefined tumor types in patients whose tumors are harboring specific alterations in ALK or MET (NCT01524926). The next-generation ALK inhibitors were developed to overcome resistance to crizotinib, which is attributed to secondary mutations within the ALK-TK domain; EML4-ALK amplification; bypass activation of alternative signaling pathways (EGFR, c-KIT, KRAS, IGF1 receptor); and progression/occurrence of central nervous system (CNS) metastases.

Ceritinib

Ceritinib is an ATP-competitive ALK inhibitor that showed greater antitumor potency than crizotinib in preclinical studies. Ceritinib is FDA approved (accelerated process) for patients with ALK-positive NSCLC previously treated with crizotinib. In a phase I study in patients with ALK-rearranged NSCLC ($n = 114$) who had received 400 mg or more of ceritinib, the response rate was 58%, and the median PFS was 7 months. The response rate for crizotinib-pretreated patients was 56%. The median PFS was longer in crizotinib-naïve (10.4 months) than in crizotinib-pretreated (6.9 months) patients⁽⁹¹⁾. In an expansion cohort of 246 patients with ALK-rearranged metastatic NSCLC treated with the MTD of 750 mg orally daily, the response rate was 58.5% (ALK inhibitor pretreated, 54.6%; ALK inhibitor naïve, 66.3%), and the median PFS was 8.2 months (6.9 months and not reached, respectively). Central nervous system responses were noted in some patients with untreated lesions.

A randomized trial for patients with ALK-rearranged metastatic NSCLC previously untreated or treated with chemotherapy and crizotinib is comparing ceritinib with pemetrexed/cisplatin or pemetrexed/carboplatin (NCT01828099). A phase III trial is comparing ceritinib with standard chemotherapy in patients with ALK-rearranged NSCLC. Other studies are investigating ceritinib as monotherapy in cholangiocarcinoma

with ROS1 or ALK overexpression or in anaplastic/undifferentiated thyroid cancer with ALK alterations or in combination with targeted therapies or chemotherapy, such as with everolimus, in solid tumors and ALK-rearranged NSCLC, with chemotherapy in pancreatic cancer, with LEE011 in ALK-positive NSCLC, and with nivolumab in NSCLC.

Alectinib

Alectinib is another second-generation ALK inhibitor. In a phase I/II study of alectinib in ALK inhibitor-naïve patients with metastatic ALK-rearranged NSCLC, no DLTs were noted up to doses of 300 mg twice daily, and the response rate was 93.5%. In another phase I/II study in patients with ALK-rearranged tumors who had progressed on crizotinib treatment, the MTD of alectinib was 600 mg twice daily. The response rate during the dose escalation part of the study was 55%. In patients with known CNS metastases treated with alectinib, the response rate was 52% within the CNS. No patient initially free of CNS metastases developed new CNS lesions during treatment. A phase III trial is comparing alectinib to crizotinib in treatment-naïve patients with advanced ALK-rearranged NSCLC.

Other ALK Inhibitors

Another ALK inhibitor with antitumor activity in NSCLC is AP26113, which has activity against ALK and mutant isoforms of EGFR without activity against wild-type EGFR. Preliminary data from a phase I/II trial in crizotinib-pretreated patients demonstrated a response rate of 63%. ASP3026 is a selective, ATP-competitive ALK inhibitor with activity against wild-type ALK and against the most frequent crizotinib resistance-mediating gatekeeper mutation, L1196 M. In a phase I trial, the MTD was 125 mg, and 44% of patients with crizotinib-resistant ALK-rearranged NSCLC had a PR. TSR-011 is an inhibitor with antitumor activity against ALK and tropomyosin-related kinase. PD-06463922 is a TKI with activity against ALK and ROS1, which appears to retain its signal-blocking effects even when several ALK mutations, leading to crizotinib resistance, are present. X-396 is a small-molecule TKI blocking ALK signaling in the wild-type conformation and with considerable activity against at least two of the crizotinib resistance-mediating ALK point mutations (L1196 M and C1156Y). An ongoing phase I study demonstrated promising activity (NCT01625234). The heat shock protein 90 (HSP90) inhibitors have also demonstrated activity against ALK-rearranged NSCLC in early clinical trials. In a phase II trial of the HSP90 inhibitor ganetespib, PRs were noted in 4 of 98 patients⁽⁹²⁾. The HSP90-inhibiting compound AUY922 has shown promising activity.

NOTCH

Notch was identified as an oncogene in T-cell acute lymphoblastic leukemia (T-ALL) in which the (7;9) chromosomal translocation fuses the N-terminal region of the T-cell receptor beta (TCR β) to the C-terminus of Notch1. This leads to expression of a truncated Notch1 protein that lacks the extracellular subunit and is thus constitutively active⁽⁹³⁾. The intracellular forms of all four Notch proteins are potentially oncogenic and capable of transforming normal cells. Deregulated expression of Notch proteins, ligands, and targets has been described in various solid tumors, including cervical, head and neck, endometrial, renal, lung, pancreatic, breast, ovarian, prostate, esophageal, hepatocellular, and gastric carcinomas; osteosarcoma; mesothelioma; melanoma; glioma; medulloblastoma; and rhabdomyosarcoma. They have also been found in T-ALL, Hodgkin lymphoma, anaplastic large-cell non-Hodgkin lymphoma (NHL), AML, B-cell chronic lymphocytic leukemia (CLL), and multiple myeloma. Notch may contribute to carcinogenesis by inhibiting differentiation, inhibiting apoptosis, or promoting proliferation. The intracellular forms of Notch induce transformation when it is expressed with oncoproteins that disable the G1-S checkpoint, such as adenovirus E1A, human papillomavirus E6 and E7, Ras, Myc, or SV40 large T antigen. Notch can activate the expression of several oncogenic pathways via direct or indirect induction of cyclins D1, D3, and A; SKP2; and c-Myc or via activation of PI3K-AKT-mTOR, nuclear factor (NF) κ B and NF- κ B2, β -catenin, or signal transducer and activator of transcription 3. Notch can also cooperate with oncogenic pathways such as WNT or HER2/Neu.

In addition to its cell-autonomous effects on oncogenic pathways, Notch is involved in tumor-stroma interactions and has a tumor suppressor effect in the epidermis. Notch activity has been reported in cancer stemlike cells (CSCs), which constitute a small subset of cancer cells with a stemlike phenotype that are a reservoir of self-sustaining cells with the ability to self-renew, presumably leading to recurrence. The stemlike phenotype is characterized by enhanced resistance to chemotherapy and radiotherapy, supporting the role of Notch signaling in the maintenance of breast CSCs. Neutralizing monoclonal antibodies directed against Notch 1, 2, and 3 have been used in the clinic. A phase I study of OMP-59R5, a humanized monoclonal antibody that blocks Notch 2 and Notch 3 signaling, was followed by two phase Ib/II trials: the ALPINE trial (Antibody Therapy in First-Line Pancreatic Cancer Investigating Anti-Notch Efficacy and Safety), which is testing OMP-59R5 with gemcitabine and abraxane as first-line therapy in patients with advanced pancreatic cancer, and the PINNACLE trial (Phase Ib/II Investigation of Anti-Notch Antibody Therapy With Cisplatin

and Etoposide in Small Cell Lung Carcinoma Efficacy and Safety), which is testing OMP-59R5 combined with cisplatin and etoposide as first-line therapy in patients with extensive-stage small cell lung cancer.

Soluble Dll4-Fc fusion proteins, which bind Notch receptors and prevent their activation by endogenous Dll4, inhibit Notch signaling in endothelial cells, causing disorganized angiogenesis and inhibiting tumor growth. Clinical trials using the OMP-21M18 antibody are ongoing for patients with pancreatic cancer (as first-line therapy with or without abraxane), small cell lung cancer (with carboplatin and pemetrexed), and platinum-resistant ovarian cancer (with paclitaxel).

Nonselective γ -secretase inhibitors (GSIs) are also known as “Notch inhibitors.” The GSI MK-0752 is being investigated in clinical trials in solid tumors and T-ALL. In a phase I trial, MK-0752 was combined with gemcitabine in patients with pancreatic ductal adenocarcinoma.

In a phase Ib trial of the GSI RO4929097 combined with exemestane in metastatic, ER-positive breast cancer, treatment was tolerable, and responses were noted (NCT01149356). The development of RO4929097 has been hampered by its pharmacokinetic liability due to the autoinduction of hepatic metabolism. GSI PF-03084014 is currently in phase I clinical trials for T-ALL and various solid tumors (NCT01981551).

In summary, deregulation of Notch proteins has been associated with cancer development and progression and with the self-propagation of CSCs. Notch-targeted therapies include nonselective GSIs, but various other agents are in development. In HER2-positive breast cancer, the effect of Notch inhibition was recurrence prevention rather than tumor volume decrease.

FIBROBLAST GROWTH FACTOR RECEPTOR

The fibroblast growth factor receptor (FGFR) family comprises four main members (*FGFR1-FGFR4*) and encodes membrane tyrosine kinase receptors involved in signaling by interacting with fibroblast growth factors. Activating mutations *FGFR3* and *FGFR4* exist^(94,95), but amplification of *FGFR3* and *FGFR4* has been described rarely in cancer. According to the public Cancer Genome Atlas (<http://cancergenome.nih.gov>), *FGFR1* amplification occurred in 3.4% of 10,648 patients and *FGFR2* amplification occurred in 0.9% of 8,352 patients. The amplifications were found in lung (16.9%), breast (13.4%), and gastric (5.1%) cancer. Amplification of *FGFR1* has been found in lung cancer, SCC of the head and neck, esophageal SCC, and breast and pancreatic cancer. Amplification of *FGFR2* has been found in gastric and breast cancer and NSCLC. In a meta-analysis, it was shown that amplification of

FGFR1 or *FGFR2* may be associated with poor OS in various cancers^(95e). Amplification of *FGFR1* was also associated with shorter disease-free survival.

In a phase II study of brivanib (an oral, multitargeted TKI with activity against VEGF and FGFR) in recurrent or persistent endometrial cancer, the ORR was 18.6% (8 of 43 patients; CR, *n* = 1; PR, *n* = 7), and 13 patients were progression free at 6 months⁽⁹⁶⁾. Dovitinib (TKI258) is a TKI that inhibits FGFR, VEGFR, and platelet-derived growth factor receptor⁽⁹⁷⁾. In a phase II study of dovitinib in metastatic renal cell carcinoma, of 67 patients enrolled, 82.1% were previously treated with one or more VEGFR TKI and one or more mTOR inhibitor. The rates of 8-week overall response and disease control were 1.8% and 52.7%, respectively. The median PFS and the median OS were 3.7 and 11.8 months, respectively⁽⁹⁷⁾. In a phase II trial of dovitinib in 81 patients with metastatic breast cancer, unconfirmed response or SD for more than 6 months was observed in five (25%) and one (3%) patient(s), respectively, with FGFR1-amplified/HR-positive or FGFR1-nonamplified/HR-positive breast cancer. Other FGFR inhibitors that are being investigated in clinical trials include AZD4547, BAY1187982, BIBF1120, lucitanib (VEGFR-FGFR inhibitor), ponatinib, TAS-120, Debio 1347 (CH5183284), BAY1163877 (pan-FGFR inhibitor), FGF401, BGJ398 (as monotherapy or combined with BYL719), nintedanib, JNJ-42756493, GSK3052230 (combined with paclitaxel and carboplatin or docetaxel or as monotherapy), ARQ 087, BAY1179470, and FPA144. Clinical trials that set FGFR copy number as an inclusion criterion and standardization of FGFR amplification testing may improve these trials⁽⁹⁸⁾.

INSULIN-LIKE GROWTH FACTOR RECEPTOR

Insulin like growth factor (IGF) signaling plays a critical role in the growth and survival of many types of human cancer cells. Although preclinical data of several inhibitors of GF1R were promising in early-phase clinical trials, serious toxicities were observed. Larger randomized phase III trials targeting this pathway failed and led to termination of the anti-IGF1R programs⁽⁹⁹⁾.

P53 MDM2 INHIBITORS

Clinical trials with other inhibitors, such as the murine double minute 2 (MDM2) inhibitor DS-3032b; RO6839921; RO5045337 in combination with doxorubicin in soft tissue sarcoma; RO5503781; HDM201 in combination with LEE011 in liposarcoma; and HDM201 in TP53 wild-type advanced tumors, are ongoing or have been completed. To date, they have demonstrated limited, if any, antitumor activity.

FUTURE PERSPECTIVES

Breakthroughs in technology and the discovery of effective drugs have led to epic advances in the war against cancer. We first demonstrated that, in early-phase clinical trials across tumor types, targeted therapy is associated with high rates of response, PFS, and survival in patients with one targetable molecular alteration^(1, 99, 100). Next-generation sequencing, circulating DNA and tumor cells, and other profiling will improve our understanding of tumor biology in individual patients. Currently, there is a gap between the plethora of preclinical data and the lack of effective therapies, which is at least partially due to suboptimal drug development for “driver” alterations of human cancer, the high cost of clinical trials and available drugs, and limited access of patients to clinical trials. The complexity of the development of anticancer drugs is evidenced by the high rate of failure of phase III clinical trials of various agents that showed promising results in early-phase studies. Ongoing clinical trials with innovative adaptive study design hold the promise of expediting effective drug development (NCT02152254, NCT01827384, NCT01771458, NCT01248247, NCT01042379, NCT02117167).

Further advances in cancer therapy will be associated with improved technology and bioinformatic analyses to understand dynamic changes in biology and tumor plasticity. Vertical access (changes in time) of cancer biological components to address molecular evolution and horizontal access (changes by site of disease involvement) to address tumor heterogeneity, the interaction between the cancer genome and the epigenome, and the surrounding microenvironment need to be considered. The computational sciences are expected to accelerate drug development by establishing methods to characterize the molecular interactions and analyze a large amount of data about activated pathways, cross talk, and interactions between various components of the cancer intracellular machinery. The power of computational medicine and data sharing is stimulating investigators to develop promising projects that involve the implementation of both bioinformatics and big data analyses. Finally, the development of effective therapeutic strategies, carefully designed clinical trials, and collaborative efforts among key stakeholders in cancer therapy ultimately hold the promise of curing cancer.

INTRODUCTION

The Department of Biostatistics at the University of Texas MD Anderson Cancer Center works on developing innovative designs for clinical trials and biological experiments, analysis of complex data, and consulting and collaborating with clinical and biological investigators. Thousands of clinical trials are conducted at MD Anderson Cancer Center each year. Most of them are phase I/II trials, and a small number are phase III trials organized by biopharmaceutical companies. A large fraction of these phase I/II trials are initiated by MD Anderson investigators. Faculty members in the Department of Biostatistics are responsible for the statistical designs of these trials.

Although many statistical designs have been developed for phase I/II trials, most were not developed specifically for oncology clinical trials. Oncology trials usually have a small sample size due to the heterogeneity of patients, the large number of competing trials, and the fact that each particular subtype of cancer is a rare disease. Oncology trials need to consider multiple end points, such as tumor response, patient survival, and toxicity. To accommodate the special needs of oncology trials, the biostatisticians develop innovative adaptive designs to maximize the benefits of both patients participating in the trial and future patients, to make the most efficient use of patients as a valuable resource for competing trials, and to accelerate the drug development, discovery, and testing processes.

STATISTICAL RESEARCH ON CLINICAL TRIAL DESIGN

Faculty in the Department of Biostatistics advocate adaptive clinical trial designs⁽¹⁻⁷⁾ and other innovative early-phase designs⁽⁸⁻¹⁵⁾. Some examples of adaptive designs are discussed next. We developed a statistical design for phase II clinical trials that better selects drug candidates for phase III trials⁽¹¹⁾. Currently, most phase II oncology trials use complete remission (CR) of the cancer as the primary end point. Drugs associated with higher CR rates are evaluated in subsequent phase III trials, which are usually required to demonstrate that the drug increases the patient's survival time. Although achieving CR is necessary to prolong survival, it is not a sufficient measurement because patients may experience cancer relapse shortly after achieving CR. This discrepancy is one of the major reasons for the high failure rates (60%) of phase III trials⁽¹⁵⁾. Thus, it is desirable to evaluate survival outcomes in phase II trials. Based on these considerations, our phase II design uses information on both CR and survival. There are several innovative features of this design. It makes full use of the information that accumulates in all stages of the trial and thus saves valuable patient resources. Interim stopping rules for toxicity, futility, and efficacy are defined. To evaluate the efficacy of treatments, patients are assigned to therapy in a randomized adaptive fashion. This means that patients in the trial tend to receive the more effective treatment, and the important aspects

of the dose-response relationship are determined in an efficient manner. In particular, simulation studies show that the design has better operating characteristics than traditional trial designs.

The statistical aspects of this innovative design were published in *Statistics in Medicine* ⁽¹¹⁾, and results of the actual trial were published in *Leukemia & Lymphoma* ⁽¹⁶⁾. Free computer software to implement this design is available on the website of the Department of Biostatistics for public use. Since the software was posted in 2009, it has been downloaded hundreds of times by people around the world, and the authors have replied to numerous e-mail inquiries. The URL for the software website is <https://biostatistics.mdanderson.org/SoftwareDownload/>.

We developed another statistical design to make the results of phase II or III clinical trials more reliable ⁽⁶⁾. In clinical trials with a relatively small sample size, patient characteristics among different treatment arms may not be well balanced. This may lead to an invalid inference. For trials that utilize response-adaptive randomization, this problem may be even more severe than for trials that use equal randomization. We developed a patient allocation scheme to adjust this imbalance during response-adaptive randomization. This design ensures that the observed differences between different treatments are real, rather than being due to an imbalance of patient characteristics between the different treatment groups. Because individuals with cancer are highly heterogeneous and oncology trials usually have relatively small sample sizes (compared with trials for some other diseases), clinical investigators have always had the concerns described. This design solves this important problem. The related research has been published in *Statistics in Medicine* ⁽⁶⁾.

Innovative statistical designs can help conduct clinical trials more ethically and more efficiently. For example, the Department of Leukemia at MD Anderson conducted a randomized phase II study of clofarabine alone versus clofarabine in combination with low-dose cytarabine (ara-c) in previously untreated patients who were 60 years of age or older and who had acute myeloid leukemia (AML) or high-risk myelodysplastic syndrome (MDS). The maximum sample size was set to be 108. The first 20 patients were equally randomized to the two treatment arms. After that, we designed an algorithm to assign more patients to the better-performing treatment arm. The trial would be stopped early if at any time the probability that one arm was superior was greater than or equal to 95%. Using this early stopping rule, the trial was stopped after 70 patients became evaluable for response. At that time, the treatment arm of clofarabine alone had 16 patients, 5 of whom (31%) had CR. The combination arm had 54 patients, 34 of whom (63%) had CR. By using this innovative statistical design, we not

only reduced the sample size (from 108 to 70), but also assigned more patients (54 vs 16) to the treatment that showed better performance. These results were published in *Blood* ⁽¹⁷⁾. Many such efficient and ethical clinical trials have been conducted ⁽¹⁸⁻³⁰⁾.

DATA ANALYSIS

Faculty in the Department of Biostatistics devote great effort into genomic research ⁽³¹⁻⁴⁸⁾, imaging data analysis ⁽⁴⁹⁻⁵³⁾, survival analysis ⁽⁵⁴⁻⁶¹⁾, biomarker data analysis ^(62, 63), drug interactions ⁽⁶⁴⁾, causal inference ⁽⁶⁵⁻⁶⁷⁾, epidemiology studies ⁽⁶⁸⁻⁷²⁾, and many other diverse topics. Next is a discussion of some issues in the analyses of disease recurrence, cancer screening, and biomarker studies.

Although curing cancer remains a challenge, medical advancements have successfully transitioned many types of cancer from a rapidly fatal disease to a chronic disease. After their initial treatments, patients may experience a few disease recurrences and receive different salvage treatments after each such recurrence. That is, cancer patients usually experience the following process:

Initial treatment → Disease recurrence →
Salvage treatment → Another disease
recurrence → Another salvage treatment ...

This is a long and complicated process. For many forms of cancer, a number of therapeutic options are available at the initial and at subsequent salvage treatment stages. In these circumstances, instead of considering only the effect of a treatment on the time to the next disease recurrence, it is important to understand the long-term effects of each treatment on the overall survival time. Optimizing treatment decisions during this process can minimize treatment toxicity, reduce drug resistance, prolong the survival time, and enhance the patient's quality of life.

The duration of disease-free survival is commonly used in medical research to compare different treatments. This method considers the time to disease recurrence or death, whichever happens first. Equating death with disease recurrence in this manner does not give sufficient penalty to treatments associated with high death rates. This is a serious problem when the lifetime after disease recurrence can be substantial. Consequently, disease-free survival is not the best basis for making treatment decisions.

A number of statistical methods have been developed to address the shortcomings of methods based on the end point of disease-free survival ⁽⁷³⁻⁷⁸⁾. We have been using frailty models to analyze recurrent events and a terminal event, such as death ⁽⁷³⁻⁷⁵⁾. We provide estimation of the effects on survival by treatment

sequence⁽⁷⁶⁾. We provide new and easily implemented statistical approaches to optimize treatment sequences for recurrent diseases^(77,78). The optimized treatment sequences are personalized; that is, treatment decisions depend on a patient's previous response, current disease status, characteristics, and genetic biomarkers. These methods can be applied to data from randomized or nonrandomized studies.

The importance of dealing with the problem of informative censoring is well known in statistics, but it remains a challenge. We have developed a frailty model for informative censoring⁽⁷⁹⁾ and a test for informative censoring in clustered survival data⁽⁸⁰⁾. They can be used to test the presence of informative censoring, to estimate the degree of association between censoring and the risks affecting survival, and to estimate treatment effects while accounting for the informative censoring. This model can also be used to assess the correlation between different competing risks. We have developed a method for conducting sensitivity tests for survival analysis⁽⁸¹⁾.

Screening for risk factors or early evidence of disease is important for cancer prevention. The distribution of the preclinical duration of cancer is unobservable, but knowledge of this distribution would be of great help in many situations. For example, such knowledge can help in making recommendations about optimal cancer-screening frequencies. We have developed a non-parametric method to estimate the preclinical duration distribution using data from a randomized early cancer detection trial⁽⁸²⁾. This estimation method is expected to have good practical use.

An important aspect of modern cancer research is the identification of molecular and genetic markers that predict an individual's cancer risk and future response to a treatment and the validation of these identified markers. We have provided a method to use in building and validating a prognostic index for biomarker studies⁽⁸³⁾. This method is especially useful when there are many markers under consideration, which is currently true of typical biomarker trials because of the use of high-throughput arrays and other modern biomedical technologies.

The statistical analyses we have conducted for numerous biomarker studies are crucial for the translation of laboratory research results into clinical innovations, with a frequent goal of replacing toxic chemotherapies with safe and effective targeted therapies. A good example of targeted therapy is the use of tyrosine kinase inhibitors (TKIs, such as imatinib) to successfully control chronic myeloid leukemia (CML). Working with the Department of Leukemia, we found that CCL3 (MIP-1a) plasma levels were associated with the risk of disease progression in chronic lymphocytic leukemia (CLL)⁽⁸⁴⁾. Then, we helped design a phase I/II study to determine the effects of an Syk-JAK

inhibitor on this biomarker. We also found that DNA methylation predicted survival and response to therapy in patients with MDS⁽²⁸⁾. Another finding was that the gene that produces the protein survivin was highly expressed in leukemic stem cells and predicted poor clinical outcomes in AML⁽⁸⁵⁾. These are examples of the biomarker discoveries to which we have contributed⁽⁸⁶⁻⁹⁴⁾.

STATISTICAL PREDICTION

Another important branch of statistics is prediction. We developed a new method for estimating the future prevalence of a particular type of cancer when it is brought under therapeutic control⁽⁹⁵⁾. This was motivated by the success of TKIs therapy, introduced around the year 2001. Since then, the all-cause annual mortality rate for CML has been reduced to 2%. More people are surviving with CML; therefore, the prevalence of CML is increasing over time.

Estimating CML prevalence in the coming years and its plateau prevalence is important for the implementation of health-care strategies and future therapeutic trials. The Department of Leukemia at MD Anderson raised this question and provided a data set of all patients with CML who have been treated at MD Anderson since 2001. With about 10 years of data, we needed to estimate the prevalence in the next 20 to 40 years. Considering the short time span covered by the data and the long time span of the prediction, this was a difficult task. Different projection methods will yield dramatically different results. To solve this problem, we first realized that using only the CML data set was not sufficient. We needed other data sources, such as the life tables of the general US population provided by the census. Our analysis integrated many factors and indicated that the prevalence of CML will continue to increase for about 40 years before reaching a near-plateau prevalence of 35 times the current annual incidence. The report of this study was published in *Cancer*⁽⁹⁵⁾. Details of this prediction are given next.

We made various attempts to conduct sensible predictions. Our first idea was to use parametric models to extrapolate to a future time. That is, we fit the 10 years (from 2001 to 2010) of survival data of patients with CML who received imatinib by using a Weibull model and then extended the model beyond 10 years. Unfortunately, this approach did not give sensible prediction results. One indication of a nonsensible prediction was that although the model fit the 10-year data well, its prediction result showed that patients with CML will have better life expectancies than the normal population of the same age mixture. We then recognized that this unrealistic outcome was not surprising because, no matter how well a parametric model fits

the first 10 years of data, there is no rationale for how it would extend beyond 10 years.

Although our attempts to use parametric models failed, they provided us with important information. That is, we needed to use the life tables of the normal population to set a boundary for the survival of patients with CML. The annual all-cause mortality rate of patients with CML treated with imatinib is about 1% to 2% in the first 8 to 10 years of follow-up⁽⁹⁵⁾. This estimate is based on a patient population that has a median age of 40 to 50 years. However, as patients age, the all-cause mortality rate is anticipated to increase. Because the follow-up time for patients with CML who were treated with imatinib is only 10 years, an extrapolation is necessary for the prediction of survival beyond 10 years. We therefore compared the mortality rates of 415 patients with newly diagnosed CML who were referred to MD Anderson from 2001 to 2010 with that of the general population with the same age distribution. We used a Cox proportional hazards model to estimate the hazard ratio between these two populations. Our calculation of the hazard ratio of patients with CML (in their first 10 years since the diagnosis of CML) versus the general population with the same age distribution was 1.53. We then assumed that this trend will remain the same for the rest of the lifetimes of these two populations. Based on the hazard rates of a general population by age group, we extrapolated the mortality rates for patients with CML for all the years after their diagnosis. This approach allowed us to obtain predictions that are in a reasonable range, in contrast to our previous attempts with parametric models that yielded predictions that were totally out of range. Exploring prediction methods and comparing them to determine the best approaches for different scenarios is an interesting topic of research.

Another important prediction task is to use a patient's biomarker history to predict future disease relapse and survival time. After a cancer patient receives treatment, during each follow-up visit, new measurements are taken for many disease-related biomarkers. It would be appealing to update the patient's prognosis in a real-time fashion based on both the historical and current biomarker measurements for that individual. This task is called dynamic prediction. Landmark analysis is a tool commonly used for such a task. However, it requires a data set with a large number of patients who have biomarker measurements taken at the same time (measured from the beginning of each patient's treatment). That is, for example, it requires patients in the data set to have follow-up visits and the appropriate measurements made on a precise posttreatment schedule, such as at exactly 3-month intervals. However, this level of follow-up precision is rarely possible. All types of conflicts and constraints commonly result in patient follow-up times that are scattered

throughout the time between 3 and 6 months, 6 and 9 months, and so on. Another popular statistical tool, the Cox proportional hazard model, can be applied with biomarker measurements taken during follow-up visits as time-dependent covariates. However, this model also needs to impute biomarker values during its parameter estimation, so we face the same difficulty in its application.

To make better use of such biomarker data collected from somewhat irregular follow-up visits, we designed a new method for dynamic prediction. The idea is to start the model on the basis of a simple case and then allow it to evolve to handle complex situations. First, if we ignore all the patient characteristics and biomarker data, we may simply use the Kaplan-Meier estimator $S(t)$ to perform predictions. At any follow-up visit time u , the chance a patient will survive an additional v years is $S(u+v)/S(u)$. Then, if we would like to conduct this prediction for different subgroups of patients, such as groups defined by gender, race, disease subtypes, or other information that is available at the time of diagnosis, we may use a Cox proportional hazards model with these factors as (time-independent) covariates. This will give each patient number k an individual survival function of $S_k(t)$. Similarly, at any follow-up visit time u , the chance this patient will survive an additional v years is $S_k(u+v)/S_k(u)$. This should yield a more accurate prediction than the first method given by $S(u+v)/S(u)$.

Next, we consider using each patient's historical and current biomarkers to make the prediction even more accurate. To do this, we first need to find out what kind of summary statistics have good predictive power, such as current biomarker values or changing slopes of biomarkers. We denote these summary statistics at time t for patient number k by $Z_k(t)$. Then, we postulate a model on the patient's future survival, conditional on the patient being alive at time u , which assumes that the patient's probability of surviving at least v additional years is $\{S_k(u+v)/S_k(u)\}$ being raised to the power of $\exp\{\beta(u)' Z_k(u)\}$. We use time-varying effects $\beta(u)$, which may be specified as a fractional polynomial or cubic spline function. The only parameters we need to estimate here are those in $\beta(u)$ since $S_k(u+v)/S_k(u)$ has already been estimated from the model. This eliminates the requirement to obtain biomarker measurements from all the patients at the same time and makes the computation easy to implement.

Fungal and Viral Infections in Cancer Patients

Bruno P. Granwehr
Roy F. Chemaly
Dimitrios P. Kontoyiannis

INTRODUCTION

Fungal and viral infections remain a significant cause of morbidity and mortality in patients with cancer. Modern management of infections in cancer requires knowledge of the epidemiology, pathogenesis, treatment, and prevention of such infections. Fungal infections range from nosocomial infections with *Candida* spp to endemic fungi acquired outside the hospital, such as *Histoplasma capsulatum*. Opportunistic fungi, especially molds, have emerged as a leading cause of death in patients with leukemia or hematopoietic stem cell transplant (HSCT) (¹). Viral infections such as varicella zoster virus (VZV), herpes simplex virus (HSV), or cytomegalovirus (CMV), have been associated with increased morbidity and mortality in patients with cancer, including patients with multiple myeloma or chronic lymphocytic leukemia (CLL), and in HSCT recipients (²⁻⁵). Respiratory viruses, such as respiratory syncytial (RSV), adenovirus, and influenza, are increasingly recognized as significant pathogens in patients with cancer, particularly as molecular diagnostic methods improve. In addition, viruses such as novel influenza H1N1, West Nile virus, bocaviruses, and noroviruses have emerged as newly recognized pathogens in patients with cancer.

FUNGAL INFECTIONS

Fungal infections pose a continuing challenge for oncology patients. Exposure to fungi is common,

with exposure typically occurring in the environment. Patients with cancer are susceptible not only to new infection with endemic fungi (such as *Histoplasma capsulatum*), but also to reactivation of latent infections. Opportunistic molds, such as *Fusarium* spp, *Scedosporium* spp, and Zygomycetes cause devastating disease in hematologic patients. Cases of nosocomial infection due to molds are reported in the setting of hospital construction, leading to routine air sampling and filtration. In contrast, *Candida* spp are a common component of the patient's or health-care workers' endogenous microbial flora. Manifestations of infection may not present until the patient receives chemotherapy or undergoes HSCT.

Diagnosis of invasive fungal infections is problematic as well, despite increased use of fungal biomarkers (⁶). The skin and lungs are accessible areas for examination and biopsy as they are commonly affected by fungal pathogens. In our institution, a retrospective study of skin biopsies in patients with leukemia suggested that ulcerated or necrotic skin lesions in the context of bacteremia or fungemia were predictive of infection (⁷). Of note, skin biopsy revealed infection in 39% of all patients undergoing biopsy and 55% of those with severe neutropenia (⁷). Of patients with biopsy-proven skin infection, 39% of those infections were fungal, led by *Candida* species (25%), *Fusarium* (19%), *Mucorales* (13%), *Aspergillus* species (9%), *Alternaria* (6%), and *Curvularia* (3%) (⁷).

In the setting of pulmonary nodules, lung biopsy, utilizing open biopsy or computed tomographic (CT)-guided percutaneous biopsy, has also proven useful in

diagnosis. Studies of CT-guided biopsy show a yield of approximately 60% for a specific diagnosis⁽⁸⁾. In a study at our center of patients with hematologic malignancy, 34% of the specific diagnoses with CT-guided biopsy were previously unidentified infection, predominantly fungal⁽⁹⁾. A recent retrospective study of open lung biopsy revealed 19% previously undiagnosed infectious etiologies⁽⁸⁾. Identified organisms included 58% endemic molds (*Histoplasma*, *Coccidioides*), 14% *Aspergillus* species, and 7% *Cryptococcus* species⁽⁹⁾.

Despite these efforts, diagnosis is often a challenge if infection is more diffuse or thrombocytopenia is too severe to safely permit biopsy. Autopsy, unfortunately after all diagnostic and treatment efforts failed, has historically been an approach to ultimate diagnosis of etiology, but autopsy rates have fallen almost 90% from 0.63/100 deaths in 1989 to 1993 to 0.06/100 deaths in 2004 to 2008 at our institution⁽¹⁰⁾. Diagnosis of fungal infections, often manifesting as pulmonary nodules or skin lesions, is challenging, but important, given the modification of therapy that may occur based on identification of a particular species of fungus or discovery of coinfection, malignancy, or other alternative diagnosis. **Figure 51-1** suggests an approach to identification of fungal (and other) pulmonary pathogens at our institution.

Risk Factors

Severe neutropenia, particularly prolonged, has long been associated with invasive fungal infections. Chemotherapy

resulting in prolonged and severe CD4 lymphocytopenia can also result in infections similar to those seen in patients with untreated human immunodeficiency virus (HIV) or AIDS, such as cryptococcosis and reactivation of endemic fungi, including histoplasmosis and coccidiomycosis. In addition, conditioning regimens for stem cell transplant and immunosuppressives to treat or prevent graft-versus-host disease (GVHD) result in deficient cell-mediated immunity, increasing risk for invasive fungal infection^(4,10). Disruption of mucocutaneous barriers predisposes to invasive candidal infection, exemplified by catheter-related bloodstream infections caused by *Candida* spp⁽¹¹⁾.

A recent study from Italy utilized a retrospective cohort of patients with hematologic malignancy to develop a risk prediction score for invasive fungal infections⁽⁴⁾. The score emphasizes the central roles played by lymphopenia, relapsed or refractory malignancy, prolonged neutropenia (>10 days), and prior history of invasive fungal infection in identifying patients at highest risk of invasive fungal infection. Of interest, the authors found that posaconazole prophylaxis was exclusively beneficial to the group with highest risk of invasive fungal infection⁽⁴⁾.

Finally, another aspect of importance is the change in flora that takes place with broad-spectrum antibacterial and antifungal therapy. The latter may result in suppression of normal bacterial flora and candidal overgrowth in the oropharynx and gastrointestinal (GI) tract. Antifungal therapy or prophylaxis may result in

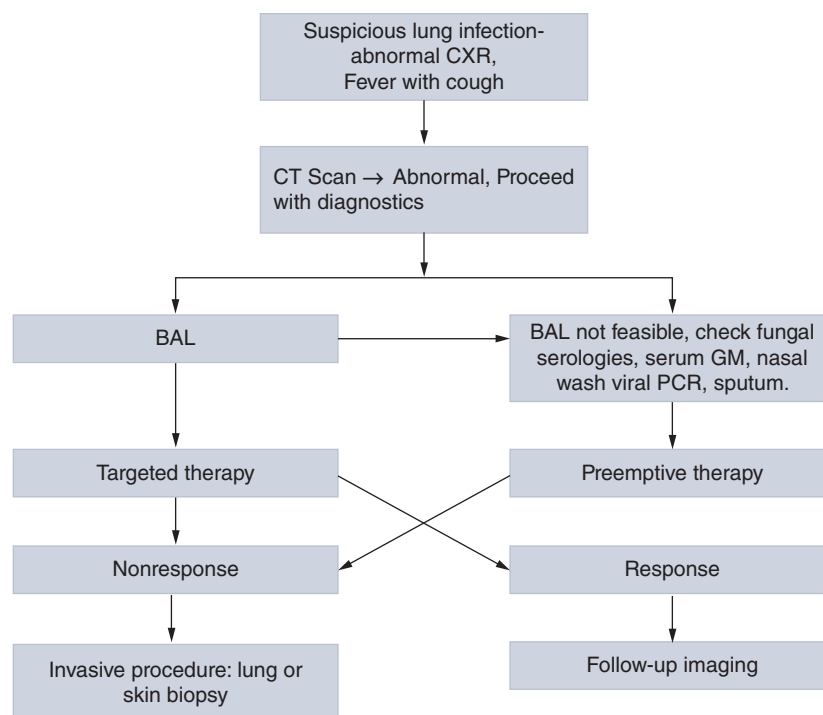

FIGURE 51-1 Evaluation of suspicion of lung infection. CXR, chest x-ray; PCR, polymerase chain reaction.; BAL, bronchoalveolar lavage; GM, galactomannan.

breakthrough infection with non-*Candida albicans* species, such as *Candida krusei* (resistant to fluconazole) ⁽¹¹⁾. Aside from non-*Candida albicans* species, prophylaxis with non-mold active antifungals (eg, fluconazole) may predispose to infection with molds, such as aspergillosis.

CANDIDIASIS

Candidiasis remains the most common invasive fungal infection in patients with cancer. Modern medical care is increasingly complex, involving frequent antimicrobial use and device utilization that alter patient flora and disrupt the mucocutaneous barrier. *Candida* spp commonly arise from the patient's endogenous flora, but rare hospital-acquired cases have been reported due to contaminated equipment, solutions, and hospital personnel. Manifestations of candidiasis range from local infection of the skin or oral mucosa to candidemia and widely disseminated infection.

Superficial Candidiasis

Oral Infection

Thrush is the most common superficial candidal infection among patients with cancer, typically those with cancers involving the head and neck undergoing chemoradiation ⁽¹²⁾. Oropharyngeal candidiasis is characterized by whitish plaques on the buccal mucosa, palate, or tongue (Fig. 51-2) that may be painful if removed, exposing the erythematous base. Oral thrush may also be a manifestation of esophagitis ⁽¹²⁾.

FIGURE 51-2 Typical appearance of oropharyngeal candidiasis on palatal and buccal mucosa.

The diagnosis is commonly made clinically but is confirmed by finding yeast and pseudohyphae on scraping or culture.

Esophagitis

Esophageal candidiasis may cause dysphagia, retrosternal pain, and odynophagia in patients with cancer ⁽¹³⁾. Serious complications of this infection can occur, including chronic esophageal strictures, bronchoesophageal fistulas, and mediastinitis. Esophagoscopy with biopsy and culture are necessary to confirm the diagnosis of candidal esophagitis ⁽¹¹⁾. Unfortunately, thrombocytopenia often makes esophagoscopy challenging, so empiric therapy is often used. Esophageal candidiasis requires systemic therapy, typically utilizing fluconazole as initial therapy ⁽¹¹⁾. Caspofungin or other echinocandins may be used if fluconazole fails or is not well tolerated, but it is available only as an intravenous preparation ⁽¹¹⁾. Itraconazole, voriconazole, posaconazole, or amphotericin B formulations are rarely indicated for these infections ⁽¹¹⁾.

Urinary Tract Infection

Patients with cancer, as with many other hospitalized patients, may develop primary infections of the urinary tract in the settings of urinary obstruction and particularly urinary catheters. Differentiating between colonization and infection is challenging in the presence of urinary catheters. Urinalysis may be normal, and high organism counts are not sufficient to confirm infection. In febrile neutropenic patients, candiduria should be considered as a harbinger of disseminated candidiasis. Recent guidelines recommend treatment with fluconazole, with amphotericin B formulations used for resistant *Candida* spp ⁽¹¹⁾. Of note, echinocandins fail to penetrate the urinary tract, so they should not be used in this setting. Relapse of infection, however, will be likely unless the urinary catheter is removed.

Candidemia

Neutropenia, presence of colonization of oropharynx and other sites, steroid use, presence of central venous catheters, and persistent fever in the setting of broad-spectrum antibacterial therapy suggest the diagnosis of candidemia ⁽¹⁴⁾. A study from a multicenter database demonstrated that *C. albicans* now represents a minority of candidemia infections (45.6%) ⁽¹⁵⁾. In that study, candidemia resulted in an overall 12-week crude mortality of 35.2%, with highest mortality rate associated with *C. krusei* (52.9%) and lowest with *Candida parapsilosis* (23.7%) ⁽¹⁵⁾. *Candida parapsilosis* candidemia has been associated with central venous catheters ⁽¹⁵⁾.

Patients with *C. parapsilosis*, including nononcology patients from a multicenter database, were less likely to be neutropenic and immunosuppressed, perhaps explaining the lower mortality rate ⁽¹⁵⁾. *Candida krusei* has been associated with prior antifungal use, hematologic malignancy (including stem cell transplant), neutropenia, and steroid use. These host factors associated with infection suggest why *C. krusei* exhibits the highest mortality rate of species causing candidemia (52.9%) ⁽¹⁵⁾.

Disseminated Candidiasis

Disseminated candidiasis is difficult to differentiate from other disseminated fungal and bacterial infections. Persistent fever in the setting of antibacterial therapy and liver dysfunction may suggest consideration of disseminated candidiasis ⁽¹⁵⁾. In patients with cancer, disseminated candidiasis typically originates from the GI tract or central venous catheters. Dissemination affects multiple organs, such as the kidneys, heart, GI tract, lung, liver, spleen, and skin ⁽¹⁶⁾. *Candida tropicalis* is more likely to cause the characteristic skin lesions associated with disseminated candidiasis and occasionally causes a syndrome of skin lesions and painful myositis ⁽¹⁷⁾. Lesions may appear as clusters of pustules or larger nodules and may even develop necrotic centers similar to ecthyma gangrenosum ⁽¹⁸⁾. Common presentation is nontender, firm, nonblanching, raised nodules that are pink to red in color (Fig. 51-3).

Diagnosis

The diagnosis of disseminated candidiasis may be difficult to establish because culture of the organism from sputum, urine, and feces may be positive in patients without infection. On the other hand, 40% of patients with widespread infection demonstrated at autopsy

FIGURE 51-3 Widespread nodular skin lesions in a patient with disseminated candidiasis.

examination had multiple negative blood cultures ⁽¹⁶⁾. Given the challenge of appropriate diagnosis and morbidity associated with failure to treat the severely immunocompromised, empiric therapy is commonly given for those who continue to be ill in the setting of broad-spectrum antibacterial therapy.

Therapy

Therapy for candidiasis includes three classes of medications: azoles (eg, voriconazole), echinocandins (eg, caspofungin), and the polyenes (eg, amphotericin B). Dosing regimens, major toxicities, and general considerations for antifungal agents are shown in Tables 51-1 through 51-3, respectively. Timely appropriate therapy is necessary because the mortality rate for candidemia ranges from 24% for candidemia caused by *C. parapsilosis* to as high as 53% for *C. krusei* ⁽¹⁵⁾. *Candida glabrata* exhibits decreased susceptibility to fluconazole ⁽¹⁴⁾. Mortality, however, is not significantly different from *C. albicans* candidemia ⁽¹⁴⁾. *Candida krusei*, inherently resistant to fluconazole, is increasingly isolated in institutions where fluconazole is commonly used for prophylaxis ⁽¹⁹⁾. *Candida lusitanae*, more commonly seen in patients with stem cell transplant or neutropenia, is of concern due to amphotericin B resistance ⁽²⁰⁾.

Recently published guidelines suggest that echinocandins be utilized as first-line therapy in neutropenic patients with candidemia, with lipid formulations of amphotericin B as second-line therapy ⁽¹¹⁾. Species-specific recommendations, however, are provided, given inherent differences in resistance. The guidelines emphasize that if a therapeutic approach is resulting in clinical improvement, then current therapy can be continued. For *C. glabrata*, an echinocandin or lipid formulation of amphotericin B is recommended ⁽¹¹⁾. For infection with *C. parapsilosis*, an azole or lipid formulation of amphotericin B is recommended. For *C. krusei*, fluconazole is contraindicated due to innate resistance ⁽¹¹⁾. For neutropenic patients with invasive candidiasis (but not candidemia), lipid formulations of amphotericin B, echinocandins, or voriconazole are recommended ⁽¹¹⁾. In candidemia and invasive candidiasis, fluconazole may be used in patients who have no prior exposure to azoles and are not critically ill ⁽¹¹⁾. If fluconazole is used, the initial recommended dose is 12 mg/kg/d. The guidelines recommend the use of lipid formulations of amphotericin B, rather than amphotericin B deoxycholate (D-AMB), to avoid nephrotoxicity ⁽¹¹⁾.

Caspofungin was the first echinocandin approved by the Food and Drug Administration (FDA), showing broad-spectrum activity against *Candida* spp. In comparison to D-AMB in a study of invasive candidiasis (80% of which was candidemia), caspofungin showed similar outcomes with fewer adverse events ⁽¹¹⁾. Of note, however, few patients were neutropenic in

Table 51-1 Dosage Regimens for Serious Fungal Infections

Drug	Loading Dose	Daily Dose	Route
D-AMB	—	1-1.5 mg/kg	IV only
Lipid AMB	—	3-5 mg/kg	IV only
Fluconazole	800 mg	400-800 mg	IV, Oral
Itraconazole IV	200 mg bid × 2 days	200 mg	IV
Itraconazole solution	200 mg bid × 2 days	200 mg	Oral
Posaconazole tabs	300 mg bid × 2 doses	300 mg	Oral
Posaconazole IV	300 mg bid × 2 doses	300 mg	IV
Posaconazole (susp)	—	200 mg every 6h	Oral
Voriconazole IV	6 mg/kg every 12 h × 2 doses	4 mg/kg every 12 h	IV
Voriconazole tabs	—	200 mg every 12 h (>40 kg)	Oral
		100 mg every 12 h (<40 kg)	
Caspofungin	70 mg × 1 dose	50 mg	IV
Micafungin	—	150 mg	IV
Anidulafungin	200 mg × 1 dose	100 mg	IV

D-AMB, amphotericin B deoxycholate; IV, intravenous; susp, suspension; tabs, tablets.

this study. The three currently available echinocandins (caspofungin, micafungin, and anidulafungin) are comparable in their efficacies, although only one study in patients with nononcologic candidemia directly compared micafungin and caspofungin and showed equivalent outcomes ⁽²¹⁾.

The management of catheter-related bloodstream infections is controversial. Debate exists with respect to need for catheter removal. Patients with indwelling

intravascular catheters typically require them for chemotherapy or supportive care. The removal of surgically implanted catheters is particularly difficult, given thrombocytopenia is often present in this patient population and also the high costs of placement. Studies suggest a role for catheter removal, particularly if it is clear that the catheter is the source or in the setting of persistent candidemia without another source. Removal of the catheter may improve response rates and reduce duration of candidemia ⁽¹¹⁾. Infection with *C. parapsilosis*, in particular, is associated with persistent candidemia without catheter removal ⁽¹¹⁾.

In brief, *Candida* causes a wide spectrum of syndromes, from superficial oral candidiasis to candidemia, in patients with cancer. The therapeutic approach should take into consideration host risk factors, medication interactions, antifungal toxicities, and comorbidities when selecting a particular agent.

Table 51-2 Major Toxicities of Antifungal Agents

Amphotericin B	Infusion related (headache, chills, hypotension, etc); nephrotoxicity; hypokalemia, hypomagnesemia; anemia
Fluconazole	Nausea, vomiting; headache; hepatotoxicity (rare); drug interactions
Itraconazole	Nausea, vomiting; headache; hepatotoxicity (rare); pulmonary edema; drug interactions
Posaconazole	Hepatotoxicity (rarely requires discontinuation)
Voriconazole	Visual disturbances; rash; nausea, vomiting; headache; hepatotoxicity; drug interactions
Echinocandins (eg, caspofungin)	Fever; nausea; flushing; rash; some drug interactions; phlebitis

ASPERGILLOSIS

One of the most common and important invasive fungal infections is aspergillosis. *Aspergillus* spp are the most common invasive mold infections in patients with hematologic cancer ⁽²²⁾. *Aspergillus fumigatus* is the species most commonly associated with infection, although *Aspergillus terreus* and *Aspergillus flavus*, more resistant *Aspergillus* spp, are becoming increasingly common ⁽²²⁾. Infections are typically acquired by spore inhalation, but construction in hospitals and surrounding areas have been associated with infection ⁽²³⁾. The most

Table 51-3 Therapeutic Options for Disseminated and Major Organ Candidiasis

Regimen	Advantages	Disadvantages
Amphotericin B deoxycholate (D-AMB)	Broad-spectrum activity.	Acute chronic toxicities; minimally effective in patients with neutropenia and with chronic disseminated candidiasis; Intravenous preparations only.
Lipid formulations of AMB	Broad-spectrum activity, reduced nephrotoxicity. Higher doses can be administered.	Only prospective randomized trial showed no advantage in efficacy over D-AMB despite higher doses. More expensive. Intravenous preparations only.
Fluconazole	Oral and intravenous preparation. As effective as AMB in randomized trials of nonneutropenic individuals. Minimal toxicity. More effective for chronic disseminated candidiasis. Little experience in neutropenic patients but appears to be as effective as AMB.	Variable activity against <i>C. glabrata</i> and <i>C. dubliniensis</i> ; inactive against <i>C. krusei</i> . Some drug-drug interactions.
Echinocandins (eg, caspofungin)	Broad-spectrum activity. Minimal toxicity. In randomized trials, as active as amphotericin B and fluconazole. Limited experience in neutropenic patients.	No oral preparation.
Flucytosine	Synergistic with AMB and fluconazole. Combination of flucytosine and AMB may be superior to AMB alone for chronic disseminated candidiasis and <i>C. tropicalis</i> infection.	No intravenous preparation. Causes myelosuppression. Often need monitoring of serum concentrations. Emergence of resistance if used alone.

important risk factor is prolonged neutropenia (22). In patients with stem cell transplants, reported risk factors for increased mortality include poor baseline pulmonary status, high doses of steroids (≥ 2 mg/kg/d), disseminated aspergillosis, proved invasive aspergillosis, increased bilirubin, increased creatinine, HLA-mismatched stem cells, and invasive aspergillosis occurring 40 or more days after transplant (24). A recent retrospective study suggested that elevated serum galactomannan index (GMI), but not bronchoalveolar lavage GMI, is associated with increased mortality (25).

Pulmonary Infection

The most common syndrome associated with aspergillosis is pneumonia. Due to the angioinvasive nature of the infection, symptoms suggesting pulmonary involvement (eg, pulmonary embolism, pleuritic chest pain, fever, hemoptysis, and friction rub) are occasionally encountered (26). Initial chest x-ray may be unremarkable, with fever proceeding in the setting of broad-spectrum antibacterials (26). Radiologic findings are variable, with wedge-shaped infarcts, necrotizing bronchopneumonia, lobar consolidation, or diffuse infiltrates noted (26). If suspicion is high for infection, early CT scan of the thorax is

essential, potentially demonstrating a halo sign (area of low attenuation surrounding a nodular infiltrate), an important early sign that disappears in 75% of cases within the first week (26) (Fig. 51-4). Analysis of radiologic studies from a clinical trial suggested that patients with the halo sign had an improved response to treatment and also improved mortality compared to those

FIGURE 51-4 Computed tomographic scan showing nodular lesions in lung of patient on high-dose adrenal corticosteroid therapy who developed sudden onset of pleuritic chest pain and a pleural friction rub due to pulmonary aspergillosis. The chest roentgenogram was normal.

who did not exhibit the halo sign ⁽²⁷⁾. Cavitation occurs as the infection progresses, with lesions often increasing in size until neutrophil recovery occurs. Differentiation from infection with other molds (ie, mucormycosis) can be difficult. A study suggested that CT of the thorax with greater than 10 nodules and pleural effusion are more often seen in pulmonary mucormycosis rather than invasive pulmonary aspergillosis ⁽²⁷⁾.

Sinusitis

Immunocompromised patients may exhibit acute sinusitis as a component of invasive diseases, occurring in 15% to 20% of neutropenic patients ⁽²⁸⁾. Fever, headache, cough, epistaxis, and sinus discharge are signs and nonspecific symptoms suggestive of fungal sinusitis ⁽²⁸⁾. On exam, necrotic lesions may be seen in the nose or palate (Fig. 51-5), with accurate diagnosis improved by examination and confirmed by biopsy by experienced otolaryngologists ⁽²⁹⁾. Imaging of the sinuses by CT or magnetic resonance imaging scan may show opacification of the sinuses or bony destruction. Mortality may be as high as 20% in patients with leukemia in remission to 100% for those with invasive sinusitis who have refractory leukemia or are undergoing HSCT ⁽²⁸⁾.

Skin Infection

Aspergillosis as part of dissemination is discussed in the next section, although primary cutaneous infection occurs with direct inoculation. These infections are rarely associated with a central venous access device ⁽³⁰⁾. The mechanism of spread is presumed to be via inoculation during catheter insertion or possibly dressing changes or application. Initially, lesions may appear as erythematous plaques, progressing to necrotic ulcers with black eschars ⁽³⁰⁾. *Aspergillus flavus* is the most common cause of cutaneous invasive aspergillosis.

FIGURE 51-5 Black eschar on bridge of the nose in a patient with *Aspergillus* sinusitis.

Disseminated Infection

Given the angioinvasive nature of aspergillosis, hematogenous dissemination occurs in approximately 20% of patients with active hematologic malignancy or HSCT ⁽³¹⁾. Common sites of dissemination include the central nervous system (CNS), GI tract, and skin. Gastrointestinal involvement is apparent in 40% to 50% of cases, affecting the esophagus and large bowel ⁽³²⁾. Perforation or massive hemorrhage may occur in this setting. Skin infection may also occur, evolving from erythematous plaques to ulcers that ultimately may be covered by black eschar ⁽³³⁾. Given the broad differential diagnosis of skin lesions in this patient population, skin biopsy is critical.

Diagnosis

A continuing challenge in management of aspergillosis is early and reliable diagnosis ⁽²⁶⁾. Tissue biopsies from infected tissue may reveal invading hyphae. Paradoxically, cultures of the biopsy specimens fail to grow the fungus in over 50% of cases, although histology and pathology correlate with culture in 78% of those cases ⁽³⁴⁾. Similarly, blood cultures will rarely (except in the case of *A. terreus*) demonstrate the organism, in contrast to fusariosis ⁽³⁵⁾. Unfortunately, *Aspergillus* spp fail to grow well from sputum or bronchoscopy, with only 30% of biopsy-proven aspergillosis cases growing mold in sputum cultures ⁽³⁶⁾. Due to these challenges of diagnosis, patients commonly receive empiric antifungal therapy while undergoing workup.

To increase the likelihood of detection of aspergillosis, various non-culture-based tests have been developed. Available tests detect circulating antigens or immune complexes. Galactomannan and 1,3- β -D-glucan are the most commonly used tests. Via a sandwich enzyme-linked immunosorbent assay used to detect the polysaccharide cell wall component of *Aspergillus* spp, galactomannan can be detected in the serum, and more recently bronchoalveolar lavage fluid, of infected patients ⁽²⁶⁾. Sensitivity ranges from 67% to 100% and specificity from 86% to 99%, but the test has been studied primarily in patients with hematologic malignancy with profound neutropenia. The positive predictive value of this test is poor in patients with solid tumor and other cancer ⁽²⁶⁾. An additional challenge occurs in interpreting a galactomannan in the context of prophylaxis with antimold activity. A recent study suggested up to 86% false-positive results for those on active antimold therapy ⁽³⁷⁾.

1,3- β -D-Glucan is an integral component of the cell wall of several yeasts and fungi ⁽²⁶⁾. Sensitivity ranges from 67% to 100% and specificity 84% to 100%, but false positives are noted due to cirrhosis, hemodialysis, and some chemotherapeutic agents ⁽²⁶⁾.

Therapy

Early diagnosis of aspergillosis utilizing the various available tools has allowed for earlier treatment, but challenges continue in assessing the impact of various treatments, given categorization of infection as proven, probable, or possible ⁽²⁹⁾. Table 51-4 describes various principles for management of aspergillosis. Persistence of neutropenia is a host factor that is critical in determining the outcome of infection, regardless of therapy. In fact, in a study of patients with acute myeloid leukemia (AML), mortality was 90% in those patients who failed to recover from neutropenia ⁽³⁸⁾.

Voriconazole is currently recommended as first-line therapy of invasive pulmonary aspergillosis ⁽²⁸⁾. A randomized trial comparing voriconazole to D-AMB for patients with definite or probable aspergillosis showed decreased mortality in the voriconazole group (71% vs 58%). Both oral and intravenous formulations are available, with decreased nephrotoxicity compared to amphotericin B. Voriconazole does, however, cause visual disturbances, hallucinations, and liver dysfunction in a subset of patients.

Posaconazole, the newest FDA-approved azole, was previously only available as an oral solution. Posaconazole tablets are now available, with considerably improved absorption, with minimal impact from food, mucositis, or elevated gastric pH ⁽³⁹⁾. Despite resultant elevated liver function tests due to dramatically increased posaconazole levels in tablet form, no clinically significant hepatotoxicity occurred ⁽³⁹⁾. Posaconazole was associated with increased response to therapy and decreased mortality compared to Liposomal Amphotericin B (L-AMB) with or without caspofungin ⁽⁴⁰⁾. In addition, nephrotoxicity and change in liver function tests were more likely in the L-AMB-containing regimens.

Lipid formulations of amphotericin B are now recommended in lieu of D-AMB, given the decreased risk of nephrotoxicity. In a randomized study of early treatment of aspergillosis in neutropenic patients, doses of 10 mg/kg/d were compared with 3 mg/kg/d with

comparable outcomes (46% high dose vs 50% low dose), but the higher dose resulted in greater nephrotoxicity (32% vs 20%) ⁽²⁸⁾.

Echinocandins inhibit the synthesis of β -(1,3)-D-glucan, an essential component of the fungal cell wall. A disadvantage of echinocandins is that they are available only as an intravenous preparation ⁽²⁸⁾. In a noncomparative trial of 90 patients with definite or probable aspergillosis who had failed other therapy, a complete or partial response occurred in 45% ⁽⁴¹⁾. Responses were observed in 50% of patients with pulmonary infection but in only 26% of those with neutropenia ⁽⁴¹⁾.

Treatment of Invasive Aspergillosis (IA) is challenging, particularly in the setting of prolonged neutropenia. This has led to the use of combination therapy. In a recent randomized, placebo-controlled trial of HSCT and patients with hematologic malignancy, voriconazole combined with placebo or anidulafungin failed to demonstrate a difference in overall or 6-week mortality ⁽⁴²⁾. In a subgroup with radiographic findings consistent with IA and elevated serum galactomannan, the mortality was significantly higher in the monotherapy group (15.7% vs 27.3%, $P = .037$) ⁽⁴²⁾.

Antifungal agents utilized for prophylaxis against aspergillosis in high-risk patients have included posaconazole, itraconazole, voriconazole, aerosolized or nebulized formulations of amphotericin B, and micafungin ^(22, 28). Posaconazole is the only agent currently FDA approved for the indication of prevention of invasive aspergillosis in patients with acute leukemia and high-risk stem cell transplant recipients, but significant expense continues to limit the utility of this agent ⁽⁴¹⁾.

CRYPTOCOCCOSIS

Cryptococci are encapsulated yeasts that have a worldwide distribution, with a dramatic increase in incidence corresponding with the advent of HIV/AIDS ⁽⁴³⁾. *Cryptococcus neoformans* is the most common pathogen, found in pigeon excretions, with infection acquired by inhalation into the lungs. Patients with HIV/AIDS had the highest incidence of infection prior to the initiation of highly active antiretroviral therapy ⁽⁴³⁾. Factors associated with cryptococcosis in patients with cancer include lymphopenia, chemotherapy, and steroid use less than 1 month prior to diagnosis ⁽⁴⁴⁾. Those at particular risk include those with lymphoma or CLL. Risk in patients with hematologic malignancy is low because of widespread use of fluconazole and other agents for antifungal prophylaxis.

Pneumonia

Given inhalation as the mechanism of entry, the lung typically serves as the primary site of infection. Despite

Table 51-4 Principles of Therapy for Aspergillosis

Early, aggressive treatment with high doses of voriconazole or a lipid formulation of amphotericin B deoxycholate (D-AMB)
Rapid tapering of dose of adrenal corticosteroids if possible
Consideration for G-CSF-primed granulocyte transfusions in select cases
Long-term antifungal therapy, which should be individualized based on response
Debridement of necrotic tissue of localized disease (onchomycosis, sinusitis, abscess)

this fact, less than 40% of patients present with symptoms suggestive of pneumonia ⁽⁴³⁾. Symptoms may, however, include chest pain, fever, or dyspnea. Chest radiographic findings may include single or multiple nodules, airspace consolidation, reticular patterns, ground-glass opacities, cavitary lesions, and occasionally pleural effusions, with all findings unilateral or bilateral ⁽⁴³⁾. Cryptococcal pneumonia can rapidly progress, resulting in higher mortality in patients with cancer. For susceptible patients, finding of this organism in a patient with chest radiography and symptoms consistent with infection is sufficient indication for therapy. In a series from a cancer center, fine-needle aspiration, bronchoalveolar lavage, and open lung biopsy had a yield of over 90% on culture ⁽⁴⁴⁾.

Central Nervous System Infection

Many series showed a predominance of CNS infection in patients with cancer, primarily with meningoencephalitis, but rarely with meningitis alone or with cryptococcoma. Depending on degree of immunosuppression, patients may exhibit an indolent course, with initial symptoms of fever and headache ⁽⁴³⁾. As the disease progresses, symptoms may include nausea, vomiting, dizziness, somnolence, irritability, confusion, photophobia, or obtundation. Absence of nuchal rigidity (a finding exhibited in only 15% of patients) does not rule out infection ⁽⁴³⁾. Patients infected with *Cryptococcus gatti* can include those with no apparent immunosuppression but with high predilection for CNS involvement ⁽⁴³⁾. In patients with CNS disease, findings include elevated opening pressure, decreased glucose, and high protein concentration. Leukocyte count may also be elevated, with lymphocyte predominance ⁽⁴⁴⁾. Available diagnostic tests include India ink, serum cryptococcal antigen, and fungal culture. India ink detects 50% of infections, whereas serum cryptococcal antigen is positive in 90% of cerebrospinal fluid (CSF) and 70% of blood in patients with CNS infection.

Disseminated Infection

Multiple organs, including the liver, prostate, eyes, skin, and bone, may serve as sites of dissemination. Serum cryptococcal antigen has greater than 90% sensitivity and specificity for invasive cryptococcal disease ⁽⁴³⁾. Skin lesions, present in only approximately 10% of patients, tend to be painless and located on the face, neck, and scalp ⁽⁴³⁾. The lesions may appear as papules, plaques, ulcerations, acneiform eruptions, lesions, or even draining sinuses. With wide use of antifungal prophylaxis, skin, soft tissue, and osteoarticular lesions appear to be less common ⁽⁴³⁾.

Therapy

Treatment of cryptococcal disease depends largely on site of infection. Combination of D-AMB with flucytosine is the traditional approach of choice for severe pulmonary cryptococcosis and CNS disease in non-HIV-infected immunocompromised patients as induction therapy ⁽⁴³⁾. Flucytosine is available only as an oral preparation with myelosuppressive toxicity (see Tables 51-1 and 51-2). The recommended dose is D-AMB 0.7 to 1.0 mg/kg/d plus flucytosine 100 mg/kg/d for 2 weeks, as induction therapy, consolidation with fluconazole 400 to 800 mg daily for 8 weeks, and then 200 mg daily maintenance therapy for 6 to 12 months ⁽⁴³⁾. In mild-to-moderate cases of pulmonary disease, fluconazole 400 mg daily alone may be given for 6 to 12 months ⁽⁴³⁾. Of note, synergy has been noted between some antifungal agents and calcineurin inhibitors, associated with improved outcomes for solid-organ transplant patients ⁽⁴⁵⁾, potentially of relevance in patients with HSCT although not established.

Management of cryptococcal meningitis requires monitoring of CSF pressure and appropriate measures if elevated pressures are noted to prevent complications and reduce mortality ⁽⁴³⁾. Complications of elevated intracranial pressures (>200 mm H₂O) include papilledema, hearing loss, vision loss, severe headache, and cognitive impairment. Therefore, management is aggressive, including daily lumbar puncture or, if necessary, ventricular shunt placement ⁽⁴³⁾. Timely intervention is necessary to prevent irreversible neurologic complications or death.

FUSARIOSIS

Humans are exposed to various *Fusarium* spp found in the air and soil. Superficial (cutaneous, keratitis, onychomycosis), locally invasive, and disseminated infection syndromes are included. The most common species that causes human disease is *Fusarium solani* (approximately 50% of cases), but others include *F. moniliforme*, *F. oxysporum*, and *F. dimerum* ⁽⁴⁶⁾. Entry points for infection by *Fusarium* spores are typically skin, onychomycosis, and respiratory tract. Risk factors for invasive fusariosis among patients with hematologic malignancy include uncontrolled cancer (71%), stem cell transplant (47%), and neutropenia (82%) ⁽⁴⁶⁾. Mortality was highest in one retrospective study in patients with fungemia, with an abysmal 6% survival at 12 weeks ⁽⁴⁶⁾. All-cause mortality was 66%, but 50% was attributable to fusariosis.

Sinus infection and pneumonia occur in 80% of patients, and blood cultures are positive in 50% to 70% of cases ⁽⁴⁷⁾. In neutropenic patients, dissemination occurs 75% of the time and is characterized by multiple skin lesions ⁽⁴⁸⁾. Skin lesions may appear as

FIGURE 51-6 Skin lesions in a patient with disseminated fusariosis.

red or gray macules, pustules, or classically papules with central necrosis or eschar (Fig. 51-6). Lesions may also appear to be different types of lesions at different stages of evolution⁽⁴⁸⁾. Myalgias or subcutaneous lesions are also noted in disseminated fusariosis. In nonneutropenic patients with less-severe immunocompromise, infection may be relatively localized, with paronychia, erythematous nodules, hemorrhagic bullae, or trauma-associated tender, necrotic lesions⁽⁴⁷⁾.

Therapy

The significance of in vitro susceptibility results is unclear, with conflicting reports of species-specific susceptibility to amphotericin B in some series, whereas others do not demonstrate such an association. Azoles, particularly voriconazole and posaconazole, exhibit variable in vitro activity against different *Fusarium* species⁽⁴⁷⁾. Posaconazole and voriconazole have both been used as salvage therapy after initial monotherapy with high-dose lipid formulations of amphotericin B failed⁽⁴⁷⁾. Combination therapy has been used with anecdotal success, but definitive evidence of effectiveness is lacking. In neutropenic patients, however, neutrophil recovery is the critical component improving outcomes⁽⁴⁶⁾.

MUCORMYCOSIS

Mucormycosis is an infection caused by molds of the order Mucorales present in the environment, acquired by inhalation of spores⁽⁴¹⁾. These molds, similar to *Aspergillus* spp, are angioinvasive, causing thrombosis and infarction. Macrophages and neutrophils are key components of the immune response to mucormycosis. Patients with acute leukemia, diabetic ketoacidosis, or iron overload; HSCT recipients; and those treated

with adrenal corticosteroids⁽⁴¹⁾ may be affected by mucormycosis. Syndromes include rhinocerebral, pulmonary, GI, and cutaneous involvement⁽⁴⁹⁾. Patients with hematologic malignancy tend to have pulmonary or disseminated disease, whereas those with diabetes have predominantly sinus involvement⁽⁵⁰⁾.

Overall mortality is 44%, but patients with cancer with definite or probably mucormycosis have a mortality rate of 71%⁽⁴¹⁾. Patients with neutropenia are more likely to have disseminated disease, which has a mortality over 90%.

Therapy

Amphotericin B, more recently in lipid formulations, has been the most commonly used approach to treatment of mucormycosis^(49, 50). High doses of amphotericin B (5-10 mg/kg/d) can be provided with lipid formulations⁽⁵⁰⁾. Other modalities that have been used include hyperbaric oxygen, iron-chelating agents (deferasirox), surgical intervention, immunomodulatory therapy with granulocyte-macrophage colony-stimulating factor (GM-CSF) or interferon gamma and granulocyte transfusions⁽⁵⁰⁾. The addition of posaconazole typically occurs in transition to oral therapy, but rarely may be used as a frontline agent if there is a contraindication to amphotericin B formulations or relatively mild, localized disease that has been surgically resected⁽⁵⁰⁾. In addition to monotherapy with amphotericin B formulations, various combinations of antifungals, including echinocandins, are given with any or all of the modalities mentioned⁽⁵⁰⁾. A review of the common nonendemic fungi and associated syndromes is provided in Table 51-5.

ENDEMIC FUNGI

The list of common endemic fungi that may infect patients with cancer in North America includes *Coccidioides immitis* and *Histoplasma capsulatum*⁽⁵¹⁾. The distribution of these organisms is determined by climate and geography. These may infect patients without severe immunosuppression and may manifest as lung lesions that may even be confused with malignancy, such as lung cancer, or as disseminated disease⁽⁵¹⁾. In patients with hematologic malignancies with cellular immunity impaired by the disease process or by treatments, including steroids (eg, CLL), these infections may represent reactivation of latent infection⁽⁵¹⁾.

Histoplasmosis

Presentation of histoplasmosis is with pulmonary lesions in patients with solid tumor, but predominantly is disseminated disease in patients with hematologic

Table 51-5 Major Fungal Infections and Syndromes

Organism	Infections/Syndromes	Comments
<i>Candida</i>	Thrush Esophageal candidiasis Urinary tract infection Candidemia Disseminated candidiasis	<i>C. parapsilosis</i> resistant to echinocandins <i>C. krusei</i> fluconazole resistant <i>C. glabrata</i> fluconazole resistant
<i>Aspergillus</i>	Pulmonary Sinusitis Skin infection Disseminated	Bronchoscopy or biopsy of nodules Head and neck surgery evaluation, debridement Biopsy skin; rare blood culture positive
<i>Cryptococcus</i>	Pneumonia CNS Disseminated	Check serum <i>Cryptococcus</i> Low threshold for lumbar puncture in immunocompromised
<i>Fusarium</i>	Sinus infection Pneumonia Skin infection Dissemination	Bronchoscopy or biopsy of nodules Head and neck surgery evaluation, debridement Biopsy skin; blood culture positive
Mucormycosis	Rhinocerebral Pulmonary Gastrointestinal Cutaneous	Urgent debridement of rhinocerebral disease Bronchoscopy or biopsy of nodules Hyperbaric oxygen

malignancy⁽⁵¹⁾. In the United States, histoplasmosis is most common in the Ohio and Mississippi River valleys. Hepatosplenomegaly and mucocutaneous ulcerations, particularly in the oral cavity, may be present⁽⁵¹⁾. Histoplasmosis is identified by culture from infected tissues, including respiratory samples and rarely the bloodstream on culture. Histoplasmosis antigen testing can be used to detect evidence of histoplasmosis in urine⁽⁵²⁾. Recent guidelines suggest utilizing liposomal amphotericin B (3-5 mg/kg/d) for severe pulmonary or disseminated disease, followed by itraconazole (200 mg twice daily for 2 days, then 200 mg daily)⁽⁵²⁾. For most infections requiring treatment, therapy is provided for 6 to 9 months⁽⁵²⁾. Severely immunocompromised patients may require even more prolonged therapy. Successful therapy with voriconazole has been used for histoplasmosis⁽⁵³⁾.

Coccidioidomycosis

Coccidioides immitis is reported to cause fever, hypoxemia, and diffuse pulmonary infiltrates in immunocompromised patients⁽⁵¹⁾. In the United States, coccidioidomycosis is endemic to western Texas, central California, southern New Mexico, and southern Arizona. Disseminated infection may involve the skin and bone. In patients with hematologic malignancy, serologic tests may be negative. In most cases, specimens from the lung, CSF, or other tissue provide the best approach for diagnosis⁽⁵⁴⁾. Current guidelines recommend therapy for severe pulmonary or severe

disseminated infection should begin with an amphotericin B formulation, D-AMB (0.7-1.0 mg/kg/d) or liposomal amphotericin B (3-5 mg/kg/d). For meningitis, guidelines recommend fluconazole (400 to 800 mg/d), possibly combined with intrathecal amphotericin B⁽⁵⁴⁾. After completing initial aggressive therapy according to syndrome on presentation, fluconazole (400 mg/d) or itraconazole (400 mg/d) is continued for at least a year for most cases and indefinitely for immunocompromised patients⁽⁵⁴⁾. Lifelong therapy with fluconazole or voriconazole, which penetrate the CNS, are recommended for those with meningitis⁽⁵⁴⁾.

ADJUVANT THERAPY FOR FUNGAL INFECTIONS

White Blood Cell Transfusions

Recovery of neutropenia is essential for recovery from invasive fungal infection. Almost five decades ago, transfusions of leukocytes were first utilized to assist neutropenic patients in recovery. Some studies have suggested that this approach could be effective in management of invasive fungal infection, but doubts remain. Issues include the challenge of the dose of cells and the length of time during which they remain active⁽⁵⁵⁾. Administration of granulocyte colony-stimulating factor (G-CSF) has allowed healthy volunteers to provide adequate numbers of cells⁽⁵⁵⁾. The effectiveness of this approach may be as a bridge to recovery of

bone marrow. Finally, clinical issues with granulocyte transfusions include an initial worsening of respiratory symptoms, although skin and soft tissue infections appear to improve.

Cytokines

Proinflammatory cytokines, exemplified by interferon gamma (IFN- γ), tumor necrosis factor alpha (TNF- α), and interleukin (IL) 2, are produced by Th1 lymphocytes, activating effector immune cells⁽⁵⁶⁾. Treatment with IFN- γ , sometimes in combination with GM-CSF, has been used to stimulate the immune response to fungal infections⁽⁵⁶⁾. The IFN- γ enhances hyphal damage to fungal pathogens by neutrophils and monocytes⁽⁵⁶⁾.

The duration and depth of neutropenia can be decreased using colony-stimulating factors, including G-CSF (filgrastim) and GM-CSF (sargramostim, molgramostim)⁽⁴¹⁾. Here, GM-CSF may be of particular use because it not only increases the number of granulocytes but also improves the function of macrophages and granulocytes⁽⁵⁶⁾. Case reports and case series have suggested the potential benefit of several of these adjunct therapies, although data are not adequate to make firm recommendations for use of these immunomodulators.

Surgical Resection

The role of surgical resection is characterized for fungal infection by organism, but a recent study described patients undergoing resection as a component of therapy for a broad array of fungal infections from 1984 through 2009; the study provided insight into use of this approach⁽⁵⁷⁾. Patients with hematologic malignancy and suspected pulmonary invasive fungal infection on appropriate systemic antifungal therapy underwent resection in select circumstances. These included progression of fungal infection despite therapy, with neutropenia not considered a contraindication. Platelets were transfused over 50 times $10^9/L$. After surgery, nearly 90% of patients underwent further chemotherapy or stem cell transplant, with mortality of 7% and 48% at 30 days and 1 year, respectively⁽⁵⁷⁾. Fungal organisms isolated were predominantly *Aspergillus* species (88%) and Mucorales (8%). Bacterial infection was noted in 8% of patients, with lung infarction in another 3%, with no evidence of fungal infection, obviating the need for active antimold therapy. Over the time of the retrospective study, the surgical procedures became less invasive, shifting from lobectomy and open limited resections to video-assisted thoracoscopic procedures⁽⁵⁷⁾. Surgical resection, via open or video-assisted thoracoscopy, presents a viable option for management of focal fungal infection that fails to respond to antifungal therapy alone,

even with patients with hematologic malignancies. In fact, these procedures have successfully been followed by subsequent chemotherapy and stem cell transplant.

VIRAL INFECTIONS

Viral infections are an important cause of morbidity and mortality in patients with cancer. Although morbidity and mortality are greater for patients with hematologic malignancies or after HSCT, viral infections, such as norovirus or influenza virus, can increase length of hospital stay and delay chemotherapy, radiation, or surgery in a broad patient population. The most common viral infections are respiratory viral infections, including adenovirus, influenza, parainfluenza, RSV, rhinovirus, and human metapneumovirus⁽⁵⁾. DNA viruses, such as herpes simplex, varicella, and CMV, are well known to cause serious infections in patients with hematologic malignancies or after HSCT, resulting in intense monitoring and prophylaxis directed against such viruses⁽⁵⁸⁾. Patients with hematopoietic stem cell transplant are at particular risk for severe viral infections. Modern tools of diagnosis can quickly identify infection, but treatment options are limited for many viral infections. The following sections provide an overview of viral infections in patients with cancer. Special focus is placed on those with hematologic malignancies and patients after HSCT because this population is uniquely susceptible to viral infections.

Human Herpesviruses

Human herpesviruses are among the most common causes of viral infections in immunocompetent as well as in immunocompromised patients. Morbidity and mortality from these viruses are high among immunosuppressed patients. Herpesviruses are double-stranded DNA viruses. The herpesvirus group has eight members, six of which are important pathogens in immunosuppressed patients (ie, patients with hematologic malignancies and solid-organ or stem cell transplant recipients)^(58, 59). This group of pathogens includes HSV 1 and 2, VZV, CMV, Epstein-Barr virus (EBV), and human herpesvirus 6 (HHV-6).

Herpesviruses establish a latent phase after primary infection. The reactivation of these DNA viruses can be triggered by several stimuli; this is perhaps best recognized in the recurrent blisters and ulcers associated with HSV. The likelihood of reactivation of these viruses is increased during profound T-cell immunosuppression, as host defenses against these viruses are dependent on virus-specific helper and cytotoxic T lymphocytes. Over the past decade, substantial improvements have been made in the techniques used to detect these infections, such as real-time polymerase

chain reaction (PCR), as well as the development of effective antiviral agents and the use of different strategies for prophylaxis and treatment.

Herpes Simplex Viruses

Among the most common causes of mucocutaneous lesions in immunocompromised patients are HSV types 1 and 2⁽⁵⁹⁾. Approximately 40% to 60% of seropositive patients undergoing induction chemotherapy for leukemia or conditioning for HSCT will experience HSV reactivation, usually in early stages, when immunosuppression is most intense⁽⁵⁹⁾. Reactivation of HSV may cause severe disease during neutropenia. Patients with a CD4 count less than 50 who received purine analogs or alemtuzumab are at highest risk of reactivation⁽⁵⁹⁾. Oropharyngeal and esophageal disease is usually but not exclusively caused by HSV-1. The clinical manifestations of oropharyngeal HSV disease can range from gingivitis to stomatitis and cheilitis. Esophagitis from HSV may occur from local spread. Clinical presentation ranges from fever, malaise, myalgia, dysphagia, and bleeding to severe oral pain and odynophagia. Disease caused by HSV-2 is more likely to cause genital and anal disease.

Diagnosis

The diagnosis of HSV infection can be made by isolating the virus in culture or by performing a biopsy showing the characteristic inclusions by immunohistochemistry. Direct detection methods of the virus

in clinical specimens are generally not as sensitive as culture methods but offer the advantage of a rapid diagnosis. Direct or indirect immunofluorescence can be used to detect HSV-1, HSV-2, and VZV from specimens of cutaneous lesions.

Prophylaxis

Antiviral prophylaxis should be strongly considered in HSV-seropositive patients at risk for reactivation during intensive chemotherapy for acute leukemia and during early stages of HSCT^(58,59). Oral acyclovir and valacyclovir are the agents of choice for prophylaxis. If patients are receiving intravenous foscarnet or ganciclovir for treatment of another viral infection, then they do not need to continue acyclovir prophylaxis⁽⁶⁰⁾. Guidelines suggest that continuing prophylaxis for over a year post-HSCT significantly reduces reactivation, with a finding that this may even decrease the risk of acyclovir-resistant HSV⁽⁵⁹⁻⁶¹⁾.

Therapy

The available antiviral agents for the treatment of HSV disease include acyclovir, valacyclovir, famciclovir, foscarnet, and cidofovir (Tables 51-6 and 51-7)^(58,60). The bioavailability of oral valacyclovir and famciclovir is three to five times superior to that of oral acyclovir. All of these drugs are dependent on the virus-encoded thymidine kinase for their intracellular phosphorylation for activity.

Established HSV disease can be treated either orally or intravenously. The most commonly used drug is

Table 51-6 Antiviral Compounds

Antiviral	Dosage	Mechanism of Action	Active Against
Acyclovir	5-10 mg/kg IV every 8 h	Inhibits DNA polymerase	HSV, VZV
Famciclovir	500 mg by mouth every 8 h	Inhibits DNA polymerase	HSV, VZV
Valacyclovir	0.5-1 g every 8-12 h	Inhibits DNA polymerase	HSV, VZV
Ganciclovir	5 mg/kg every 12 h	Inhibits DNA polymerase	CMV
Foscarnet	60 mg/kg IV every 8 h	Inhibits DNA polymerase	CMV, HSV, VZV, HHV-6
Cidofovir ^a	5 mg/kg IV once a week	Inhibits DNA polymerase	CMV, ADV, HSV, VZV, BK
Ribavirin	Oral or aerosolized	Inhibits viral replication	HCV, RSV
Amantadine	100 mg by mouth every 12 h or 200 mg by mouth daily	Inhibits M2 protein	Influenza A only
Ramantadine	100 mg by mouth every 12 h	Inhibits M2 protein	Influenza A only
Oseltamivir	75 mg by mouth every 12 h	Neuraminidase inhibitor	Influenza A and B
Peramavir	600 mg IV daily	Neuraminidase inhibitor	Influenza A and B
Zanamivir	2 inhalations every 12 h (IV formulation available, clinical trial)	Neuraminidase inhibitor	Influenza A and B

ADV, adenovirus; CMV, cytomegalovirus; HCV, hepatitis C virus; HSV, herpes simplex viruses; IV, intravenous; RSV, respiratory syncytial virus; VZV, varicella zoster virus.

^a Licensed for CMV retinitis.

Table 51-7 Common and Serious Toxicities of Antivirals

Acyclovir	Transient renal insufficiency (IV), nausea, vomiting, agitation, confusion, TTP (rare)
Famciclovir	Headache, somnolence, nausea, diarrhea
Valacyclovir	Headache, nausea, vomiting, TTP (rare)
Ganciclovir	Anemia, neutropenia (more common), thrombocytopenia, fever, phlebitis, anorexia
Foscarnet	Nephrotoxicity (major toxicity), electrolyte disturbances (hypocalcemia, hypophosphatemia, hyperphosphatemia, hypomagnesemia, hypokalemia), diarrhea, nausea, vomiting
Cidofovir	Headache, rash, severe nephrotoxicity, metabolic acidosis, decreased intraocular pressure, neutropenia
Ribavirin	Fatigue, headache, nausea, rash, pruritus, conjunctivitis (risk of toxicity to healthcare workers during administration), hemolytic anemia (cardiac and pulmonary events have occurred), worsening respiratory status, including death (inhalation)
Oseltamivir	Insomnia, vertigo, nausea, vomiting (most common), bronchitis
Zanamivir	Headache, nausea, diarrhea, cough, bronchospasm, decline in lung function (some fatal outcomes)

IV, intravenous; TTP, thrombotic thrombocytopenia purpura

acyclovir. Immunosuppressed patients with disseminated or severe HSV disease should be treated with intravenous acyclovir (5-10 mg/kg every 8 h). Otherwise, an oral regimen can be used for milder HSV disease (famciclovir, 500 mg three times a day, or valacyclovir, 1 g three times a day) ^(58, 59). Foscarnet and cidofovir can be used for resistant disease but are only available in intravenous formulations ⁽⁶⁰⁾.

Varicella Zoster Virus

Reactivation of VSV occurs primarily in elderly individuals, seropositive organ transplant and HSCT recipients, patients with cancer, and those with AIDS. Disseminated VZV infection can be life threatening in HSCT recipients and patients receiving intensive corticosteroid therapy ⁽⁵⁹⁾.

The clinical manifestations of VZV infection are primary varicella infection (chickenpox) and herpes

FIGURE 51-7 Hemorrhagic vesicular lesions of herpes zoster.

zoster. The clinical presentation includes low-grade fever, malaise, and a vesicular rash that evolves to scabs. Constitutional symptoms usually develop after the onset of rash and include pruritus, anorexia, and listlessness. Primary VZV infection (chickenpox) occurs mainly in children under 10 years of age.

Reactivation of latent VZV or herpes zoster is frequently observed among patients with cancer, mainly patients with leukemia or lymphoma, as well as in HSCT recipients ^(58, 59). Visceral herpes zoster may follow cutaneous dissemination in immunocompromised patients and can result in pneumonia, encephalitis, retinal necrosis, hepatitis, and small bowel disease. Cutaneous VZV eruption can be complicated by secondary bacterial infections, thrombocytopenia, and vasculitis (Fig. 51-7).

Diagnosis

Immunocompromised patients may exhibit single dermatomal disease, but more commonly develop multi-dermatomal or disseminated cutaneous disease, which can make the clinical diagnosis less certain on visual inspection alone. The diagnosis can be established within hours by the direct method of immunofluorescent staining on material collected from a skin lesion or from a skin biopsy. Viral culture should also be performed. In some cases, a biopsy is required to establish the diagnosis because other diseases can mimic VZV, such as streptococcal impetigo, GVHD, and various noninfectious bullous diseases.

Therapy

The treatment of choice for chickenpox or VZV in immunocompromised patients is high-dose intravenous acyclovir (10 mg/kg every 8 h) (see Tables 51-6 and 51-7). Early initiation of acyclovir is paramount because it may reduce progression to end-organ disease

and usually prevents death in patients with reactivated disease. Therapy can be changed to an oral agent once clinical improvement has occurred, including resolution of fever or healing/crusting of lesions. The options for an oral regimen for treatment of localized herpes zoster among patients with mild immunosuppression include acyclovir (rarely used because of bioavailability and pill burden), valacyclovir, and famciclovir ⁽⁶²⁾.

Prevention of Infection

Varicella zoster virus can be transmitted from person to person, and this can become problematic in a hospital or clinic setting. To prevent nosocomial transmission, immunocompromised patients with cutaneous lesions suspicious of VZV eruption and those with disseminated zoster should be placed under contact and respiratory isolation. In addition, it is recommended that the family members, caregivers, and visitors of patients scheduled to undergo transplant be vaccinated against VZV, preferably at least 4 weeks prior to conditioning regimen ^(59, 60).

Immunosuppressed patients with negative VZV titers and no history of chickenpox should be offered VZV immune globulin after being in close contact with individuals with either chickenpox or herpes zoster. Close contact includes prolonged face-to-face contact, a household or playmate contact, or exposure to a roommate in a shared hospital room. Varicella zoster immune globulin, if available, should be administered within 96 h of exposure to be most effective in preventing infection ⁽⁵⁹⁾.

Immunocompromised persons should avoid contact with individuals who developed a rash after receiving zoster vaccine. No additional precautions are required if a rash has not developed ^(59, 60). A study of an inactivated varicella vaccine in HSCT patients resulted in decreased incidence and severity of zoster but is not commercially available ⁽⁵⁹⁾.

Cytomegalovirus

Evidence of prior CMV infection is present in approximately 85% of the US population ⁽⁵⁹⁾. Therefore, reactivation of latent CMV infection is the primary concern in the hematologic malignancy and HSCT patient populations ^(59, 60). Reactivation can manifest as viremia alone, a mononucleosis-like syndrome with lymphadenopathy, or more severe disease with end-organ damage. Other symptoms of CMV reactivation include fever, lymphadenopathy, splenomegaly, lymphocytosis, and polyradiculopathy. Manifestations of end-organ disease include retinitis, encephalitis, and hepatitis, but pneumonitis and GI disease are the most common and can be life threatening ⁽⁵⁹⁾.

The most common sites of CMV infection in the GI tract are the esophagus and colon. The hallmarks of

CMV colitis are abdominal pain and diarrhea. Esophagitis caused by CMV is associated with pain and dysphagia. On upper GI endoscopy, ulcerations can be seen in the esophagus, and a biopsy must be obtained to rule out other infectious etiologies, such as HSV or candida esophagitis. As with esophagitis, the diagnosis of colitis requires biopsy. In a retrospective study at our institution, 72% of patients diagnosed with GI CMV disease had hematologic malignancies, 25% had AIDS, and overall CMV-attributable mortality rate was 42% ⁽⁶³⁾. Independent predictors of mortality were disseminated CMV and diagnosis of AIDS ⁽⁶³⁾.

Cytomegalovirus pneumonitis is associated with a mortality rate of 80% to 100% in patients with high-risk leukemia and HSCT ⁽⁵⁹⁾. Pneumonitis typically presents with severe dyspnea, hypoxia, and interstitial disease on chest radiograph. Similar to GI disease, finding of CMV from bronchoscopy specimens without accompanying pathology is of unclear significance. The thrombocytopenia present in most patients with leukemia and HSCT often prevents acquisition of a biopsy specimen that can accurately confirm diagnosis of CMV pneumonitis. A study of autopsy-proven CMV pneumonia in patients with HSCT and hematologic malignancy showed that incidence decreased over the time of the study (from 1990 to 2004) ⁽⁶⁴⁾.

Risk Factors

Patients with HSCT and hematologic malignancies are at highest risk for CMV infection and reactivation. In patients with leukemia, those at highest risk include patients who have received purine analogues (eg, fludarabine) and T-cell-depleting monoclonal antibodies (eg, alemtuzumab) ⁽⁵⁹⁾. Reactivation can occur in almost 5% of those receiving purine analogues and in 15% to 66% of those receiving alemtuzumab, with the highest risk period for the latter group being in the first 1 to 3 months after therapy ⁽⁵⁹⁾. Reactivation in the setting of alemtuzumab therapy, however, was significantly reduced (0% vs 35% in the control arm) with prophylaxis utilizing valganciclovir 450 mg orally twice per day when compared to 500 mg daily valacyclovir ⁽⁶⁵⁾.

In patients with HSCT, the highest-risk group is the CMV-seropositive recipient, regardless of donor serostatus, followed by the CMV-seronegative recipient with seropositive donor ⁽⁵⁹⁾. Nonmyeloablative regimens for HSCT patients have resulted in decreased risk of CMV reactivation, although cases have occurred later after transplant ⁽⁶⁶⁾. The period of highest risk is in the first 100 days after transplant, although prophylaxis and preemptive strategies have resulted in CMV infections after day 100 from transplantation ⁽⁶⁷⁾. Risk factors for late disease in HSCT patients include GVHD, CMV reactivation before day 100 posttransplant, steroid use, low CD4 count (<50), use of unmatched stem

cells, cord blood, T-cell-depleted stem cells, and receipt of allograft-negative donors in CMV-positive recipients (^{60, 68}). Also, CMV can be transmitted to HSCT recipients from seropositive donors and from blood products (⁵⁹). The utilization of CMV-seronegative blood for transfusions and leukoreduction of blood products has resulted in significantly reduced CMV infection (⁵⁹).

Diagnosis

Diagnosis of CMV depends on the site of infection. For detection of disseminated infection or reactivation, two types of tests are available and recommended for diagnosis of CMV: pp65 testing and detection of DNA (⁶⁰).

Serologic testing is not useful, except for donor selection for transplant, because CMV antibodies demonstrate evidence of prior exposure, rather than active infection. For detection of end-organ disease such as in the liver and lungs, the recommended approach is biopsy with detection of viral inclusions on histopathology or by immunohistochemistry (Fig. 51-8), which has greater sensitivity. If available, *in situ* PCR and nucleic acid hybridization are also useful diagnostic tools for biopsy samples. Detection of CMV DNA is a widely available test in transplant centers, utilizing quantitative real-time polymerase chain reaction (RT-PCR) for CMV DNA detection (^{59, 60, 69}).

Therapy

Antiviral agents are used for prevention and treatment of CMV infection. Available agents are described in Tables 51-6 and 51-7. Strategies for utilization of these agents include treatment of established disease, preemptive therapy, or prophylaxis (⁵⁹). The last two strategies focus on disease prevention in high-risk HSCT patients. At MD Anderson Cancer Center, prophylaxis

with ganciclovir or foscarnet used to be the strategy in high-risk HSCT patients; now, preemptive therapy is used in all HSCT patients at risk for reactivation.

A recent study compared daily oral 900 mg valganciclovir to placebo (paired with preemptive therapy) for prophylaxis against late CMV infection after allo-BMT. The study failed to show the impact of valganciclovir on reduction in mortality, CMV disease, or other invasive infections, although less CMV infection was detected (⁶⁷). Another multicenter study compared a novel anti-CMV agent, letermovir, targeted against the viral terminase complex, to placebo for prophylaxis for allo-BMT patients. In the modified intention-to-treat analysis, a dose-dependent reduction of 30% in CMV reactivation was noted in the letermovir group, without any noted adverse hematologic events (⁷⁰). A similar study in allo-BMT patients showed a 27% reduction in CMV events with CMX001, a lipid acyclic nucleoside phosphatase. Diarrhea was the most common adverse effect of the study medication (⁷¹).

Ganciclovir functions as a competitive inhibitor of viral DNA polymerase. Its major side effect is myelosuppression, limiting its use as a prophylactic agent and requiring frequent blood count monitoring (⁵⁹). Dosing for treatment is 5 mg/kg intravenously every 12 hours (⁵⁹). Valganciclovir, a prodrug of ganciclovir available in capsule form, is significantly better absorbed than its prodrug ganciclovir in oral form (⁵⁹). A common induction dose is 900 mg twice daily by mouth.

An alternative agent, foscarnet, functions as a noncompetitive inhibitor of the pyrophosphate-binding site of CMV DNA polymerase, which does not require phosphorylation to become active (⁵⁹). Foscarnet is typically used when resistance to ganciclovir is suspected or bone marrow suppression is excessive with ganciclovir. It is also useful in patients with delayed engraftment (⁶⁹). Side effects of foscarnet include nephrotoxicity, azotemia, and electrolyte abnormalities.

Cidofovir, a nucleotide analogue, has been approved for treatment of CMV retinitis in patients with HIV. It works as a competitive inhibitor of the CMV DNA polymerase. Its role in treatment or prophylaxis of CMV in immunocompromised patients, however, is limited due to nephrotoxicity. The long half-life not only makes once-weekly administration possible, but also results in a lasting impact of adverse effects (⁶⁹). Modalities used to reduce risk of nephrotoxicity include hydration and probenecid.

Human Herpesvirus 6

Human herpesvirus 6 is a beta-herpesvirus with two subtypes (A and B). Primary infection with HHV-6 is common in children. Exanthem subitum, the most

FIGURE 51-8 Typical cytomegalovirus inclusions in the lung parenchyma of a patient with lymphoma with pneumonia.

common cause of fever and hospitalization of infants less than 1 year of age, is caused by HHV-6 subtype B^(58, 59). In addition to fever, children present with mild upper respiratory symptoms and a classic diffuse maculopapular exanthem. It is unclear whether HHV-6 subtype A causes any primary infection. In immunosuppressed individuals, typically patients with AIDS and transplant recipients, HHV-6 may cause opportunistic viral infections. As this infection is common early in life, positive titers are found in more than 95% of adults. In immunosuppressed individuals, especially HSCT recipients, this virus occasionally may cause interstitial pneumonia, fever, encephalitis, hepatitis, and delayed engraftment⁽⁶⁰⁾. Up to 40% to 60% of HSCT patients may demonstrate viremia by PCR, but the significance of this finding is unclear, so routine surveillance is not currently recommended⁽⁵⁸⁻⁶⁰⁾.

Therapy

Both ganciclovir and foscarnet are used to treat HHV-6 infections, but this is based on *in vitro* studies only because clinical experience is minimal. Both ganciclovir and foscarnet have been reported to be effective against HHV-6 meningoencephalitis after HSCT in a small number of patients⁽⁵⁸⁾.

Epstein-Barr Virus

Epstein-Barr virus infection is common in the adult population. It is the cause of infectious mononucleosis and has also been linked to several geographically defined cancers. Posttransplant lymphoproliferative disorder (PTLD) associated with EBV is an important cause of morbidity and mortality in HSCT and solid-organ transplant recipients. Posttransplant lymphoproliferative disorder is reported in 0.45% to 29% of HSCT patients, depending on the source of hematopoietic cells (cord blood with the higher risk), manipulation of those cells, and immunosuppressive regimen⁽⁷²⁾.

Although variable in incidence, PTLD can be fulminant and lethal. The disease results from suppression of cytotoxic T-cell function.

The first step in the management of PTLD is to reduce the dose of any immunosuppressive therapy if possible. Another therapeutic approach using the anti-CD20 monoclonal antibody (rituximab) has been tested for therapy for EBV-induced PTLD. It has been successful for the treatment or prevention of PTLD in solid-organ transplant and HSCT recipients as well as those with proven EBV lymphomas^(58, 59). Another approach is utilization of EBV-cytotoxic T lymphocytes (CTL), typically derived from EBV-positive stem cell donors or from third-party donors⁽⁷²⁾. There is no apparent role for antivirals in treatment of EBV-associated PTLD. Treatment with rituximab and

EBV-targeted CTLs has resulted in over 85% survival, compared with less than 20% before these modalities were available⁽⁷²⁾.

Community Respiratory Viral Infections

Infections caused by community respiratory viruses (CRVs) were not considered to be a significant problem for patients with cancer until the early 1990s. Since then, it has been recognized that they represent a threat to patients undergoing chemotherapy for acute leukemia and to HSCT recipients, especially recipients of allogeneic transplants⁽⁷³⁾. Early surveys indicated that about 30% of respiratory illnesses occurring during the winter and spring among these patient populations were due to CRVs. Recent studies have reported CRVs as the cause of as few as 5% to as many as 48% of respiratory infections⁽⁷³⁾. Although many patients acquire only upper respiratory infections (URIs), some develop pneumonias, which may be fatal. In a retrospective study conducted at our institution, progression from URI to pneumonia was noted in 35% of patients with HSCT and hematologic malignancy⁽⁷³⁾. Many of these pneumonias may be due to bacterial or fungal pathogens and not attributed to the virus. For example, it has been recognized for many years that influenza can predispose to bacterial pneumonia.

Epidemics of CRV have occurred on leukemia and transplant units, where the virus may be transmitted by patients, visitors, and hospital personnel. Clinics may serve as an important starting point for epidemics. Also, epidemics may occur among these susceptible patients in the absence of a recognized epidemic in the community. An additional problem is that these immunocompromised patients may have prolonged viral shedding (in some cases >100 days) after resolution of symptoms^(59, 74). Shedding of influenza virus continued despite antiviral therapy, halting only when lymphopenia resolved^(59, 74).

The most commonly reported viruses causing infection are influenza A and B (predominantly influenza A), RSV, and parainfluenza virus (almost entirely type 3)⁽⁶⁾. Rhinoviruses are the most common cause of community respiratory illnesses but are identified infrequently in most surveys of patients with cancer, suggesting that they are underdiagnosed. Rhinoviruses have been associated with pneumonia in HSCT patients, but commonly are accompanied by bacterial coinfection⁽⁷⁵⁾. Influenza, RSV, and parainfluenza types 1 and 2 occur during the winter and spring, whereas parainfluenza 3 infection occurs throughout the year. Some patients may be infected by multiple viruses simultaneously or have multiple episodes of the same viral infection separated by only a few weeks. There is considerable variability in the relative frequency of the three major viruses in different geographical areas and

in different years, most likely reflecting the relative prevalence of the infections within the community.

A study of parainfluenza virus pneumonia in HSCT patients pointed to high oxygen requirement, low monocyte counts, and high-dose steroids as predisposing to mortality, ranging from 13% to 55% (⁷⁶). A retrospective study conducted at our center emphasized relapsed or refractory malignancy, high APACHE (Acute Physiology and Chronic Health Evaluation) II score, and high-dose steroids as predictors of mortality in a mixed population of patients with leukemia and HSCT (⁷⁷). Human metapneumovirus is a paramyxovirus similar to RSV that was first described in children but has now been described in immunocompetent and immunocompromised adults (^{78, 79}). Fatal cases in HSCT patients were reported from Seattle, Washington, with mortality rates as high as 43% (⁸⁰), but HSCT patients from France demonstrated a low mortality rate, even with lower respiratory tract infection (⁸¹). One of the continuing challenges in comparison of mortality between studies is the degree to which individual investigators consider viral infection the cause or major contributor to death, particularly when considering the significant underlying disease in the oncology populations studied to date (⁸¹).

Finally, influenza virus infection is associated with different presentation and natural course of disease in severely immunocompromised hosts. In a recent study at the US National Institutes of Health, immunocompromised hosts exhibited less prominent symptoms, such as cough, chills, myalgias, or dyspnea than hosts who were not immunocompromised (⁷⁴). Physical exam findings demonstrating pulmonary compromise were also more common in nonimmunocompromised hosts, but radiographic abnormalities on chest imaging were more common in immunocompromised hosts (⁷⁴). Finally, immunocompromised patients exhibited more severe disease, despite similar cytokine profiles, with prolonged viral shedding and higher risk of developing drug-resistant influenza virus (⁷⁴).

Predisposing Factors

Several important predisposing factors for these infections have been identified in HSCT recipients and patients with hematologic malignancies. These include age more than 65 years, severe neutropenia, severe lymphopenia, allogeneic transplantation, transplant conditioning regimen, GVHD, and adrenal corticosteroid therapy (over 1 mg/kg body weight) (^{58, 73, 79, 82}). Recipients of HSCT are at greatest risk within the first 100 days posttransplant, although nonmyeloablative transplant has resulted in an increase in disease occurring after this initial period (^{58, 82}). Neutropenia, lymphopenia, marrow or cord blood as source of transplant, age over 65 years, GVHD, smoking history,

and allogeneic HSCT were risk factors for progression from RSV URI to pneumonia (^{5, 73}).

An immunodeficiency scoring system developed at MD Anderson has been useful in estimating outcomes and appropriate focus of expensive therapy for RSV infection (⁸³). Factors given the most weight are neutropenia, lymphopenia, and age 40 years or older, followed by other factors such as GVHD, corticosteroid use, myeloablative conditioning regimen, and preengraftment or within 30 days of engraftment (⁸³). Without therapy, those patients in the highest-risk category all progressed to pneumonia, compared to 15% of those who received antiviral therapy. The subsequent mortality in untreated high-risk patients who progressed to pneumonia was 100%, compared to 50% for those who received antiviral therapy (⁸³).

Pneumonia

There is great variability in the frequency of viral pneumonia in different studies, ranging from 15% to over 70%, but most surveys have reported only small patient populations. Fatality rates from viral pneumonia vary widely in different reports, but most include only small numbers of cases. In our institution, mortality in patients with hematologic malignancies was 15%, although reports in HSCT patients range as high as 50% to 70% (⁷³). The same factors that predispose for pneumonia may predispose to fatal outcome.

Diagnosis

The diagnosis of CRV infection is established from nasopharyngeal wash, sputum, swab, or bronchoalveolar lavage specimens (⁷³). Rapid antigen detection tests are available for influenza and RSV, whereas tissue cell cultures are used for detecting parainfluenza and rhinoviruses. Modern tools for diagnosis include available multiplex PCR platforms that are capable of detecting multiple respiratory viruses simultaneously with improved sensitivity compared to cell culture or direct fluorescent antibody (⁸⁴).

Therapy

Therapy for these infections has been limited (see Tables 51-6 and 51-7). At present, there is no demonstrably effective therapy for parainfluenza infection, with DAS-181, a fusion protein inhibitor, under evaluation (⁵). Neuraminidase inhibitors, inhaled zanamavir, oral oseltamavir, and intravenous peramavir are currently approved antivirals against influenza (^{85, 86}). In the pandemic 2009 H1N1 influenza A outbreak, early therapy was shown to be critical in improving mortality in patients with cancer (⁵). Viral resistance to these agents developed in some patients during therapy, particularly among those with lymphopenia, who may

shed the viruses for weeks to months (⁷⁴). Given the predisposition to prolonged shedding in immunocompromised hosts, innovative approaches to treatment are required to prevent poor outcomes and antiviral resistance (^{74,86}). Considerations have included immunomodulatory medications from statins to naproxen to mTOR inhibitors (⁸⁶). Steroids should be used with caution because they may prolong the duration of shedding, leading to emerging resistance. Steroids are also associated with increased risk of secondary fungal and bacterial infections (⁸⁶).

Ribavirin is available for therapy for RSV infection (Fig. 51-9). Ribavirin is administered by aerosolization 2 to 3 hours every 8 hours or continuously over 18 hours, requiring the patient to be confined in a tent (⁸⁷). In patients with leukemia, lack of aerosolized ribavirin and high APACHE II scores were independent predictors of developing pneumonia in this population (⁸³). Use of aerosolized ribavirin was suggested to be the key predictor of progression to pneumonia and mortality in allo-HSCT recipients in a study conducted at our center (⁸⁸). Ribavirin may also be combined with immunoglobulin (Ig) therapy when the infection progresses to the lower tract (⁸). Palivizumab, a humanized monoclonal antibody directed against the F glycoprotein of RSV, is currently available and approved for prophylaxis of RSV infection in high-risk pediatric patients (⁸). Most patients with RSV pneumonia are being treated

with combination therapy, but the limited numbers of patients and lack of clinical trial data reported make interpretation of results difficult.

Hepatitis Viruses

Hepatitis B

Hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are common in many countries. There is a global epidemic of HBV infections, affecting more than 350 million people worldwide. Chronic HBV or HCV infections lead to progressive liver disease, cirrhosis, and hepatocellular cancer. Hepatitis can be a serious problem in patients with cancer for various reasons. Chemotherapy-induced immunosuppression may lead to reactivation and fulminant infection in patients with chronic HBV infection. Furthermore, the presence of hepatitis may require substantial delays in the administration of antineoplastic therapy. In HSCT patients, reactivation is more likely in those who have received high-dose steroids, fludarabine, rituximab, or alemtuzumab (⁶⁰).

Hepatitis C

Hepatitis C is the most common chronic blood-borne infection. In the United States, 4 million individuals (1.6% of the population) have been infected (⁸⁹). It is

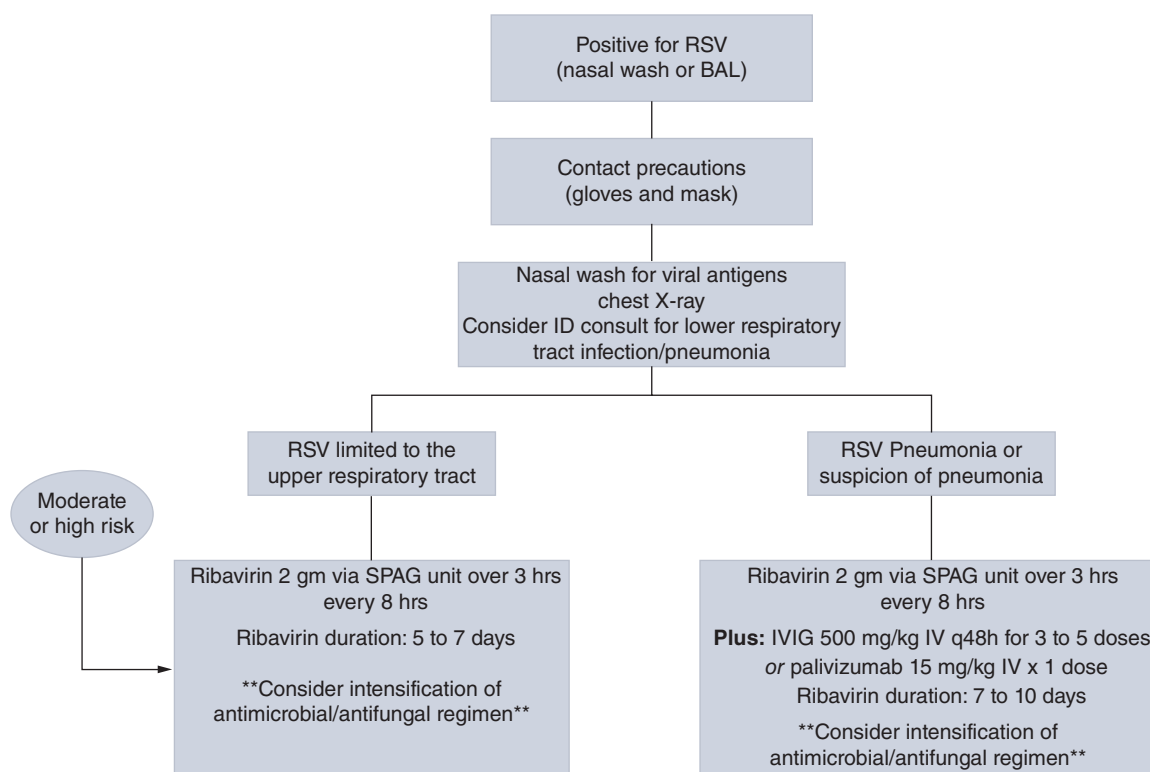

FIGURE 51-9 Management of RSV infection after hematopoietic stem cell transplantation. ID, infectious disease; IVIG, intravenous immunoglobulin; RSV, respiratory syncytial virus SPAG, small particle aerosol generator; BAL, bronchoalveolar lavage.

the leading indication for liver transplantation. Transmission of HCV occurs primarily through exposure to infected blood. It can be acquired from intravenous drug abuse, blood transfusion before 1992, solid-organ transplantation from infected donors, unsafe medical practices, occupational exposure to infected blood, birth to an infected mother, sexual contact with an infected person, and possibly via intranasal cocaine use⁽⁵⁸⁾.

Antibody testing should be used first to assess exposure to HCV, but in cases of persistent liver disease with immunocompromised status that may prevent adequate response, HCV RNA testing should be undertaken⁽⁸⁹⁾. Patients who are seropositive for HCV should be tested for HCV RNA to determine if virus is circulating⁽⁸⁹⁾. If virus is circulating, then the MD Anderson algorithm (Fig. 51-10), can be used

for further management⁽⁸⁹⁾. The combination of pegylated INF- α plus ribavirin produced sustained virologic responses (SVRs) in only 4% of genotype 1 infections⁽⁸⁹⁾. Notably, even treated patients without SVR exhibited slower progression to cirrhosis and portal hypertension⁽⁸⁹⁾. The authors also cited an important link between HCV infection and various cancers, including hepatocellular carcinoma, lymphomas, and esophageal, prostate, and thyroid cancers⁽⁸⁹⁾.

This intriguing suggestion points to an expanded role for testing and treatment of HCV infection in prevention or treatment of malignancy. The treatment of HCV is also being revolutionized by new directly acting antivirals (DAAs) that are being rapidly introduced and promise to reduce the complications associated with HCV infection as well as improve outcomes. Treatment is uniformly recommended for HCV-infected HSCT recipients, although timing should be at least 2 years after transplant with no evidence of GVHD and off immunosuppression⁽⁶⁰⁾. At present, no active or passive immunizations are available for HCV.

Adenovirus

Adenoviruses are a common cause of self-limited respiratory and GI infections in normal individuals. Transmission occurs by aerosolized droplets or the oral-fecal route. Adenovirus infections have been recognized in patients undergoing intensive chemotherapy for hematologic and occasionally other malignancies, but they are especially prevalent among HSCT recipients⁽⁵⁸⁾. The frequency of infection among HSCT recipients has varied from 3% to 21%, and it is more prevalent among children than adults. There is no seasonal variation, and the onset of infection from time of transplantation can be variable, although the median interval is about 50 days⁽⁵⁸⁾.

Important risk factors have been identified for adenovirus infection, including childhood, allogeneic transplantation (particularly umbilical cord blood), GVHD, total-body irradiation (in children), T-cell-depleting conditioning regimens, alemtuzumab, corticosteroid therapy, and lymphopenia⁽⁵⁸⁾.

Immunocompromised patients may have asymptomatic infection, single-organ disease, or disseminated disease⁽⁵⁸⁾. The most common disease is gastroenteritis, presenting as fever and diarrhea, which may become bloody. Infections of the respiratory tract may vary from mild URI to severe pneumonitis with respiratory failure. Adenovirus may cause nephritis, and as many as 50% of patients with positive urine cultures develop hemorrhagic cystitis. Hepatitis may lead to liver failure and death. Other types of infection include encephalitis, pancreatitis, and disseminated infection with multiple-organ failure.

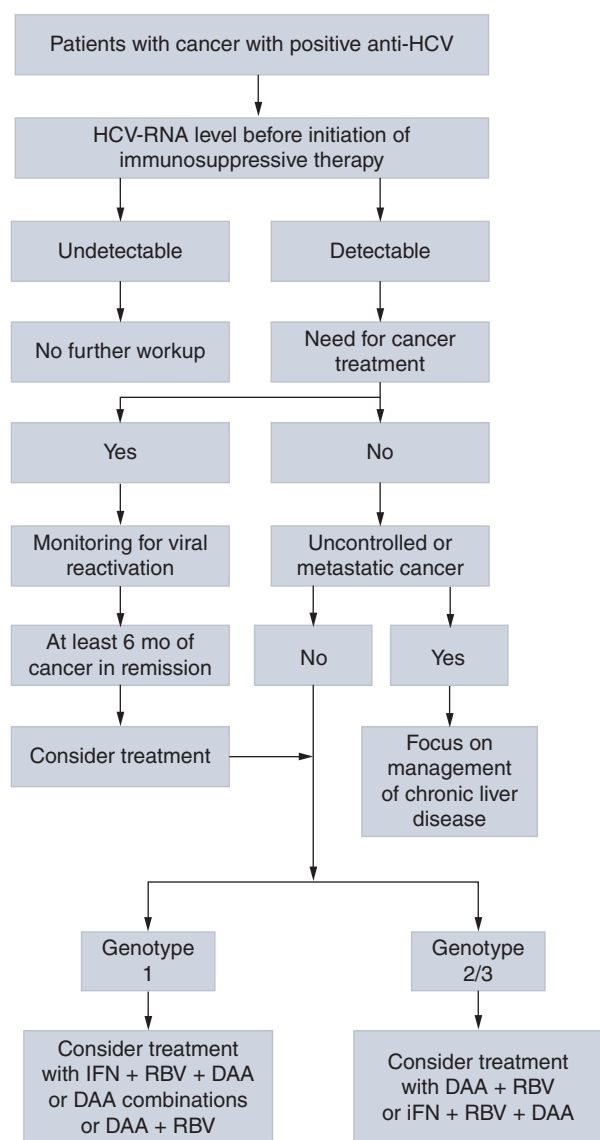

FIGURE 51-10 Management of hepatitis C viral infection. IFN, pegylated IFN; RBV, ribavirin; DAA, direct-acting antivirals.

Diagnosis

The virus may be identified from nasopharyngeal washings, throat swabs, lower respiratory specimens, urine, stool, blood, and infected tissues. The diagnosis can be established by culture or more rapidly by the use of commercially available tests for antigen detection. Positive cultures are most often obtained from stool or urine specimens. Polymerase chain reaction is a useful diagnostic tool, particularly in screening those HSCT recipients at highest risk⁽⁵⁸⁾. Unfortunately, however, there is no threshold for viral load that definitively correlate with clinically relevant infection.

Outcome

The mortality rate from symptomatic infection is about 25%, but it is 60% to 75% in patients with disseminated disease⁽⁹⁰⁾. Death is mainly due to pneumonia, hepatitis, or multiorgan failure. Many patients who die have other concomitant infections. There is no established therapy for these infections. In one series of 45 patients, intravenous cidofovir produced successful results in 69% and was as effective in asymptomatic patients as in those with definite disease⁽⁹¹⁾. Lipid esters of cidofovir have been developed to improve bioavailability and reduce toxicity associated with this compound⁽⁹²⁾ and are currently under evaluation in immunocompromised patients with either localized or disseminated infection. Immunotherapy with adenovirus-specific cytotoxic T-lymphocyte infusions is a promising future approach⁽⁵⁸⁾.

Parvovirus B19 Infection

Parvovirus B19 causes erythema infectiosum in children. It has been associated with aplastic crises in diseases in which the life span or production of red blood cells is reduced⁽⁹³⁾. Anti-B19 IgG has been found to be more prevalent among patients with cancer undergoing chemotherapy than among the general population. In this study, 63% of the seropositive patients with cancer had unexplained anemia⁽⁹⁴⁾. Prolonged erythroid aplasia in childhood acute lymphocytic leukemia was associated with detection of B19 DNA in the bone marrow. Several patients with CLL have developed severe parvovirus B19 infection, manifested by a flulike illness followed by anemia owing to pure red cell aplasia in the bone marrow. The infection may be followed by an incapacitating polyarthritis. Intravenous Ig is a treatment available for this infection, but with significant risk of relapse⁽⁹⁵⁾. A concern is the potential risk posed for infection or reactivation with parvovirus B19 for patients on dasatinib (a tyrosine kinase inhibitor)⁽⁹⁶⁾.

Polyoma Viruses Infection

BK Virus

Polyoma hominis, or BK virus, infects 80% of the general population without causing clinical manifestations⁽⁵⁸⁾. It persists in the genitourinary tract and is a major cause of hemorrhagic cystitis among HSCT recipients. About 60% to 80% of these patients have persistent viremia, and 5% to 15% develop hemorrhagic cystitis⁽⁵⁸⁾. Risk is higher in allo-HSCT recipients⁽⁵⁸⁾. Patients with hemorrhagic cystitis have higher viral loads in the urine, as detected by PCR⁽⁶⁰⁾. The disease may vary from asymptomatic microscopic hematuria to severe dysuria, frequency, and passage of clots, which may cause outflow obstruction and renal failure. Symptomatic therapy includes red blood cell and platelet transfusions, saline bladder irrigations, and cauterization. The use of quinolones is of unclear benefit. Intravenous cidofovir has been utilized, and successful treatment of refractory cystitis with hyperbaric oxygen therapy was reported⁽⁹⁷⁾, but no specific therapy is currently recommended⁽⁵⁸⁾.

JC Virus

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of the brain caused by the JC virus, a polyomavirus that is related to BK virus⁽⁹⁸⁾. The disease results from reactivation of latent infection. About 80% of normal adults demonstrate JC virus antibodies by middle age. Progressive multifocal leukoencephalopathy was first described in patients with CLL and Hodgkin's disease. Subsequent reports centered on patients with HIV, who currently account for 80% of new PML cases⁽⁹⁸⁾. Symptoms include visual disturbances, speech defects, and mental deterioration leading to dementia and coma. The mortality rate is 80% at 1 year, and the mean time from diagnosis to death is 4 months. An association has been reported with steroid use, fludarabine, cyclophosphamide, methotrexate, mycophenolate, and, more recently, monoclonal antibodies, including rituximab^(98, 99). Therapeutic choices are limited, with individual and combination therapy attempted with cytarabine, cidofovir, IL-2, IFN- α , Ig, zidovudine, ganciclovir, donor lymphocyte infusion, and if possible, discontinuation of GVHD prophylaxis⁽¹⁰⁰⁾. No consistently effective therapy is available.

Endocrine and Metabolic Complications of Cancer Therapy

Levent Ozsari
Naifa L. Busaidy
Mouhammed A. Habra

In the past two decades, cancer research has rapidly advanced, spurred by the development of high-throughput technology and the maturation of genomic and proteomic research methods. These advances have resulted in treatments that have substantial effects on the outcomes of certain cancers. The continuous development of new antineoplastic agents adds increasing challenges for practicing physicians.

Current cancer treatments include surgery, radiation, cytotoxic chemotherapy, hormonal therapy, bio-immunotherapy, and targeted therapy. Adverse effects of antineoplastic agents on the endocrine system are caused by several different mechanisms and can range from a subtle laboratory abnormality with limited clinical significance to potentially lethal clinical syndromes. Antineoplastic agents in general can be cytotoxic to endocrine cells and result in glandular dysfunction. Antineoplastic agents can also interfere with the synthesis or postsynthesis processing of hormones at different levels (ie, transcription, translation, or posttranslation). An agent may inhibit or induce secretion of a hormone by interacting with receptors, perturbing intracellular second messenger metabolism, or may affect hormone delivery by changing carrier protein levels in serum or by competing for binding on the carrier protein. Finally, antineoplastic agents can interact with signal transduction pathways to inhibit or enhance hormonal action in the end organs.

In this chapter, we summarize the major and common endocrine complications of cancer therapy and discuss screening and surveillance of these complications in cancer patients and survivors.

METABOLIC DISORDERS

Glucose Metabolism Disorders

Diabetes Mellitus

Serum glucose is under continuous complex regulation. Many processes can affect glucose levels, including gut absorption, cellular uptake, gluconeogenesis, and glycogenolysis. Multiple hormones also play important roles in overall glucose homeostasis, including insulin, glucagon, growth hormone (GH), cortisol, somatostatin, and incretins.

Glucocorticoids are frequently used with many chemotherapy protocols and can have profound effects on glucose levels by increasing insulin resistance. Glucocorticoids can unmask preexisting prediabetic states by precipitating overt diabetes or make diabetes more difficult to control. The severity may range from asymptomatic hyperglycemia to nonketotic hyperosmolar coma. Most patients taking glucocorticoids with elevated glucose require insulin therapy to achieve blood glucose control, especially when given high-dose steroids. Long-acting and intermediate-acting insulin formulations are often combined with mealtime rapid-acting or short-acting insulins. Currently, there are emerging studies about the management of steroid-induced diabetes mellitus in cancer patients by using multiple daily injections including mealtime short-acting insulin to counteract postprandial glucose excursions. Recent concerns about the promotion of malignancy by the mitogenic effect of insulin (¹) and

especially insulin analogs ⁽²⁾ that cross-activate insulin-like growth factor 1 (IGF-1) receptors ⁽³⁾, in combination with conflicting clinical study results on insulin glargine and cancer, have brought attention to the gap in knowledge about proper diabetes management for maximization of survival in cancer patients and survivors. A large cohort study showed that insulin analogs including insulin glargine are associated with a lower risk of cancer in general than human insulin ⁽⁴⁾.

Mammalian target of rapamycin (mTOR) inhibitors, L-asparaginase, streptozocin, and interferon- α (IFN- α) have also been associated with impaired glucose homeostasis and frank diabetes mellitus ⁽⁵⁾.

Phosphoinositide-3 (PI3) kinase/Akt/mTOR pathway-targeted therapy can cause hyperglycemia. Inhibition of this pathway results in peripheral insulin resistance, increased gluconeogenesis, and hepatic glycogenolysis ⁽⁶⁾. Everolimus, a tyrosine kinase inhibitor, is used in patients with advanced breast cancer, progressive neuroendocrine tumors of pancreatic origin, and advanced renal cell carcinoma. Fifty percent of patients taking everolimus have hyperglycemia (Table 52-1) ⁽⁶⁾. Temsirolimus is another kinase inhibitor used in patients with advanced renal cell carcinoma. The incidence of hyperglycemia in patients using this drug is 26% ⁽⁷⁾. The mechanism by which temsirolimus leads to diabetes may be similar to that of tacrolimus, which decreases glucose-stimulated insulin release in the pancreatic islets by reducing adenosine triphosphate (ATP) production and glycolysis ⁽⁸⁾.

Idelalisib, a PI3 kinase inhibitor, is indicated in patients with chronic lymphocytic leukemia. One of the idelalisib's emergent laboratory abnormalities is hyperglycemia, which occurred in 54% of patients taking both idelalisib and rituximab in a phase III study ^(9, 10). Another study showed that idelalisib alone in different dose regimens increased serum glucose in 40% of patients ⁽¹¹⁾.

L-Asparaginase is used mainly to treat hematologic malignancies. The risk of hyperglycemia associated with pegylated *Escherichia coli* asparaginase has been reported to be similar to the risk associated with native asparaginase; in one study, the risk was about 20% in children with acute lymphoblastic leukemia treated with either agent. The exact mechanism of L-asparaginase-associated hyperglycemia is not known, although it has been postulated that inhibition of insulin, insulin receptor synthesis, or both may be the cause, leading to a combined insulin deficiency–insulin resistance syndrome ⁽¹²⁾. Pancreatitis, which can occur with L-asparaginase therapy, is another possible mechanism for hyperglycemia. Pancreatitis can cause islet cell destruction, and some patients might require insulin therapy ⁽¹³⁾. One potential complication is hypoglycemia after cessation of L-asparaginase; thus, close monitoring of blood glucose is recommended. Diabetic ketoacidosis has been reported during L-asparaginase therapy. Long-term insulin therapy may not be needed in some cases of L-asparaginase-induced diabetes mellitus ⁽¹²⁾.

Streptozocin, used primarily to treat malignant islet cell tumors and other neuroendocrine tumors, is an *N*-nitrosourea derivative of glucosamide. Streptozocin's effect on islet cells is species specific and dose related; rat islet cells appear to be more susceptible to the cytotoxic effects of streptozocin than human islet cells. Most of streptozocin's effects are reversible upon discontinuation of the drug. Although the reported incidence of glucose intolerance varies from 6% to 60%, most cases are mild to moderate in severity ⁽¹⁴⁾.

Interferon therapy activates immune system cells to fight some cancers and certain infections. According to a survey on IFN therapy in Japan, some patients may experience earlier development of type 1 diabetes, resulting in initiation of insulin therapy ⁽¹⁵⁾. These

Table 52-1 Select Small-Molecule Kinase Inhibitors With Metabolic Adverse Effects

Drug	Type	Mechanism	Main Indications	Endocrine Adverse Effect(s) (rate)
Everolimus	Rapamycin analog	Inhibits mTOR	Advanced hormone receptor–positive, HER2-negative breast cancer; progressive neuroendocrine tumors of pancreatic origin; and advanced renal cell carcinoma	Hyperglycemia (50%) Hypercholesterolemia (76%) Hypertriglyceridemia (71%)
Temsirolimus	Rapamycin analog	Inhibits mTOR	Advanced renal cell carcinoma	Hyperglycemia (26%) Hypercholesterolemia (24%)
Idelalisib	Small-molecule inhibitor	Inhibits PI3 kinase selectively	Chronic lymphocytic leukemia	Hyperglycemia (54%)

HER2, human epidermal growth factor receptor; mTOR, mammalian target of rapamycin.

patients were positive for islet cell antibody and anti-glutamic acid decarboxylase antibodies (¹⁶).

We recommend monitoring of fasting serum glucose levels prior to the start of and during these therapies and possibly determining the levels of anti-islet autoantibodies before IFN therapy in patients with family history of type 1 diabetes mellitus (¹⁵).

Glucosuria

Some antineoplastic drugs (eg, ifosfamide and mercaptopurine) cause a proximal tubular defect and lower the renal threshold for glucosuria without affecting glucose metabolism. Glucosuria has been detected with an increased incidence in 67% of adult and 75% of pediatric patients treated with high-dose ifosfamide, cisplatin, and high-dose methotrexate, compared to the early postchemotherapy assessment (13% adults and 29% children) (¹⁷).

Lipid Disorders

Lipid disorders are seldom evaluated in the process of active anticancer therapy, because patients are often encouraged to maintain a positive metabolic balance via liberal oral intake. Investigation or treatment of mild lipid abnormalities is often overlooked because the focus is on maintaining a positive caloric balance during cancer treatment. Some lipid disorders may be short-lived without clear clinical consequences, but some may be of clinical importance and need to be detected and treated. In general, triglyceride levels higher than 1,000 mg/dL increase the rate of complications, including pancreatitis.

Lipid disorders are among the main side effects of vitamin A derivatives, which are commonly used in dermatologic disorders. One vitamin A derivative, bexarotene, has been used against malignancies like cutaneous T-cell lymphoma, acute promyelocytic leukemia, and head and neck cancer. Bexarotene is an agonist of retinoid X receptors, a family of peroxisome proliferator-activated receptors that are upregulated by the binding of bexarotene to a receptor on the nucleus. This upregulation not only regulates lipid metabolism but also affects thyroid hormone synthesis (¹⁸). Hypothyroidism contributes to lipid disorders in patients receiving bexarotene. Because bexarotene causes hypertriglyceridemia in approximately 40% of patients, lipid levels and thyroid functions should be checked before bexarotene therapy. If triglyceride levels are 200 to 400 mg/dL, dietary modifications are recommended. If triglyceride levels are 400 to 1,000 mg/dL, omega-3 fatty acids with fibrates or nicotinic acid should be started. Lipid levels should be checked after initiation of therapy, because triglyceride levels over 1,000 mg/dL increase the risk of acute pancreatitis (¹⁹).

Hypercholesterolemia is the second most common side effect of bexarotene, having been reported in 48% of treated patients (²⁰). The long-term significance of drug-induced hypercholesterolemia is unclear; however, atorvastatin has been successfully used to treat bexarotene-associated hypercholesterolemia in patients at the University of Texas MD Anderson Cancer Center (MDACC).

Mitotane, an analog of the insecticide dichlorodiphenyltrichloroethane, is used in patients with adrenocortical carcinoma as adjuvant therapy. The potential side effects of this therapy include hypercholesterolemia. Although the exact mechanisms of hypercholesterolemia remain unclear, mitotane stimulates hydroxymethylglutarate-coenzyme A reductase. A study from MDACC showed that mitotane increases high-density lipoprotein cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels (²¹). Patients with adrenocortical carcinoma usually have a poor prognosis, making the clinical significance of mild to moderate elevation of cholesterol uncertain. However, in long-term survivors on adjuvant mitotane therapy, hyperlipidemia can lead to early development of atherosclerotic disease. The benefits of treating mitotane-induced lipid abnormalities in long-term survivors have not been established.

Mammalian target of rapamycin inhibitors have metabolic side effects that include hypercholesterolemia and hypertriglyceridemia (see Table 52-1). Although the mechanisms of these side effects are unclear, hypercholesterolemia can be caused by dysregulation of sterol regulatory element binding proteins in the mTOR pathway (²²). Another possible mechanism is reduction in lipid clearance from the bloodstream (²³).

Before starting mTOR inhibitor therapy, baseline fasting glucose, LDL cholesterol, and triglyceride levels should be checked. The lipid profile should be monitored for every cycle. The goals of lipid-reducing therapy are to keep fasting LDL cholesterol at or below 190 mg/dL and triglycerides at or below 300 mg/dL, if life expectancy is >1 year. Therapeutic lifestyle changes are the first appropriate approach for patients with hyperlipidemia. If such lifestyle changes fail to reduce LDL cholesterol to ≤190 mg/dL, statin therapy should be started. The goals of LDL cholesterol reduction vary with patients' cardiovascular risk factors. Patients with triglyceride levels above 1,000 mg/dL have an increased risk for acute pancreatitis. Fibrate, omega-3 acid esters, niacin, and combination therapy are the treatment options for hypertriglyceridemia (⁵).

Water and Electrolyte Disorders

Serum osmolality is tightly regulated, primarily by interaction between the hypothalamic osmoreceptors

that regulate secretion of antidiuretic hormone from cells in the paraventricular and supraoptic nuclei, the hypothalamic thirst center, and the kidneys. Disruption of any of these regulators may lead to a disturbance in free water clearance and subsequent abnormalities in serum sodium levels.

Syndrome of Inappropriate Antidiuretic Hormone Secretion and Hyponatremia

Hyponatremia is a relatively common electrolyte abnormality in patients with cancer. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is one of the most common underlying causes for hyponatremia in this patient population. In addition to its association with hyponatremia, SIADH is characterized by low serum osmolality and an inappropriately high urine osmolality with elevated urine sodium. SIADH is a diagnosis of exclusion after ruling out hypovolemia, heart failure, renal insufficiency, cirrhosis, adrenal insufficiency, hypothyroidism, salt-wasting syndrome, and the use of diuretics. In patients with cancer, SIADH may be caused by ectopic antidiuretic hormone production by a variety of tumors. Syndrome of inappropriate antidiuretic hormone secretion is most commonly seen in patients with small cell lung cancer. Other tumors described (less commonly) in association with SIADH include malignant thymoma, oral squamous cell carcinoma, prostate carcinoma, and pancreatic carcinoma. Chemotherapy-induced lysis of antidiuretic hormone-containing cancer cells may lead to severe hyponatremia at the time of chemotherapy induction.

Other factors that may increase antidiuretic hormone secretion include nausea, pain, narcotics, and nicotine. Antineoplastic agents such as high-dose intravenous cyclophosphamide, vincristine, vinblastine, and cisplatin can also increase antidiuretic hormone secretion.

In cases of hyponatremia secondary to SIADH, urine osmolality is higher than plasma osmolality, and urine sodium is determined by sodium intake. In patients with SIADH, urine sodium is usually higher than 40 mEq/L. Fluid restriction (usually 500-1,500 mL of free water a day), an increase in salt intake, and occasionally, loop diuretics are attempted first in most cases of SIADH when the patient is asymptomatic or has mild symptoms. In the presence of severe symptoms (seizures or obtundation), hypertonic saline infusions might be needed with close and frequent monitoring of sodium levels to avoid rapid correction and possible osmotic demyelination syndrome (previously called central pontine myelinolysis). Demeclocycline (600-1,200 mg/d) can be used in cases in which hyponatremia does not respond to more fluid restriction. Vasopressin receptor (V2) antagonists (tolvaptan and

conivaptan) have been approved by the US Food and Drug Administration for treatment of clinically significant hypervolemic or euvolemic hyponatremia associated with heart failure or SIADH ⁽²⁴⁾.

Diabetes Insipidus and Hypernatremia

Central diabetes insipidus can occur after surgery for brain tumors and occasionally in cases of tumors near the sella or the hypothalamus that invade the neurohypophysis or disrupt the pituitary stalk. These cases are often recognized by a clinical presentation of polyuria or polydipsia and are usually treated with 1-deamino-8-D-arginine vasopressin (subcutaneously, intranasally, or orally) to control the symptoms and correct the associated hypernatremia.

Nephrogenic diabetes insipidus can also occur in patients with cancer, and multiple antineoplastic agents have been described in association with this syndrome. Ifosfamide is well known to induce damage to the proximal renal tubule and, to a lesser extent, the distal renal tubule, and thereby induce nephrogenic diabetes insipidus. Streptozocin has also been reported to cause nephrogenic diabetes insipidus.

In addition to being associated with diabetes insipidus, hypernatremia in patients with cancer is commonly caused by insufficiency of free water, especially when patients are on parenteral or tube feeding regimens or are too debilitated to obtain water for themselves.

DISORDERS OF BONE AND BONE MINERAL METABOLISM

Osteoporosis

Normal bone remodeling requires a delicate balance between bone formation by osteoblasts and bone resorption by osteoclasts. Antineoplastic therapy may affect this balance by increasing the activity of osteoclasts (eg, interleukin-2) and sometimes by having direct toxic effects on osteoblast function. Hormones and cytokines (ie, parathyroid hormone [PTH], PTH-related peptide, and interleukin-1) can also affect the overall bone turnover rate.

Bone mineral loss is one of the side effects of cancer treatment. Hormone-suppressive therapies, chemotherapeutics, and corticosteroids can cause osteoporosis in cancer patients ⁽²⁵⁾. Improved oncologic treatments and patient longevity have increased the importance of skeletal health in cancer patients.

Breast cancer patients are at high risk for osteoporosis after hormone-suppressive therapy ⁽²⁶⁾. Aromatase inhibitors, including anastrozole and letrozole, have been shown to decrease bone density and increase the rate of fractures in postmenopausal women. This

FIGURE 52-1 Mechanism of action of selective estrogen receptor modulators and aromatase inhibitors. Aromatase inhibitors, including anastrozole and letrozole, inhibit conversion of androstenedione or testosterone to estrone, which causes a decrease in bone mineral density. Tamoxifen, a selective estrogen receptor modulator, has a positive effect on bone.

is in sharp contrast to the positive effect on bone (both bone mineral density and fracture rates) seen with tamoxifen, a selective estrogen receptor modulator (Fig. 52-1). In the ATAC (Arimidex [anastrozole], Tamoxifen, Alone or in Combination) trial, 9,366 postmenopausal women with invasive operable breast cancer who had completed primary therapy were randomly assigned to receive anastrozole, tamoxifen, or both. More fractures were seen in patients receiving anastrozole compared with patients on tamoxifen⁽²⁷⁾. According to these findings, patients should undergo bone mineral density testing prior to treatment with aromatase inhibitors, and annual follow-up should be conducted thereafter. Antiresorptive therapy is usually added if a patient's bone density is within the osteoporotic range (T score ≤ -2.5) before treatment or if a significant decline in bone mineral density was seen during follow-up.

Osteoporosis can also occur in prostate cancer patients treated with androgen deprivation therapy (ADT), which can consist of gonadotropin-releasing hormone (GnRH) agonists, nonsteroidal antiandrogens, bilateral orchiectomy, and/or androgen blockers. These therapies can result in bone mineral loss and fractures⁽²⁸⁾ due to hypogonadism that increases bone resorption. The risk of fractures is higher in prostate cancer patients undergoing ADT than in those not undergoing ADT⁽²⁹⁾.

Patients with prostate cancer should be evaluated with dual-energy x-ray absorptiometry before starting ADT. Patients with fragility fractures or osteoporosis should be offered antiosteoporosis treatment. Before such treatment, nonpharmacologic approaches such as lifestyle modifications and calcium and vitamin D supplementation can be helpful⁽³⁰⁾.

Antineoplastic agents have also been implicated in chemotherapy-associated osteoporosis. Prolonged therapy with oral methotrexate for acute lymphoblastic leukemia has led to distal extremity pain, severe osteoporosis, and associated fractures, with significant improvement after cessation of methotrexate therapy⁽³¹⁾. Other agents reported to reduce bone density include cisplatin and carboplatin. In addition, many chemotherapy protocols include corticosteroids, which are known to decrease bone density and increase the risk of fractures.

Patients who have undergone bone marrow transplantation have been reported to have low bone mass. The reduced bone density is likely to be secondary to the long-term side effects of bone marrow radiation, chemotherapy, corticosteroids, and hypogonadism.

Osteoblasts and osteoclasts are under the influence of many hormonal and signaling pathways, including tyrosine kinase receptors for platelet-derived growth factor (PDGF receptors α and β) and c-Abl. Activation of the PDGF pathway improves bone mineral density in ovariectomized rats and accelerates fracture healing. The absence of c-Abl is associated with impaired osteoblast maturation, leading to an osteoporosis phenotype⁽³²⁾.

Multikinase inhibitors such as sorafenib, sunitinib, and imatinib, among others, can inhibit pathways that affect bone remodeling. Not much is known about the clinical effects of tyrosine kinase inhibitors, small molecules with variable receptor affinity and an intracellular signal blocking effect, on bone. Imatinib has been the best studied and will be discussed here.

After 2 to 4 years of treatment with imatinib in patients with chronic myelogenous leukemia, a significant increase in the volume of the trabecular bone in the iliac crest has been observed⁽³³⁾. Pre-osteoblast cells exposed to imatinib undergo suppression of PDGF-induced PI3 kinase/Akt activation with upregulation of genes associated with osteoblast differentiation and bone formation.

More studies are needed to determine the effects of imatinib and other tyrosine kinase inhibitors on bone and bone mineral metabolism.

Osteomalacia and Rickets

Osteomalacia occurs when normal mineralization of the organic bone matrix fails. In children, abnormal mineralization and maturation of the growth plate at

the epiphysis is called rickets. Nutritional deficiency (especially vitamin D deficiency) and renal wasting of phosphorus leading to hypocalcemia or hypophosphatemia are among the common causes of osteomalacia. Other contributing factors include drugs such as anticonvulsants or aluminum and systemic acidosis. Antineoplastic agents can also cause or worsen osteomalacia.

Ifosfamide-induced tubular damage leads to renal phosphate wasting, hypophosphatemia, and rickets. Although renal and skeletal consequences of ifosfamide therapy have been well described in children, only four adult patients with osteomalacia have been reported⁽³⁴⁾. Another antineoplastic agent, the estrogen derivative estramustine, used in prostate cancer metastatic to bone, can cause hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and osteomalacia with normal vitamin D levels⁽³⁵⁾.

Hypercalcemia

Calcium homeostasis is normally maintained by the interplay of PTH, calcitonin, phosphorus, and vitamin D metabolites in several target organs, including bones, parathyroid glands, intestines, and kidneys. In patients with cancer, multiple factors can affect this delicate balance, including nutritional status, medications, and tumor secretion of cytokines, hormones, or other humoral factors.

Hypercalcemia occurs in 5% to 10% of all patients with advanced cancer, and severe hypercalcemia (calcium level >12 mg/dL) is seen in about 0.5% of all patients with cancer⁽³⁶⁾. Squamous carcinoma, renal cell carcinoma, non-small cell lung carcinoma, breast carcinoma, leukemia, non-Hodgkin lymphoma, and multiple myeloma are among the most common malignancies associated with hypercalcemia. Retinoic acid derivatives have been reported to induce hypercalcemia in treatment of acute promyelocytic leukemia⁽³⁷⁾.

Hyperparathyroidism occurs 2.5 to 3 times more often in patients treated with low-dose (2-7.5 Gy) external radiation to the head and neck area than in the age-matched control population. Hyperparathyroidism after high-dose irradiation is uncommon. Radiation exposure from radioactive iodine treatment has also been reported in association with hyperparathyroidism⁽³⁸⁾.

Hypocalcemia

Many factors can increase a cancer patient's risk of hypocalcemia. These factors include the patient's nutritional status, the antineoplastic agents used, and the type of surgical procedures performed (eg, neck

dissection). Cytotoxic chemotherapy can result in tumor lysis syndrome and its resultant hypocalcemia, as commonly seen in treatment of hematologic malignancies. Hyperphosphatemia, hyperkalemia, hypocalcemia, and hyperuricemia can occur after induction chemotherapy; it is of vital importance to prevent the complications of tumor lysis by hydration, alkaline diuresis, inhibition of uric acid synthesis, and administration of oral calcium or aluminum-based compounds to bind intestinal phosphate and enhance calcium absorption. Intravenous calcium administration can potentially cause calcium phosphate precipitation in the presence of severe hyperphosphatemia and should be used with extreme caution. Dialysis may be needed in cases of symptomatic hypocalcemia and serum phosphorus levels higher than 10 mg/dL.

Cisplatin has been associated with hypocalcemia. One proposed mechanism of cisplatin's ability to induce hypocalcemia is through hypomagnesemia resulting in decreased PTH secretion⁽³⁹⁾. Other theories include inhibition of 1,25-dihydroxy-vitamin D formation by hypomagnesemia or cisplatin inhibition of mitochondrial function in the proximal renal tubule. Other agents reported to induce hypocalcemia include dactinomycin, carboplatin, doxorubicin, and cytarabine. Hypocalcemia has been seen following administration of bisphosphonates (zoledronic acid and pamidronate) or denosumab (a monoclonal antibody that inhibits receptor activator of nuclear factor- κ B ligand [RANKL]), both used to reduce skeletal complications in treatment and prevention of advanced malignancies involving the bone⁽⁴⁰⁾. Serum calcium levels and 25-hydroxyvitamin D levels should be checked prior to and during therapy with bisphosphonates or denosumab.

Hypomagnesemia

Hypomagnesemia is a well-known side effect in patients receiving platinum-based chemotherapy. Cisplatin has toxic effects on the kidneys, causing morphologic changes and necrosis in the proximal tubule, a major site of magnesium reabsorption. Hypomagnesemia is a frequent complication of cisplatin chemotherapy, affecting up to 90% of patients; 10% of these patients have symptoms of muscle weakness, tremulousness, and dizziness. A recent study showed that premedication with magnesium reduced cisplatin-induced nephrotoxicity in patients with thoracic cancers⁽⁴¹⁾.

Carboplatin, a second-generation platinum compound, was developed to reduce the side effects of cisplatin. However, hypomagnesemia has been seen with increasing frequency and severity at higher doses of carboplatin.

Oxaliplatin, a third-generation platinum derivative that has become an integral part of various chemotherapy protocols, particularly in advanced colorectal cancer, has dose-limiting cumulative sensory neurotoxicity similar to that of cisplatin. Oxaliplatin chelates to calcium and decreases magnesium levels. Hypomagnesemia was seen in 11% of patients with advanced epithelial ovarian cancer treated with oxaliplatin in a phase II trial⁽⁴²⁾. Oxaliplatin is considered to carry a lower risk for hypomagnesemia compared with cisplatin and carboplatin.

Cetuximab, a monoclonal antibody against the epithelial growth factor receptor (EGFR), is used to treat metastatic colon cancer. Because EGFR is common in the loop of Henle, cetuximab blocks reabsorption of magnesium in the kidneys. Increased renal wasting of magnesium can cause supplement-resistant hypomagnesemia. Magnesium levels should be checked before and during cetuximab therapy. Cetuximab-induced hypomagnesemia is also used as a marker of worse overall survival⁽⁴³⁾.

PITUITARY AND HYPOTHALAMIC DISORDERS

Hypothalamic-pituitary damage leading to single or multiple hormonal deficiencies can occur in patients treated with cranial or craniospinal irradiation or intracranial surgery. Cranial radiation therapy is often

used to treat leukemia and lymphoma, nonpituitary brain tumors, pituitary tumors, nasopharyngeal carcinoma, and skull base tumors⁽⁴⁴⁾. The hypothalamus appears to be more radiosensitive than the pituitary gland and may be damaged by low radiation doses (<40 Gy), but high radiation doses are likely to damage both hypothalamic and pituitary functions. Deficiency in one or more pituitary hormones occurs following irradiation (>40 Gy) of the hypothalamic-pituitary area in about 90% of patients 5 years after radiation treatment (Fig. 52-2)⁽⁴⁵⁾.

Ipilimumab, an immunoglobulin G1 antibody that blocks cytotoxic T lymphocyte-associated antigen 4 (CTLA4), is used to treat melanoma and renal cell carcinoma. Ipilimumab-induced autoimmune hypophysitis was reported in 11% of patients in a retrospective study (Table 52-2)⁽⁴⁶⁾. The risk factors for ipilimumab-induced hypophysitis are male gender and old age⁽⁴⁷⁾. The typical clinical presentation includes headache, fatigue, and nausea. Magnetic resonance imaging (MRI) may reveal pituitary gland and stalk enlargement. After cessation of the drug, pituitary morphology returns to normal (Fig. 52-3)⁽⁴⁸⁾. The earliest and most frequently affected hormone is adrenocorticotrophic hormone (ACTH), but other hormones can also be affected; the effects often disappear after drug cessation. Physicians should be aware of hypopituitarism symptoms and test for adrenal insufficiency, hypogonadism, and hypothyroidism.

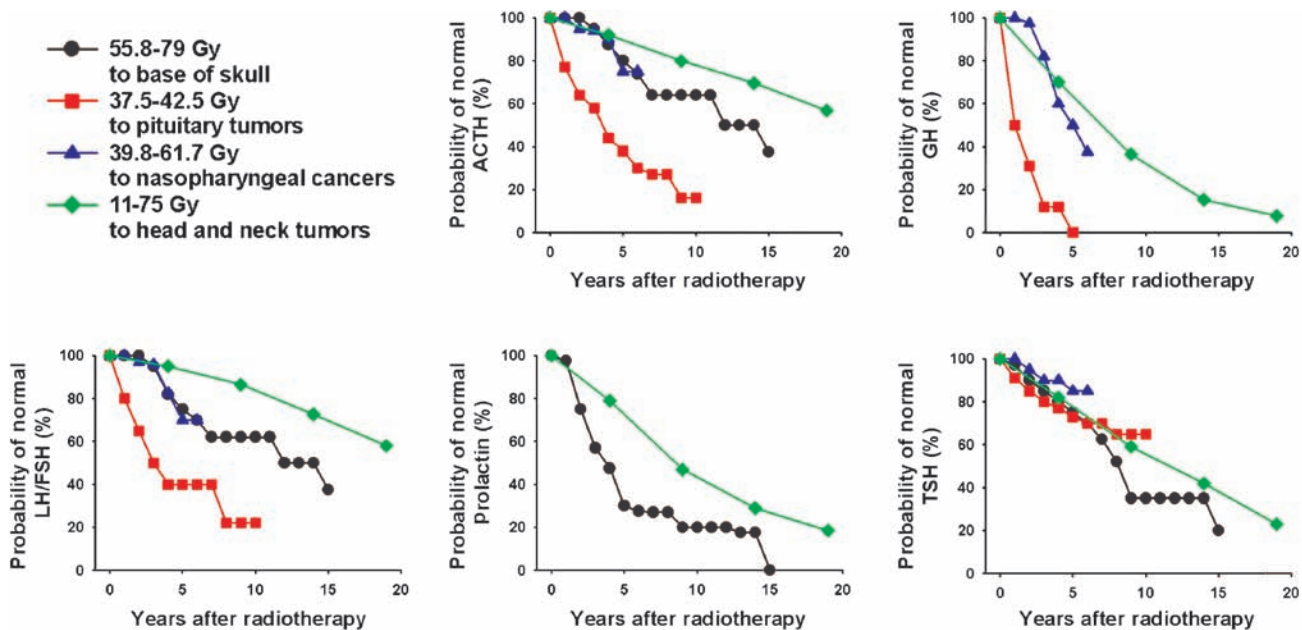

FIGURE 52-2 Probability of normal pituitary hormone secretion over time after irradiation of the hypothalamic-pituitary area. The data are from four studies: Pai et al⁽⁵⁵⁾, in which 55.8 to 79 Gy was administered to the base of the skull; Shalet et al⁽⁴⁵⁾, in which pituitary tumors were treated with 37.5 to 42.5 Gy; Appelman-Dijkstra et al⁽⁵⁴⁾, in which nasopharyngeal carcinoma was treated with 39.8 to 61.7 Gy; and Samaan et al⁽⁵⁶⁾, in which 11 to 75 Gy was administered to treat head and neck tumors. ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Table 52-2 Novel Immunotherapeutic Agents With Endocrine Adverse Effects

Drug	Type	Mechanism	Endocrine Adverse Effects
Ipilimumab	IgG1 monoclonal antibody	Blocks CTLA4 receptor	Hypophysitis Thyroiditis Graves disease
Pembrolizumab	IgG4 monoclonal antibody	Blocks PD-1 receptor	Hypothyroidism Transient thyrotoxicosis

CTLA4, cytotoxic T lymphocyte-associated antigen 4; Ig, immunoglobulin; PD, programmed death.

Growth Hormone Deficiency

Growth hormone deficiency is frequently noted after cranial irradiation. In children, isolated GH deficiency can occur after low radiation doses, but high doses may produce panhypopituitarism. Hypopituitarism appears to be dose dependent. At low doses (20-24 Gy), the only effect may be an altered pulsatile secretory pattern. At doses higher than 30 Gy, deficient GH secretion and growth retardation are observed in more than a third of patients (Fig. 52-4). Children who receive cranial irradiation require long-term follow-up (49).

Growth hormone deficiency is also common in adults who have undergone cranial radiation therapy. In those patients, GH deficiency is thought to cause decreased bone and muscle mass, fatigue, impaired sense of well-being, lowered exercise capacity, increased volume of adipose tissue, and altered myocardial function. In addition, patients with GH deficiency may have a higher occurrence of atherosclerotic plaques and an increased risk for cardiovascular diseases. GH replacement in these patients can restore normal adipose tissue composition, bone metabolism, quality of life, sense of well-being, lipid profile, and cardiac function. Despite the apparent benefits, data on the effect of GH replacement in long-term cancer survivors are still lacking. Growth hormone replacement is contraindicated in any patient with an active malignant condition, but it can be initiated in an adult in whom malignant disease has been absent for at least 5 years. Another treatment reported to result in GH deficiency is long-term intrathecal opioids. Patients receiving this treatment have about a 15% elevation in the risk of developing GH deficiency (50).

Central Hypothyroidism

Radiation therapy can cause immediate and long-term effects. One such effect, central hypothyroidism, may be a result of the possible effects of brain or head and neck irradiation on hypothalamic and pituitary regulation of thyroid-stimulating hormone (TSH) secretion. Not only cranial irradiation but also craniospinal irradiation can cause central hypothyroidism. In one study, central hypothyroidism was detected a year after the end of radiation treatment in 6% of patients (51). In that study, 15% to 20% of patients who had undergone cranial irradiation had diminished TSH secretion 5 years after the end of treatment, and approximately 35% of those patients had it after 10 years. Because of the combined effect of irradiation on the thyroid gland and the hypothalamic-pituitary axis, we suggest measuring patients' levels of both serum free thyroxine and TSH concentrations yearly or if the patients is having symptoms suggestive of hypothyroidism to replace thyroid hormones when necessary.

Chemotherapy may enhance the deleterious effect of radiation. Children with brain tumors (not involving the hypothalamic-pituitary axis) who receive vincristine, carmustine, lomustine, or procarbazine in combination with brain irradiation have a 35% incidence of hypothyroidism, compared with a 10% incidence in children who undergo brain irradiation alone (52).

Bexarotene was found to cause central hypothyroidism in 40% of patients with cutaneous T-cell lymphoma (20). Reversible, retinoid X receptor-mediated suppression of TSH secretion is one explanation for this side effect. Bexarotene patients often require higher levothyroxine dose compared with patients with other causes of hypothyroidism. This observation

FIGURE 52-3 Magnetic resonance images of a patient before (A), during (B), and 8 weeks after (C) ipilimumab therapy.

FIGURE 52-4 A patient with short stature due to growth hormone deficiency resulting from radiation treatment of a brain tumor.

is related to bexarotene-related increase in thyroid hormone metabolic clearance ⁽⁵³⁾.

Hypogonadotropic Hypogonadism

Brain surgery and irradiation of the skull carry the potential for hypothalamic-pituitary damage, including hypogonadotropic hypogonadism. Hypogonadism occurs within 7 years after cranial irradiation for non-pituitary neoplasia in 25% of patients. Hypogonadism is transient in the presence of hyperprolactinemia and is treated with antidopaminergic therapy ⁽⁵⁴⁾. Hyperprolactinemia is the most commonly reported hormonal abnormality in patients who have undergone head and neck irradiation, occurring in more than 66% of patients ^(55, 56). Hyperprolactinemia inhibits

FIGURE 52-5 Loss of axillary hair in a patient who developed secondary hypogonadism after cranial irradiation.

gonadotropin secretion from the pituitary gland and decreases the responsiveness of the pituitary gland to GnRH, causing secondary hypogonadism. In children, inadequate sexual development, delayed puberty, and absent menarche are significant problems, whereas in adults, gonadotropin deficiency may cause sex steroid hormone deficiency, infertility, and loss of axillary and pubic hair (Fig. 52-5). Sex steroid hormone deficiency lowers libido and may have deleterious effects on bone and lipid metabolism.

Early or even precocious puberty has also been reported in patients with acute lymphoblastic leukemia treated with combined chemotherapy and cranial irradiation and in patients with brain tumors treated with cranial irradiation. This phenomenon is more common in girls. Coexisting GH deficiency is frequently noted. In a recent study of male cancer survivors (excluding those who had undergone treatment that may have otherwise affected gonadal function), chronic opioid therapy, given in morphine-equivalent daily doses of at least 200 mg daily, was associated with secondary hypogonadism ⁽⁵⁷⁾.

THYROID DISORDERS

Thyroid Neoplasms

Ionizing radiation is implicated in the etiology of thyroid cancer. Irradiation of the thyroid, especially in children and young adults (such as young patients with Hodgkin disease), increases the risk of papillary thyroid carcinoma ⁽⁵⁸⁾.

Hyperthyroidism

Radiation-induced hyperthyroidism has been described but is far less common than radiation-induced hypothyroidism.

Radiation-induced silent thyroiditis with transient thyrotoxicosis has been reported in patients treated with radiation. Thyroiditis-induced thyrotoxicosis occurs within a few months of radiation therapy in most cases; hypothyroidism occurs several months later. The risk of Graves disease increases following radiation therapy. Patients with lymphoma treated with radiation constitute the largest number of patients who have developed Graves disease after radiation therapy; this finding raises the possibility of a relationship between the two clinical entities. Patients treated with radiation for nasopharyngeal, breast, and/or laryngeal carcinomas may also develop Graves disease. Cytokines have also been reported to lead to Graves disease. Interferon is known to induce the production of autoantibodies and can lead to autoimmune thyroid disease, such as autoimmune primary hypothyroidism, transient thyrotoxicosis, or more rarely, Graves disease. Women have a higher risk than men of developing autoimmune thyroid disease upon starting IFN treatment⁽⁵⁹⁾. It is important to distinguish the cases in which IFN induces transient thyrotoxicosis followed by hypothyroidism from the cases in which IFN induces Graves disease. Thyroid scans showing increased homogeneous uptake in the presence of hyperthyroidism are highly suggestive of Graves disease and warrant treatment with antithyroid medications (eg, methimazole).

Systemic therapies can also be linked to hyperthyroidism. Monoclonal antibodies directed against CTLA4 (ipilimumab and tremelimumab) and anti-CD52 antibody (alemtuzumab) are associated with painful thyroiditis and Graves disease⁽⁶⁰⁾. Interleukin-2 (denileukin diftitox) treatment alone causes transient hyperthyroidism followed by hypothyroidism in about 50% of patients⁽⁶¹⁾. The mechanism of interleukin-2-induced autoimmune thyroid dysfunction is unclear, although interleukin-2-induced disruption of self-tolerance has been suggested as a mechanism. Tyrosine kinase inhibitors can cause transient thyrotoxicosis via destructive thyroiditis⁽⁶⁰⁾. Pembrolizumab treatment caused hyperthyroidism in 1 of 135 patients in a safety study⁽⁶²⁾.

Hypothyroidism

Head and neck irradiation frequently causes dysfunction of the thyroid gland. Radiation can induce primary hypothyroidism when given in doses higher than 25 Gy to the region near the thyroid gland (Fig. 52-6). Secondary and tertiary hypothyroidism can be seen with doses

FIGURE 52-6 Mapping of radiation ports on a patient with squamous cell cancer of the head and neck. The patient developed primary hypothyroidism 2 years after radiation therapy.

of 40 Gy or higher to the hypothalamic-pituitary area. Most cases of primary hypothyroidism occur about 5 years after radiation therapy. The probability of hypothyroidism is dose related and increases with duration of follow-up after radiation treatment. In a study of 1,677 patients with Hodgkin disease whose thyroid had been irradiated, the risk of thyroid disease was 52% and 67% after 20 and 26 years, respectively⁽⁶³⁾. Four hundred eighty-six patients (29%) received thyroxine therapy because of elevated serum TSH concentrations, and 27 (2%) had transient elevations in serum thyrotropin level that were not treated. A recent review estimated the rate of hypothyroidism after thyroid irradiation to be 20% to 30%, with half of the cases occurring within the first 5 years⁽⁶³⁾.

A significant number of patients develop subclinical hypothyroidism (elevated TSH with normal thyroxine levels), not overt hypothyroidism, when less than 40 Gy of radiation is administered. Subclinical hypothyroidism (20%) is more frequent than overt hypothyroidism (5%) 5 years after chemotherapy and radiation therapy⁽⁶⁴⁾. Multiple factors increase the risk for hypothyroidism, including high doses of radiation to the head and neck, combined radiation and surgical treatments, time interval since therapy, and failure to shield midline structures. Other risk factors include thyroid resection during a laryngectomy or disruption of the vascular supply of the thyroid gland during surgery.

The use of iodine-131 (¹³¹I) may result in thyroid dysfunction. The use of ¹³¹I-metaiodobenzylguanidine in treatment of metastatic pheochromocytoma carries the possibility of inducing primary hypothyroidism and requires routine use of potassium perchlorate to block the thyroid ¹³¹I uptake.

Interferon therapy is associated with primary hypothyroidism in about 10% of treated patients and was not related to IFN dosage⁽⁶⁵⁾. The presence of pretreatment serum antithyroid antibodies in patients treated with IFN therapy increases the risk for development of IFN-induced thyroid disease. During 6 years of observation after IFN therapy, the absence of thyroid autoantibodies at the end of IFN treatment was found to be a protective factor against development of thyroiditis, whereas positivity for thyroid antibodies at high titers at the end of IFN treatment was significantly related to chronic subclinical hypothyroidism. Interferon-related thyroid autoimmunity is not a completely reversible phenomenon, because some patients develop chronic thyroiditis, especially in the presence of high autoantibody titers.

Interleukin-2 causes painless thyroiditis with acute onset, with initial hyperthyroxinemia followed by primary hypothyroidism. The hypothyroidism may last months but is occasionally permanent; 9% of patients require replacement thyroid hormone therapy⁽⁶⁶⁾.

Patients treated with multiple antineoplastic agents (with or without radiation) also have a higher than normal incidence of primary hypothyroidism. Fifteen percent of patients who received a combination of cisplatin, bleomycin, dactinomycin, vinblastine, and etoposide developed elevated TSH levels with normal free triiodothyronine (T_3) and free thyroxine (T_4), compatible with subclinical primary hypothyroidism, in contrast to the control group⁽⁶⁷⁾.

The targeted therapy has also been linked to development of a variety of thyroid abnormalities. For example, autoimmune thyroid disease has been seen in 23% of patients receiving alemtuzumab⁽⁶⁸⁾.

Imatinib use was reported to increase levothyroxine requirements in thyroidectomized patients, whereas nonthyroidectomized patients had no significant alterations of their thyroid functions. These data suggest that imatinib and maybe tyrosine kinase inhibitors in general may accelerate the clearance of levothyroxine, leading to clinical hypothyroidism in patients who are dependent on exogenous levothyroxine⁽⁶⁹⁾.

Thyroid dysfunction was reported in 21% of renal cell carcinoma patients receiving sorafenib⁽⁷⁰⁾. Prospective studies estimated the risk of thyroid dysfunction to reach 68%; however, only 6% of patients had clinical symptoms requiring thyroid hormone replacement⁽⁷¹⁾. Sorafenib-related thyroiditis has been suggested as a mechanism of thyroid dysfunction in some of the patients, but it is unclear if thyroid dysfunction represents an autoimmune process or a manifestation of vascular endothelial growth factor blockade affecting the thyroid blood supply.

Sorafenib also affects the thyroid hormone replacement dose requirement in thyroidectomized patients with differentiated or medullary thyroid cancer. In

one study, the dose of L-thyroxine had to be changed in 42% of the patients using sorafenib⁽⁷²⁾. Another study showed that the daily dose of L-thyroxine was increased in 19% of patients and decreased in 16% of patients with anorexia and weight loss⁽⁷³⁾.

Similarly, thyroid dysfunction was reported in 62% of patients receiving sunitinib, including 36% of patients who had persistent elevation of TSH, which was suggestive of primary hypothyroidism, especially in patients with longer sunitinib use. Destructive thyroiditis has been suggested as an explanation, although some patients became athyrotic on sunitinib after having normal thyroid function at baseline⁽⁷⁴⁾. Another study showed that thyroid size was reduced to 59% after 12 months of sunitinib use in patients with renal cell carcinoma⁽⁷⁵⁾. Other prospective studies found that 27% of patients receiving sunitinib had elevated TSH requiring hormone replacement⁽⁷⁶⁾. Some patients were reported to present with thyrotoxic phase preceding hypothyroidism, which further supports the theory of sunitinib-related destructive thyroiditis leading to hypothyroidism in these patients⁽⁷⁷⁾. Impaired iodine uptake and inhibition of peroxidase activity were also suggested as potential mechanisms to explain hypothyroidism^(78,79).

Ipilimumab-induced activation of T cells results in not only antitumor activity but also immune infiltration of endocrine glands. The major endocrine glands affected by ipilimumab are the pituitary and thyroid glands. Although hypophysitis causes central hypothyroidism, thyroiditis causes primary hypothyroidism⁽⁸⁰⁾.

Pembrolizumab is an anti-programmed cell death (PD)-1 antibody that blocks interaction of PD-1 with the PD-L1 or PD-L2 ligand (see Table 52-2). Although PD-1 is expressed by T lymphocytes, PD-L1 or PD-L2 on tumor cells inhibits T-lymphocyte action. Anti-PD-1 antibody reverses this inhibition. The US Food and Drug Administration granted the approval to use pembrolizumab in patients with unresectable or metastatic melanoma. Primary hypothyroidism has been reported to occur in 8.3% of patients receiving pembrolizumab, with median time to onset being 3.5 months (range, 0.7 weeks to 19 months). Because the timing of the onset of thyroid dysfunction varies widely, patients who have received pembrolizumab should be monitored closely for changes in thyroid function⁽⁶²⁾.

Abnormalities in Thyroid Hormone-Binding Proteins

Thyroid hormones are preferentially bound to thyroid hormone-binding globulin (TBG) (65%-70%), transthyretin (15%-20%), and albumin (10%-15%). Multiple factors can affect the levels of these binding proteins and the subsequent levels of bound thyroid hormones.

In patients with malignancies, changes in sex hormone levels, glucocorticoids, narcotics, nutritional status, and some antineoplastic agents are the major factors affecting the protein-binding properties. Overall, the level of total T_3 and T_4 may be affected, but in general, the levels of free (biologically active) hormones are normal. The effect on TBG synthesis or clearance is usually reversible. Not only are estrogens known to increase TBG and total thyroid hormone levels, but tamoxifen also causes elevated plasma concentrations of TBG in postmenopausal women with breast cancer after 6 months of therapy. Nonsteroidal aromatase inhibitors (anastrozole and letrozole) are known to lower estrogen levels, but the effect on TBG has still not been fully documented in the literature; when letrozole was given at 2.5 mg/d, however, there was a statistically significant decrease in total T_4 but not total T_3 levels⁽⁸¹⁾.

Glucocorticoids are frequently used in combination with chemotherapy and are known to suppress TSH secretion and inhibit TBG synthesis. L-Asparaginase can inhibit the synthesis of albumin and TBG, which affects serum thyroid hormone levels. 5-Fluorouracil increases total T_3 and T_4 levels and maintains a normal free thyroxine index, suggesting that this agent increases serum thyroid hormone-binding proteins, resulting in normal thyroid function⁽⁸²⁾.

Mitotane increases the levels of hormone-binding globulins, but the increase in TBG is less remarkable than mitotane's effect on corticosteroid-binding globulin.

ADRENAL DISORDERS

Primary Adrenal Insufficiency

Mitotane is an orphan drug mostly used to treat adrenocortical carcinoma. Mitotane has selective toxicity to both normal and malignant adrenocortical cells. It also causes an increase in serum levels of cortisol-binding globulin⁽⁸³⁾. Glucocorticoid replacement therapy is needed when mitotane is used; high doses are required because of the increased levels of binding globulin and enhanced metabolic clearance of corticosteroids by mitotane.

Animal studies found cases of adrenal necrosis associated with sunitinib use, leading the Food and Drug Administration to recommend monitoring adrenal functions in patients receiving sunitinib. However, there was no evidence of adrenal hemorrhage or clinical evidence of adrenal insufficiency in subsequent clinical safety data⁽⁸⁴⁾.

Secondary Adrenal Insufficiency

Prolonged glucocorticoid treatment is the most common cause of adrenal dysfunction in patients with cancer. Secondary (central) adrenal insufficiency may

develop up to 2 years after discontinuation of glucocorticoids and can persist for months. Irradiation of the hypothalamic-pituitary region causes ACTH deficiency with resultant secondary adrenal insufficiency in 19% to 42% of patients. The median time to development of adrenal insufficiency after radiation therapy is 5 years, but onset can occur in as little as 2 years. The 1- μ g cosyntropin stimulation test has been proposed to screen central adrenal insufficiency in cancer survivors who received >30 Gy of radiation to hypothalamic and pituitary areas⁽⁸⁵⁾.

Prolonged therapy with busulfan was initially reported to cause a reversible clinical syndrome resembling central adrenal insufficiency as evidenced by metyrapone testing. No recent reports have corroborated this finding. Long-term intrathecal opioid therapy for intractable nonmalignant pain resulted in central adrenal insufficiency in 15% of patients tested for insulin-induced hypoglycemia⁽⁵⁰⁾.

Megestrol acetate is used to stimulate appetite in patients with cancer, but its prolonged use can lead to a Cushing-like syndrome, and sudden withdrawal after prolonged treatment may result in adrenal insufficiency. Megestrol shows glucocorticoid-like effects with an acute suppressive effect on the hypothalamic-pituitary axis and ACTH secretion, leading to central adrenal insufficiency as determined with the 1- μ g cosyntropin stimulation test^(86, 87). Secondary adrenal insufficiency can be diagnosed by a variety of tests with varying sensitivity and specificity, but in our practice, we frequently use a combination of basal (8:00 AM) serum cortisol and ACTH measurement as well as 1- μ g cosyntropin stimulation testing. Rarely, insulin-induced hypoglycemia is used to assess the overall cortisol and GH response to hypoglycemia when evaluating patients for panhypopituitarism.

GONADAL DISORDERS

Direct radiation exposure and cytotoxic chemotherapeutic agents are common causes of hypogonadism and infertility in cancer survivors. Because of the considerable differences between female and male gametogenesis, cancer therapy can have a variety of effects on fertility and gonadal functions in the two sexes.

Female Gonadal Disorders

Oogenesis occurs during embryonic life, and oocytes remain quiescent most of their lifespan; it is this property that makes oocytes resistant to the adverse effects of cytotoxic chemotherapy. However, because the number of oocytes is limited, damage to oocytes may in effect shorten a woman's reproductive period. Granulosa cells are also susceptible to cytotoxic drugs, as

FIGURE 52-7 Hematoxylin and eosin staining of a biopsy sample showing atrophy of ovarian tissue after cytotoxic chemotherapy.

evidenced by the results of ovarian biopsies performed after chemotherapy (Fig. 52-7). Infertility may occur as a result of impairment of either granulosa cells or oocytes.

With advances in cancer treatment, an increasing number of women survive malignancies to face reproductive disorders. It is of vital importance to discuss fertility issues before radiation or systemic chemotherapy, because these modalities carry significant risks for ovarian dysfunction and infertility. The effects of radiation treatment on the ovaries differ with patient age, radiation dose, and field of treatment. Radiation treatment that includes the pelvis increases the risk of infertility more than radiation treatment that includes only the abdomen⁽⁸⁸⁾. Pregnancy rates decrease at doses between 5 and 10 Gy⁽⁸⁹⁾. Fractionated radiation seems to carry less risk for permanent sterility. When possible, fractionated radiation should be used with shielding of the gonads, and restriction of radiation fields reduces the risk of ovarian failure. Ovarian transposition (oophoropexy) to the paracolic gutters before pelvic irradiation has been suggested to preserve ovarian function in women less than 40 years of age with cervical carcinoma less than 3 cm in diameter⁽⁹⁰⁾. Ovarian transposition can also be used prior to pelvic irradiation in other diseases, including lymphoma. This procedure can be done by either a laparotomy or a laparoscopy with the intent of preventing radiation-induced (but not chemotherapy-induced) ovarian failure. Assisted fertilization is often needed after this procedure.

Oocyte cryopreservation has been proposed as a means of preserving fertility in women treated for cancer, but it has been less successful in humans than in animal models. Ovarian tissue cryopreservation and transplantation have also been proposed for patients before cancer treatment.

The ethical issues behind these techniques are still being disputed, and there is still the concern of potential disease recurrence from residual disease in autografted ovarian tissues. Obtaining unilaminar follicles from cryopreserved, thawed tissue and growing

them in vitro has been proposed to reduce the risk of recurrence. The cytotoxic effects of chemotherapeutic agents are seen more in rapidly dividing cells than in cells at rest, which led to the hypothesis⁽⁹¹⁾ that GnRH agonists would suppress the hypothalamic-pituitary-ovary axis and make the ovaries less susceptible to the cytotoxic effects of chemotherapy. In animal models, GnRH agonist therapy lowered cyclophosphamide-induced but not radiation-induced ovarian toxicity. Some studies have reported encouraging results of the use of this approach in women with breast cancer, leukemia, and lymphoma⁽⁹¹⁾. Another study showed that GnRH agonist therapy may protect ovarian reserve but does not decrease the risk of premature ovarian failure in patients treated for lymphoma⁽⁹²⁾.

In premenopausal women with breast cancer treated with regimens based on anthracyclines (5-fluorouracil, epirubicin, and cyclophosphamide), the rate of chemotherapy-related amenorrhea is 93%. At the end of therapy, menstrual periods resumed in 24% of the patients⁽⁹³⁾.

Alkylating agents, which are non-cell-cycle specific, are generally highly gonadotoxic. Mechlorethamine is usually used in combination with vincristine, procarbazine, and prednisone. This combination is highly gonadotoxic, but the exact contribution of mechlorethamine to the gonadotoxicity is difficult to evaluate. Chlorambucil, melphalan, busulfan, and cyclophosphamide also carry a high risk of ovarian damage. Ovarian failure with alkylating agents was found to impose the highest risk with an estimated odds ratio (relative to no treatment) of 3.98⁽⁹⁴⁾. The extent of cisplatin toxicity in women is less well defined, with an odds ratio (relative to no treatment) of 1.77. Temporary amenorrhea developed in 2 of 12 female patients in whom cisplatin (0.4-0.6 g/m²) was used in combination with bleomycin and vinblastine to treat ovarian germ cell tumors; the amenorrhea lasted from 12 to 15 months after the cessation of chemotherapy⁽⁹⁴⁾.

Transient and permanent ovarian failure has been reported with etoposide use⁽⁹⁵⁾.

Antimetabolites, which are cell-cycle specific, may exert few toxic effects on the ovaries. As a single agent, doxorubicin has few, if any, adverse effects on ovarian function, although a synergistic effect of the combination of doxorubicin and cyclophosphamide is a concern.

Vinblastine has been known to cause reversible and dose-related amenorrhea when combined with alkylating agents⁽⁹⁶⁾.

Male Gonadal Disorders

Spermatogenesis occurs in a continuous cycle of meiosis, mitosis, differentiation, and maturation. Germ cells and spermatogonia, in contrast to Leydig or

Sertoli cells, are sensitive to cytotoxic agents. If sufficient germ cells remain after cytotoxic chemotherapy, resumption of spermatogenesis usually occurs; the longer the duration of azoospermia, the lower is the likelihood of spermatogenesis recovery⁽⁹⁷⁾.

Radiation damage to the gonads is dose dependent. Low-dose testicular irradiation leads to a transient suppression of sperm counts with a recovery time proportional to the radiation dose⁽⁹⁸⁾. However, permanent infertility was reported in patients who received fractionated radiation doses of more than 2 Gy (Fig. 52-8), whereas clinically significant Leydig cell impairment occurs rarely with doses of less than 20 Gy⁽⁹⁹⁾.

Therapy with alkylating agents such as cyclophosphamide or chlorambucil administered alone may result in reversible but prolonged azoospermia. Chlorambucil causes azoospermia at cumulative doses of

400 to 800 mg; recovery may take 3 to 4 years after a mean total dose of about 750 mg/m²⁽¹⁰⁰⁾. Cyclophosphamide affects spermatogenesis more than Leydig cell function, causing reduced sperm count with normal testosterone levels.

Antineoplastic agents causing azoospermia in humans can be classified in four groups. The first group consists of chemotherapeutics that cause prolonged azoospermia: chlorambucil, cyclophosphamide, procarbazine, melphalan, and cisplatin. The chemotherapeutics in the second group, carmustine and lomustine, cause azoospermia in adults who had chemotherapy treatment prior to puberty. The agents in the third group cause prolonged azoospermia when given with other sterilizing agents; this group consists of busulfan, ifosfamide, nitrogen mustard, and dactinomycin. The agents in the fourth group have additive

FIGURE 52-8 A young male patient after therapeutic irradiation of the left testicle for a testicular tumor. Note the loss of body hair, hypogonadal facial puffiness, decreased muscle mass, and increased body fat (A). The left testicle was small and firm (B). The patient was infertile.

and temporary effects on azoospermia when combined with agents from the other three groups; this group consists of doxorubicin, thiotepa, cytosine arabinoside, and vinblastine⁽¹⁰¹⁾.

Multiple methods of preventing or reversing infertility in men treated for cancer have been suggested. In rats, fertility can be restored by suppressing testosterone with GnRH agonists or antagonists, either before or after cytotoxic therapy. This approach does not protect survival of stem cells in the testes but enhances the ability of the testes to maintain differentiation of type A spermatogonia⁽¹⁰²⁾. It would be premature to apply this method to everyday clinical practice, as the limited data from human trials did not show this benefit. Semen cryopreservation before starting gonadotoxic therapy followed by assisted fertilization is another strategy to preserve fertility in men with cancer.

SURVEILLANCE FOR COMPLICATIONS IN CANCER SURVIVORS

Primary care physicians and oncologists should be aware of the major long-term consequences of cancer therapy for early detection and management of treatment-related side effects. Long-term follow-up is frequently needed because many of the complications occur years after treatment and can have subtle clinical presentations.

For long-term cancer survivors who were treated with streptozocin, L-asparaginase, or partial pancreatectomy, screening for delayed development of diabetes mellitus is recommended.

In children with a history of cranial irradiation or craniospinal irradiation, the growth rate should be assessed at 6-month intervals. A more detailed evaluation, including measurement of the levels of GH and IGF-1, thyroid function tests, and bone age assessments, should be performed when there is evidence of an abnormal growth pattern. The T_4 and TSH measurements should be performed annually for the first 5 years and less frequently thereafter. Careful physical examination should be performed annually to detect thyroid nodules, and if any are detected, a more detailed examination should be performed using ultrasound and, if necessary, fine-needle aspiration biopsy.

In adults who have undergone cranial irradiation with >20 Gy, clinical monitoring with measurement of serum cortisol, ACTH, free T_4 , IGF-1 (if the patient is a candidate for GH replacement), prolactin, luteinizing hormone, follicle-stimulating hormone, and serum testosterone and documentation of menstrual history should be undertaken annually for 15 years and then every 2 years for another 15 years⁽⁵⁴⁾.

In survivors of childhood malignancies, bone mass may be assessed in the early 30s, an age at which peak

bone mass has been attained in most people. It is also important to consider the possibility of bone loss in androgen- or estrogen-deficient adults. If bone mass is normal, no further evaluation is needed beyond the usual recommendations for prevention of osteoporosis. In those with low bone mass, an active program of calcium and vitamin D supplementation, exercise, and occasionally, medical therapy (bisphosphonates or recombinant parathyroid hormone) should be combined with assessment of bone mass every 12 to 18 months.

Patients who have been treated with chemotherapeutic agents that cause hypophosphatemia, hypomagnesemia, or hypocalcemia, such as ifosfamide, platinum compounds, fludarabine, or estramustine, are particularly at risk for osteomalacia and should undergo an evaluation of serum calcium, phosphorus, magnesium, alkaline phosphatase, and vitamin D metabolite levels.

Patients who have been treated with aromatase inhibitors should have bone mineral density measurements before and during treatment and should be given calcium and vitamin D. Patients can be given bisphosphonates if deemed necessary. Because multitarget tyrosine kinase inhibitors can cause thyroid dysfunction, thyroid hormone levels should be checked before treatment begins. During treatment, thyroid hormone levels should be checked periodically to adjust thyroxine replacement. Multitarget tyrosine kinase inhibitors can cause new-onset hypothyroidism or increase the levothyroxine requirements in patients on chronic thyroid hormone replacement.

Oncologic Emergencies

Sai-Ching Jim Yeung
Ellen F. Manzullo

Oncologic emergencies can result from either the cancer or its treatment. Cancer patients often have immunologic, metabolic, and hematologic defects, which can lead to complex emergency conditions when they present to an emergency center. In addition, emergencies resulting from comorbid conditions also occur in cancer patients. It is important for practitioners who treat patients with cancer to be aware of the various oncologic emergencies so that they can be recognized and treated promptly. This chapter discusses many of these emergencies, including their signs and symptoms, causes, and management.

NEUROLOGIC EMERGENCIES

Spinal Cord Compression

Spinal cord compression is a serious complication of cancer progression, affecting about 2.5% of cancer patients overall (¹). It is not immediately life-threatening unless it involves the first three cervical vertebrae, but involvement in the rest of the spine leads to significant morbidity (²). The spinal cord is compressed at the thoracic vertebrae in 70% of patients, cervical vertebrae in 10% of patients, and lumbar vertebrae in 20% of patients. In 10% to 38% of cases, spinal cord compression occurs at multiple levels (³). Such compression is predominantly due to metastatic tumors, with lung, breast, and prostate cancer comprising 50% of these. Other tumors that commonly metastasize to the spine are multiple myeloma, renal cell carcinoma,

melanoma, lymphoma, sarcoma, and gastrointestinal (GI) cancers. The mechanisms by which tumors can appear in the spine are hematogenous spread of tumor cells to the vertebral bodies, metastasis of primary lesions to the posterior spinal elements, and direct extension of paraspinal tumors. Spinal cord compression is caused by epidural metastases in 75% of cases and bony collapse in 25% of cases (⁴).

The most common presentation of spinal cord compression is back pain, occurring in over 90% of patients. Depending on the location of the tumor in the spinal canal, the pain can be unilateral or bilateral following dermatomal patterns. Patients typically report that their pain is worse when they are supine and better when they are upright. Ataxia due to compression of the spinocerebellar tracts can be confused with cerebellar metastasis, overmedication with analgesics, or other disorders. Metastasis to the spinal cord can precede spinal cord compression by weeks or months. The patient may also note sensory symptoms, including numbness or tingling in the toes, which can progress proximally. Preexisting peripheral neuropathy must be differentiated from spinal cord compression and acute worsening of existing symptoms or experienced new numbness or tingling. Motor symptoms are the second most common complaint after pain; difficulty walking, buckling under of the legs, and a feeling of heaviness in the legs are all frequent symptoms. The last symptoms to appear are autonomic symptoms, such as urinary retention and constipation. Autonomic symptoms are late findings in spinal cord compression and must be distinguished

from the effects of chemotherapy, pain medicines, and antihistamines. It is important to remember that the patient may present with intractable pain only, so a high level of suspicion for spinal cord compression is important in treating cancer patients.

The physical examination usually reveals tenderness to percussion over the affected level of the spine, but the spine might not be tender if there is no bone involvement. Other possible findings are urinary retention, decreased rectal sphincter tone, and muscle weakness. The patient might have pain at a referred site; for instance, patients with L1 compression might have pain in the sacroiliac area. Sensory changes are more difficult to diagnose than motor deficits and can either precede or accompany motor effects. The patient might have decreased sensation in the lower extremities, which may ascend to the level of spinal cord involvement with dorsal column deficits, including loss of light touch sensation, proprioception, and position sense. When the cauda equina is compressed, the sensory changes are dermatomal, with loss of

sensation in the perineal area, the posterior thigh, or lateral leg.

The differential diagnosis of spinal cord compression includes osteoarthritis, degenerative disk disease, spinal abscess, hematoma/bleeding, hemangioma, chordoma, meningioma, and neurofibroma. A standard x-ray is generally ordered first to analyze the area of the spine within which compression is suspected. However, simple roentgenography yields false-negative results in 10% to 17% of cases, in part because approximately 30% to 50% of the bone must be destroyed before bony lesions can be seen on x-ray films ⁽⁵⁾. Magnetic resonance imaging (MRI) is the imaging technique of choice today for suspected spinal cord compression (Fig. 53-1).

For patients with suspected spinal cord compression, physicians should consider imaging the entire spine because spinal epidural disease is often multifocal. Findings for the whole spine can help the physician optimize the type and extent of therapy needed. For any patient with rapidly progressive neurologic

FIGURE 53-1 A. Precontrast T1-weighted magnetic resonance image (MRI) of thoracic cord compression at the T8 level produced by an epidural tumor from vertebral body metastasis (*large arrow*). Smaller *arrows* point to other sites of bony metastasis. The patient is a 67-year-old man with melanoma and back pain. B. Postcontrast T1-weighted MRI of the same patient. The epidural tumor is visualized better with contrast (*black arrows*). (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

symptoms, diagnostic imaging should be performed on an emergency basis. Magnetic resonance imaging of the spine is the diagnostic study of choice. Gadolinium enhancement will be helpful in detecting other causes of neurologic symptoms such as epidural abscess or leptomeningeal metastasis. Patients who are not able to undergo MRI (eg, the presence of paramagnetic cerebral aneurysm clips, or cardiac pacemakers) can undergo computed tomography (CT) myelogram.

Clinical guidelines for diagnosis and management of spinal cord compression are available^(6,7). Corticosteroid is a temporizing measure to stabilize or even improve neurologic function until definitive treatment. Conventionally, dexamethasone is initially given at 10 to 100 mg intravenously and then 4 to 24 mg every 4 to 6 hours⁽⁸⁾. The duration of therapy with high-dose glucocorticoids should be minimized to prevent complications of steroid use.

Surgery is indicated for recurrent or progressive disease at an area with previous maximal radiotherapy, spinal mechanical instability, an unknown tissue diagnosis of malignancy, or for compression of the spinal cord by bony structure/fragment^(6,7). Currently, anterior decompression with spinal stabilization is the surgery of choice, allowing removal of the affected vertebral body and stabilization above and below the vertebrae by metal hardware. Surgical resection followed by radiotherapy may improve ambulation ability and survival better than radiotherapy alone⁽⁹⁾. Benefit from decompressive surgery is evident in ambulatory patients with poor prognostic factors for radiotherapy and in paralyzed patients with a single spinal area of compression, paraplegia less than 48 hours, non-radiosensitive tumors, and an expected survival of more than 3 months⁽¹⁰⁾. If surgery is not indicated, radiation therapy can be used for radiosensitive tumors; the most common dosage is 3,000 cGy delivered in 10 fractions⁽³⁾. The incidence of myelopathy, which can occur as a complication of radiation therapy, increases with increasing total dosage of therapy and can appear from months to several years after such therapy is given. Palliative radiotherapy is recommended for those with paraplegia longer than 48 hours, expected to live for fewer than 3 months, unable to tolerate surgery, and with multiple areas of compression. An ambulatory patient with a stable spine may be considered for radiation treatment⁽⁸⁾. Chemotherapy is occasionally used for chemotherapy-sensitive tumors, such as Hodgkin disease, neuroblastoma, non-Hodgkin lymphoma, germ cell tumors, and breast cancer.

One of the most important prognostic factors at diagnosis is the patient's neurologic function. Of patients who are ambulatory at the time of presentation, approximately three-fourths will be able to regain

their strength with treatment. By contrast, only a small percentage of patients who are paralyzed at the time of presentation are likely to walk again. This difference illustrates why it is imperative to diagnose spinal cord compression at an early stage. A scoring system based on tumor type, interval between tumor diagnosis and spinal cord compression, other bone or visceral metastases, ambulatory status, and duration of paralysis can estimate survival⁽¹¹⁾. The median overall survival following the first episode of spinal cord compression is about 3 months⁽¹⁾.

Increased Intracranial Pressure

Increased intracranial pressure in cancer patients is commonly due to hemorrhage (from thrombocytopenia or tumor bleeding), brain metastasis with vasogenic edema and mass effect, or hydrocephalus due to obstruction of the flow of cerebrospinal fluid (CSF). Increased intracranial pressure can also be caused by tumor treatments, such as radiation therapy and surgery. The normal CSF pressure is less than 10 mm Hg. As intracranial pressure increases, herniation syndromes may develop, including uncal, central, and tonsillar herniation. Uncal herniation is caused by unilateral supratentorial lesions that push brain tissue through the tentorial notch. Signs and symptoms include ipsilateral pupil dilation, decreased consciousness, and hemiparesis, first contralateral and then ipsilateral to the mass. Central herniation involves bilateral supratentorial lesions that displace tissue symmetrically and bilaterally. Signs and symptoms of central herniation include decreased consciousness leading to coma and Cheyne-Stokes respiration, followed by central hyperventilation, midposition unreactive pupils, and posturing. Tonsillar herniation involves increased pressure in the posterior fossa, which forces the cerebellar tonsil through the foramen magnum, thereby compressing the medulla. Signs and symptoms of tonsillar herniation include decreased consciousness and respiratory abnormalities leading to apnea. Headache is the most frequent symptom reported in increased intracranial pressure. Headache is a common symptom in any patient population, but in cancer patients, the clinician must always maintain a high index of suspicion for increased intracranial pressure. Headaches due to increased intracranial pressure are typically present on waking in the morning, recur throughout the day, and are increased with Valsalva maneuver; they can be associated with nausea and vomiting, altered mental status, vision changes, seizures, or focal neurologic deficits. On physical examination, the patient might have papilledema, focal neurologic deficits, or a decreased level of consciousness.

The diagnosis of increased intracranial pressure can be ascertained from CT scans of the brain. Noncontrast

CT imaging of the brain is superior to MRI in detecting acute hemorrhage (Fig. 53-2).

Computed tomography scans with contrast will usually reveal cerebral metastasis and occasionally leptomeningeal disease (LMD). Contrast-enhanced MRI is more sensitive than CT in revealing cerebral neoplasms and metastases as small as 3 mm (Fig. 53-3), LMD (Fig. 53-4), and early strokes (Fig. 53-5). Lumbar puncture should not be used to diagnose increased intracranial pressure, because this can lead to brain herniation.

The differential diagnosis of increased intracranial pressure includes bleeding, tumor edema, hydrocephalus, postradiation effects, postradiosurgery effects, brachytherapy-induced changes, benign tumor effects, subdural hematomas, meningitis, encephalitis, and abscess formation.

Brain metastases may develop in 10% to 40% of cancer patients⁽¹²⁾. Leptomeningeal disease occurs in 5% of all patients with cancer⁽¹³⁾. Two-thirds to three-quarters of brain metastases are recognized as multiple lesions on MRI. Lung cancer is the neoplasm that most frequently metastasizes to the brain, followed by breast cancer and melanoma. Other cancers that commonly metastasize to the brain are colorectal, kidney, prostate, testicular, and ovarian cancers and sarcomas, although any systemic cancer can metastasize to the brain. Melanomas have the highest propensity to metastasize to the brain, with up to 40% of cases behaving in this manner at some point. Tumors most commonly metastasize to the gray-white junction

FIGURE 53-2 Acute intracranial hemorrhage within the right frontoparietal lobe (arrows) with edema (E) in a 79-year-old woman with ovarian cancer. The hemorrhage was revealed by noncontrast computed tomography imaging. This modality is superior to magnetic resonance imaging in detecting acute hemorrhage. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

FIGURE 53-3 A. Precontrast T1-weighted magnetic resonance images in a 40-year-old woman with breast cancer and multiple cerebellar metastases. B. Postcontrast images of the same patient reveal dramatic enhancement of the cerebellar metastases.

FIGURE 53-4 A. Sagittal postcontrast T1-weighted magnetic resonance imaging (MRI) showing subarachnoid spread of melanoma metastasis to the brain in a 29-year-old man. Abnormal enhancement of the cortical sulci (*large arrows*) and cerebellar sulci (*small arrows*) is noted. B. Coronal postcontrast T1-weighted MRI in the same patient. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

where the vessels are small and narrow and tumor emboli can be trapped. Eighty percent of tumors metastasize to the cerebral hemispheres, 15% to the cerebellum, and 5% to the brainstem. Pelvic tumors have an increased propensity to metastasize to the posterior fossa, possibly by means of venous drainage of these tumors through Batson plexus⁽¹⁴⁾. The tumors that are most often hemorrhagic include melanoma, renal cell carcinoma, and choriocarcinoma.

The treatment for increased intracranial pressure depends on the underlying etiology⁽¹⁵⁾. Infectious sources, such as meningitis, should be treated with antibiotics, and brain abscesses should be drained. Hydrocephalus should be treated with surgical shunting or ventriculostomy, and subdural hematomas should be either drained or, if small, monitored under the guidance of a neurosurgeon. Edema associated with brain tumors is initially treated with oral dexamethasone at a dosage of 16 mg/d or 4 mg every 6 hours⁽¹⁶⁾. For patients with impending herniation, very large doses of intravenous (IV) dexamethasone can be used, initially 40 to 100 mg intravenously and subsequently 40 to 100 mg/d⁽³⁾. Dexamethasone is the steroid of choice because of its lack of mineralocorticoid effect. Steroids may not be needed in asymptomatic brain lesions⁽¹⁷⁾.

For life-threatening edema or brain herniation, emergency treatments include hyperventilation and administration of mannitol in addition to steroids⁽¹⁵⁾. Hyperventilation after intubation to achieve a partial

FIGURE 53-5 Acute infarction involving the territory of the right middle cerebral artery in a 58-year-old patient with renal cell carcinoma. Magnetic resonance imaging (MRI; fluid-attenuated inversion recovery [FLAIR] image) demonstrates abnormal thickening, with a T2-weighted increase in signal intensity (*arrows*) involving the right temporo-occipital lobe cortex and subcortical white matter. MRI is more sensitive than computed tomography in detecting early stroke. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

pressure of carbon dioxide of 25 to 30 mm Hg is the most rapid way to decrease intracranial pressure, but the benefit is generally short lived, and equilibration may occur within a few hours. Mannitol is a hyperosmotic agent that can shift water out of brain cells and into the vessels. The recommended dose of mannitol is a 20% to 25% solution at 0.5 to 2.0 g/kg administered intravenously over 10 to 30 minutes. Mannitol has a rapid onset of action and lasts for hours, but prolonged use can lead to hyperosmolarity and an inadvertent increase in intracranial pressure⁽³⁾. Further treatment in intensive care may include IV infusion of hypertonic saline, propofol, and hypothermia⁽⁴⁾. Neurosurgical intervention such as placement of a ventricular drain or decompressive craniectomy may be necessary if the patient has neurologic deterioration despite appropriate medical management.

Radiation therapy can be used to treat brain metastasis. The dosage for whole-brain radiation therapy (WBRT) typically ranges between 20 Gy over 1 week and 50 Gy over 4 weeks. Treatment with WBRT can increase survival in patients by 3 to 6 months relative to no treatment⁽¹⁶⁾. Increased intracranial pressure should be treated before WBRT is instituted because radiotherapy can further increase pressure. Common side effects of WBRT are nausea and vomiting, alopecia, headache, hearing loss, loss of taste, and fever. Possible delayed complications of WBRT are progressive leukoencephalopathy with dementia, ataxia, apraxia, and incontinence syndrome, which can mimic normal-pressure hydrocephalus. This dreaded side effect can occur as long as 1 year after therapy, and elderly patients are more susceptible.

Surgery can be used to treat accessible brain metastases. A stereotactic biopsy can be performed for the patient with multiple brain metastases, which are then generally treated with radiation⁽¹⁸⁾. Surgery is generally not indicated for patients with widespread systemic disease, poor functional status, or tumors in critical or hard-to-access locations⁽¹⁶⁾. In selected patients with good functional status, even when multiple brain metastases are present, survival time is longer for patients who have all tumors removed than for those who do not. Consequently, it is common for the neurosurgeons at our institution to remove up to four metastatic lesions at a time⁽¹⁷⁾. Patients with single brain metastases who underwent WBRT after surgery had longer survival than those who had surgery alone⁽¹⁹⁾.

For patients with brain lesions that are not amenable to surgery, stereotactic radiosurgery can be used in single doses as high as 1,400 cGy. This approach is typically used for brain tumors less than 4 cm in diameter and has the benefit of being noninvasive and relatively fast acting⁽⁶⁾. Brachytherapy can be used on larger tumors, but this approach requires that

radioactive seeds be invasively implanted in the designated area and left for 5 or 6 days, delivering approximately 6,000 cGy to the area. Brachytherapy may cause radiation necrosis in up to 50% of patients 6 months after treatment. No treatment exists for radiation necrosis, although the symptoms may respond to corticosteroids.

Chemotherapy can be used in some patients with brain metastasis. Dexamethasone, which is thought to aid in reestablishing the blood-brain barrier, should not be used if possible, so that the selected chemotherapeutic agent(s) can reach the tumor cells. Cancers for which chemotherapy has been used include choriocarcinoma, small cell cancer of the lungs, and breast cancer^(16, 20, 21).

Leptomeningeal Disease

Leptomeningeal disease can involve invasion of the brain, the spinal parenchyma, the nerve roots, and blood vessels of the nervous system. The cancers that most commonly result in LMD are breast and lung cancer, melanoma, non-Hodgkin lymphoma, and leukemia. Patients present with a variety of symptoms depending on the location of the leptomeninges affected, but they can include headache, altered mental status, cranial nerve palsies (in about 50% of patients), incontinence, back pain, sensory changes, seizures, isolated neurologic findings, and even a stroke-like presentation^(5, 21). Leptomeningeal metastases occur in 0.8% to 8% of all cases of cancer⁽⁵⁾.

The diagnosis of LMD can be difficult. Computed tomography scans will occasionally be suggestive of LMD. Magnetic resonance imaging scanning has better sensitivity than CT for detecting LMD, including leptomeningeal enhancement, hydrocephalus, and cortical nodules. However, MRI results are not diagnostic. Inflammation of the meninges can also be found in cases of meningitis, trauma, infection, and hematoma formation. Lumbar puncture and evaluation of the CSF is the gold standard for diagnosing LMD, although multiple lumbar taps may be required to make the diagnosis because only 50% of patients will have positive cytologic evidence of LMD on the first CSF evaluation^(5, 22). Cerebrospinal fluid findings consistent with LMD include a high opening pressure, low glucose and high protein levels, and a mononuclear pleocytosis⁽⁵⁾. Among patients with normal values for CSF protein, glucose, and opening pressure and cytology negative for LMD, fewer than 5% will have LMD⁽²²⁾.

The treatment of LMD can include chemotherapy through an implanted subcutaneous reservoir and ventricular catheter (SRVC) or through lumbar puncture instillation. Lumbar tap administration does not require placement of a catheter, but 10% to 15% of the subarachnoid space might be missed using this

technique. Chemotherapeutic agents frequently used are methotrexate and thiopeta. Cytarabine can also be used in patients with leukemias and lymphomas, but it is generally not effective against solid tumors. Radiation therapy is commonly used for localized LMD or in areas of nerve root involvement where intrathecal chemotherapy is not likely to reach adequate concentrations. Fixed neurologic deficits caused by LMD are not likely to improve with therapy, but encephalopathy may ⁽²²⁾. The prognosis of patients with LMD is poor, with a median survival of 3 to 6 months and only a 15% to 25% chance of surviving longer than 1 year ⁽³⁾.

Seizures

Seizures are the presenting symptom in 15% to 20% of patients with brain metastases ⁽²¹⁾. In cancer patients presenting with seizures, metabolic, infectious, and coagulopathic causes should also be considered. The initial laboratory work should include analysis of glucose level, electrolytes, blood urea nitrogen (BUN), creatinine, liver enzymes, calcium, urine analysis,

prothrombin time (PT), activated partial thromboplastin time (PTT), and toxicology screening if indicated (Fig. 53-6).

Patients can have seizures during withdrawal from high-dose, short-acting benzodiazepines (such as alprazolam), alcohol, antibiotics (such as the carbapenems), pain medicines (such as meperidine), and many other medicines. The patient's family can be helpful in sorting out the etiology of seizures by providing information about the patient's medications, social history, and preceding symptoms, such as fever or headache. Computed tomography without and with contrast is also helpful and can identify increased intracranial pressure, bleeding, or brain metastasis. Electroencephalography (EEG) is also helpful in the evaluation of seizures and can determine whether an epileptic focus is present. Lumbar tap for CSF analysis can be helpful if the seizures are suspected to be secondary to infection or LMD, provided that there are no contraindications on brain imaging (signs of increased intracranial pressure or impending herniation) and that the convulsions have stopped.

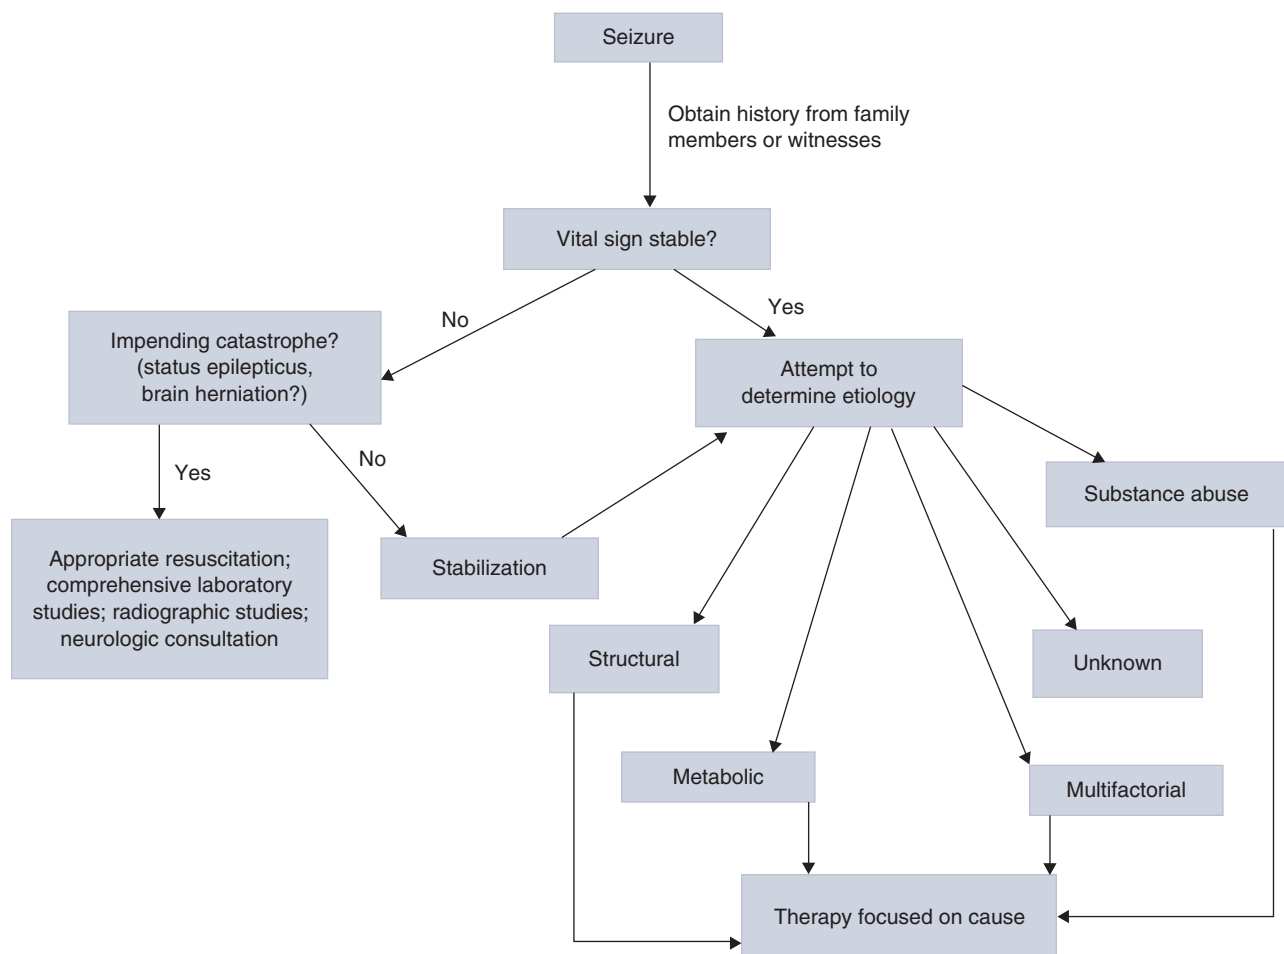

FIGURE 53-6 Algorithm for the evaluation of seizure. (Adapted with permission from Yeung SJ, Escalante CP [eds]: *Oncologic Emergencies*. Hamilton, Ontario, Canada: BC Decker; 2002.)

Status epilepticus occurs when a patient has prolonged seizures with continuous seizure activity lasting >5 minutes or two or more sequential seizures without full recovery of consciousness between seizures. When patients present with status epilepticus, airway, breathing, and circulation should be assessed immediately (^{23, 24}). Initial care for patients with status epilepticus includes placing the patient in a safe environment, administering 100% oxygen by non-rebreather mask, monitoring with a continuous pulse oximeter providing suction, and administering IV fluids (normal saline). Priority should be placed on exclusion of hypoglycemia, protecting the airway, and terminating the convulsions. Anticonvulsant therapy with IV benzodiazepines (eg, diazepam, 0.2 mg/kg at 5 mg/min, up to 10 mg, or lorazepam, 0.1 mg/kg at 2 mg/min, up to 4 mg) should be administered to halt seizure activity. For patients with continuing seizures, therapy can be escalated in steps; second-line therapy includes fosphenytoin IV at 15 to 20 mg of phenytoin equivalents (PE) per kilogram. Patients with refractory seizures might require high-dose anticonvulsant therapy (eg, pentobarbital, thiopental, propofol, midazolam) with complete sedation, intubation/ventilator support, EEG, and careful monitoring in the intensive care unit.

It is the general consensus of the American Academy of Neurology that routine use of prophylactic antiepileptic drugs (AEDs) for patients with brain metastases who have not experienced a seizure is not indicated (¹⁶). Once new-onset seizure in a cancer patient has been controlled, the patient should be placed on an AED. Several drugs can be used, including phenytoin, carbamazepine, clonazepam, gabapentin, lamotrigine, phenobarbital, primidone, topiramate, and valproate. Because of no significant interaction with antineoplastic drugs, some clinicians prefer levetiracetam in cancer patients.

Altered Mental Status

Altered mental status is a common neurologic complaint in cancer patients, with metabolic encephalopathy being the most common cause. Altered mental status can range from a slight decrease in normal intellectual functioning to coma. A cancer patient's mental status may change in response to several factors, such as infections/sepsis, metabolic derangements, bleeding, medications, hypoxemia, cancer therapies, paraneoplastic neurologic syndromes, and intracranial events, such as brain metastases. Organ failure, whether hepatic, renal, adrenal, thyroid, or pulmonary, can also produce fluctuations in mental status. The most common metabolic deficiencies causing such alterations are hyponatremia, hypercalcemia, hypoglycemia, and vitamin B₁₂ deficiency. The causes of altered mental

status are numerous; an extensive history and physical examination can help to identify the underlying cause and determine appropriate therapy (Fig. 53-7). The differential diagnosis and diagnostic evaluation are beyond the scope of this chapter, but a few entities are unique to cancer patients.

For instance, cancer therapy is a common cause of altered mental status. Many neurologic manifestations, such as dementia, cognitive decline, and encephalopathy, can result from chemotherapy. Table 53-1 highlights some of the common neurologic complications of chemotherapy (^{5, 17, 25}).

Radiation therapy can also cause complications, among them leukoencephalopathy, radiation necrosis, and decreased memory and mental functioning. (The preceding section on increased intracranial pressure provides a fuller discussion of the cognitive side effects of radiation therapy.) Other possible causes of cognitive decline are narcotics (commonly prescribed for pain), infections (pneumonia, sepsis, urinary tract infection), and cerebral infarction.

Paraneoplastic syndromes are unique to cancer patients and should be considered in cases of altered mental status. In many instances, the paraneoplastic syndrome will precede the cancer diagnosis. Paraneoplastic syndromes must be differentiated from symptoms caused by progression of cancer or the side effects of cancer therapy. The two common paraneoplastic syndromes that cause mental status change through electrolyte abnormalities are hypercalcemia of malignancy and hyponatremia due to syndrome of inappropriate antidiuretic hormone (SIADH). Paraneoplastic neurologic syndromes associated with mental status changes and neurophysiologic abnormalities are paraneoplastic cerebellar degeneration and Lambert-Eaton myasthenic syndrome (⁶).

CARDIAC EMERGENCIES

Cardiac Tamponade

Tumors involving the heart are much more frequently metastatic than primary. The tumors that most often metastasize to the heart are lung, breast, and GI tract cancers; leukemia; lymphoma; melanoma; and sarcoma. Metastatic involvement of the heart has also been noted in leukemia and lymphoma patients. Certain therapies can also affect the myocardium and cause pericardial disease, especially cyclophosphamide and ifosfamide at high doses, all-*trans*-retinoic acid (ATRA), doxorubicin, and radiation therapy (²⁶). Cardiac tamponade occurs when pericardial fluid accumulates and presses on the heart, increasing diastolic pressure in the ventricles and thereby decreasing stroke volume. The patient develops decreased cardiac output and systemic

arterial pressure and can present with a shock-like syndrome. Most patients with pericardial effusions report no symptoms, but patients with cardiac tamponade present with shortness of breath, cough, hoarseness, epigastric pain, or chest pain that is made worse by lying down or leaning forward. On examination, the patient typically has distended neck veins, low systemic blood pressure, and low pulse pressure, and can have a pericardial rub or decreased heart sounds. The presence of pulsus paradoxus, which is an inspiratory decline in systolic blood pressure of >10 mm Hg, should be ruled out. Pulsus paradoxus can also occur in chronic obstructive pulmonary disease (COPD), pulmonary embolism, right ventricular infarction, and shock. Chest x-ray often reveals a “water bottle” configuration if the effusion has accumulated slowly, but the cardiac silhouette can appear normal if the effusion accumulates rapidly. Prior chest x-ray images can be useful in determining changes in the size of the cardiac silhouette. The electrocardiogram (ECG) might reveal electrical alternans (a variation of voltage in individual QRS complexes) and low-voltage or ST-segment and T-wave changes. Transthoracic echocardiography is the best test to determine whether tamponade exists. If cardiac tamponade is present, echocardiography can help determine whether the effusion is localized or loculated, and it can also aid in planning pericardiocentesis. On echocardiograms, tamponade can be evidenced by collapse of the right ventricle and atria in diastole (Fig. 53-8).

Treatment of tamponade includes the administration of oxygen, IV fluids, and vasopressors if necessary. Pericardiocentesis can be performed under ultrasound guidance and is relatively safe. A scoring system may help to decide whether pericardiocentesis needs to be performed emergently (²⁷). At the University of Texas MD Anderson Cancer Center (MDACC), a drainage catheter is commonly placed in patients with tamponade, with drainage performed daily. When the total volume of fluid drained is less than 50 mL/d, the catheter can be removed. Fibrinolytic agents may be used to unclog the catheter to avoid repeat pericardiocentesis or replacement of the catheter (²⁸). Long-term management focuses on preventing reaccumulation of fluid. Creation of a pleuropericardial window can prevent reaccumulation of fluid and avoid repeated pericardiocentesis. Radiation therapy and chemotherapy can also be used to prevent reaccumulation of fluid, as can sclerosis of the pericardial sac.

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is characterized by low blood flow from the SVC to the right atrium. Malignancy is by far the most common cause of SVC syndrome, although nonmalignant causes, such as indwelling central venous catheters, aneurysms, and goiters, can also cause this syndrome (²). Lung cancer is the most common malignant neoplasm causing SVC syndrome, but lymphoma, breast and GI cancers,

FIGURE 53-8 Two-dimensional echocardiogram in the apical four-chamber view demonstrating a large pericardial effusion. The right ventricle is not well visualized because of acoustic shadowing, which commonly occurs with large effusions. (Used with permission from Dr. Joseph Swafford, MD Anderson Cancer Center.)

sarcomas, melanomas, prostate cancer, and any mediastinal tumor can also cause this disorder. Among mechanisms that can lead to this syndrome are extrinsic compression by tumor, intrinsic compression by tumor or clot, or fibrosis. Patients may present with headache; dizziness; confusion; swelling of the upper extremities, face, and neck; shortness of breath; and dysphagia. Physical examination often reveals engorgement of veins and collaterals in the upper extremities due to elevated pressure in the venous system.

Diagnosis of SVC syndrome requires imaging (^{28a}). Routine chest x-rays will often reveal mediastinal widening, a right-side chest mass, or a mediastinal mass. Computed tomography scanning of the chest using IV contrast is an excellent means of delineating the cause of the obstruction and any associated finding (Fig. 53-9). If IV iodine contrast is contraindicated, radionuclide venography and MRI are alternatives. Doppler ultrasound may be helpful to evaluate for the presence of a clot.

The treatment of SVC syndrome depends on the nature of the obstruction. Patients might respond to elevation of the head, corticosteroids if the intracranial pressure is increased, and occasionally diuretics. If thrombosis is present, local lytic therapy or anticoagulation can be used. Intravascular stenting with metallic stents can be used, as can angioplasty. Stent placement has been associated with a faster resolution of symptoms relative to radiation therapy (²⁹) (Fig. 53-10).

Stenting may be first-line treatment of SVC syndrome (^{29, 30}), especially in emergent situations of impending airway obstruction or increased intracranial pressure (³¹).

It is important to obtain a tissue specimen of the tumor if its type is not known, so that it can be treated adequately. For patients with tumors that are chemotherapy sensitive, such as small cell lung cancer, chemotherapy can be instituted. Patients with non-small cell lung cancer will often respond to radiation therapy, and SVC syndrome symptoms begin to improve in about 1 week. Radiotherapy is also justified if a histologic diagnosis cannot be established in a timely manner. Surgical treatment with reconstruction is also possible for certain tumor types or selected patients (³²).

Myocardial Ischemia

Patients with cancer can present to the emergency center with myocardial ischemia. A full discussion of ischemic heart disease is beyond the scope of this chapter, but there are special considerations in cancer patients that should be mentioned.

Many cancer patients have thrombocytopenia due to chemotherapy, radiation therapy, or bone marrow infiltration with tumor. Despite platelet counts in the single or double digits, these patients can still present with acute cardiac syndrome. Although the

FIGURE 53-9 Computed tomography scan revealing superior vena cava (SVC) syndrome from extrinsic compression of the SVC in a patient with non-small cell lung cancer. *Large arrow* indicates compression of the left pulmonary artery; *small arrow* indicates obliteration of the right pulmonary artery. (Adapted with permission from Yeung SJ, Escalante CP [eds]: *Oncologic Emergencies*. Hamilton, Ontario, Canada: BC Decker; 2002.)

practitioner might feel uncomfortable giving aspirin to these patients, cardiologists at MDACC have found that patients with platelet counts less than 50,000/ μ L who have cardiac ischemia and are treated with aspirin have a better 24-hour survival rate than those who are not given aspirin.

Certain chemotherapeutic agents can predispose patients to myocardial ischemia, including 5-fluorouracil (5-FU), interferons, and presumably capecitabine, which is a metabolite of 5-FU. Radiation therapy can also be a

predisposing factor⁽²⁶⁾. It is important to consider myocardial ischemia in patients who have undergone any of these therapies, especially those who otherwise have no risk factors for ischemic heart disease.

The cardiac markers troponin, creatine phosphokinase (CPK), and CPK-MB are useful in diagnosing myocardial infarction. Cardiac troponins are more sensitive and specific markers for ischemic heart disease than CPK-MB, which can be influenced by skeletal muscle injury; however, cardiac troponin levels can also be

raised by chronic renal insufficiency (CRI), cardiomyopathy with severe congestive heart failure, myocarditis, and massive pulmonary embolism. In one small study evaluating 24 patients with submassive pulmonary embolism, troponin levels were higher than normal in 5 patients⁽³³⁾. In this study, patients who presented with chest pain and for whom a ventilation/perfusion (V/Q) scan revealed a high probability of submassive pulmonary embolism were analyzed. High troponin was defined as a level >0.4 $\mu\text{g/L}$, and myocardial infarction was evidenced by a level >2.3 $\mu\text{g/L}$. It was found that four of the five patients with submassive pulmonary embolism had slightly elevated troponin levels and the fifth patient had a troponin level of 11.1 $\mu\text{g/L}$. The study was limited in that it did not investigate the possibility of underlying ischemia in patients with documented pulmonary embolism. Such patients commonly present with chest pain, and pulmonary embolism and ischemic heart disease are both in the differential diagnosis of myocardial infarction. In patients with small increases of troponin, pulmonary embolism (even submassive) can be the cause, rather than ischemic heart disease; this possibility should be considered in patients presenting with chest pain.

HEMATOLOGIC EMERGENCIES

Hyperviscosity Syndrome

Hyperviscosity syndrome is due to abnormally high concentrations of paraproteins in the serum, which increase viscosity and cause red blood cell (RBC) sludging and low oxygen delivery to the tissues. This disorder occurs in 15% of patients with Waldenström macroglobulinemia, which is characterized by the presence of high-molecular-weight (IgM) macromolecules and thus predisposes patients to this syndrome. Aggregation of IgG macromolecules and polymerization of IgA macromolecules, as well as purely light-chain myeloma, are also capable of causing this syndrome⁽³⁴⁾. Other conditions that can cause hyperviscosity syndrome are polycythemia vera, dysproteinemias, and occasionally leukemias.

Hyperviscosity syndrome can present with either bleeding due to abnormal platelet functioning or thrombosis due to hyperviscosity. Visual complaints, headache, dizziness, alterations in mental status, and mucosal bleeding are all symptoms of hyperviscosity syndrome. Patients can also develop retinal hemorrhages, congestive heart failure due to increased plasma volume, peripheral neuropathy, weakness, and fatigue⁽³⁴⁾. Funduscopic examination can reveal venous dilatation, retinal vein occlusion, or papilledema (Fig. 53-11).

The diagnosis is made on the basis of a high serum viscosity. Normal serum viscosity ranges between 1.4

FIGURE 53-11 Funduscopic examination revealing a Roth spot (the white-centered retinal hemorrhage). The Roth spot is the hallmark of leukemic retinopathy. (Used with permission from Dr. Bitá Esmaeli, MD Anderson Cancer Center.)

and 1.8 Ostwald units (relative to water, at 1). Patients start to develop symptoms when serum viscosity exceeds 4.0 Ostwald units⁽³⁴⁻³⁶⁾.

The treatment for hyperviscosity syndrome includes the administration of IV fluids followed by diuresis. Plasma exchange can decrease symptoms quickly and can be followed by chemotherapy.

Hyperleukocytosis

Hyperleukocytosis is typically defined as a white blood cell (WBC) count in the peripheral blood higher than $100,000/\mu\text{L}$. Acute myelogenous leukemia (AML), chronic myelogenous leukemia (CML), and less frequently (because of the smaller size of the lymphocytes) acute and chronic lymphocytic leukemia (CLL) are associated with leukostasis. From 5% to 30% of adult patients with acute leukemias present with leukostasis that requires prompt recognition and initiation of therapy to prevent respiratory failure or intracranial hemorrhage⁽³⁵⁾. The WBC count in acute lymphocytic leukemia (ALL) typically must be greater than $400,000/\mu\text{L}$ before leukostasis will develop. The highest rate of mortality is in patients with AML who have high blast counts.

Symptoms of hyperleukocytosis are headache, dizziness, vertigo, shortness of breath, altered mental status, and hemoptysis. WBCs are poorly deformable and can become lodged in the microvasculature of the kidneys, lungs, brain, and other organs. The pulmonary and neurologic systems are most critically affected in hyperleukocytosis syndrome. In the lungs, WBCs can get caught in the pulmonary circulation, causing adult respiratory distress syndrome (ARDS), or can mimic pulmonary embolism because of WBC stasis in the pulmonary vasculature, thereby causing a V/Q mismatch⁽³⁶⁾. Patients with the latter condition should not be given diuretics,

because this will further increase stasis. Most patients with leukemia are anemic; this condition can offset the WBC elevation, so hyperviscosity is not as common in these patients. It is important not to give these patients blood transfusions unless absolutely necessary, because this treatment can exacerbate hyperleukocytosis and increase the RBC mass without changing the total blood volume. Patients can present with decreased mental status, which can be caused by endothelial leakage from the small vessels of the brain or hemorrhage, but other causes of altered mental status should also be considered, including infection, LMD from leukemia, and metabolic sources. Imaging studies, such as CT scan and MRI, as well as lumbar tap should be performed when indicated (³).

The treatment of hyperleukocytosis involves lowering the WBC count, which can be accomplished with leukapheresis or chemotherapy. Leukapheresis can lower the WBC count by 30% to 60% from pretreatment levels. These effects can be transient; therefore, repeat leukapheresis might be necessary. Patients undergoing leukapheresis should also be monitored closely to prevent tumor lysis syndrome.

Thrombosis

Venous thromboembolism (VTE) is influenced by Virchow triad: venous stasis, higher than normal coagulability, and intimal injury. Patients with cancer have a high risk of VTE, and up to 15% of patients will develop VTE because of hypercoagulability, the use of central venous catheters, and high stasis (³⁷). Cancer patients

can have increased serum viscosity due to dehydration or, less frequently, hyperviscosity syndrome (described previously). Stasis and intimal injury can be caused by numerous events—for example, tumor encroachment on blood vessels or indirect effects of cancer, such as spinal cord compression, brain metastasis, dehydration, or impaired ambulation. Some chemotherapeutic cancer agents can also induce VTE, among them tamoxifen, cisplatin, cyclophosphamide, methotrexate, and 5-FU (³⁷).

Symptoms of pulmonary embolism (PE) include chest pain, shortness of breath, palpitations, fever up to 102°F, and syncope in the case of massive PE. Electrocardiogram findings can include T-wave inversion in the precordial leads, sinus tachycardia, right bundle branch block, or rightward movement of the QRS axis. Chest roentgenograms can be normal or might reveal a pleural effusion or elevation of the diaphragm on the involved side. Physical examination can reveal tachypnea, tachycardia, and leg edema or erythema in the case of associated deep vein thrombosis.

Diagnosis of PE can be made by V/Q scanning, spiral CT angiography, pulmonary angiography, or MRI (Fig. 53-12).

Ventilation/perfusion scans are noninvasive, and the results are useful in patients with a high probability of PE, which can be treated as VTE; normal results on V/Q scans can rule out PE. Clinical suspicion based on the patient's risk factors and results of other tests can guide the clinician regarding the patient's pretest probability of PE. Patients with indeterminate result from V/Q scans who are strongly suspected of having

FIGURE 53-12 Spiral computed tomography angiogram in a patient with a saddle pulmonary embolism (arrow). AO, aorta; PA, main pulmonary artery. (Used with permission from Dr. Joel Dunnington, MD Anderson Cancer Center.)

a PE can undergo further testing, such as spiral CT angiography, pulmonary angiography, or MRI. Spiral CT scanning and MRI can detect segmental PE but not necessarily subsegmental PE. Both of these tests are useful in that they give further information about the condition of the lung, such as whether pneumonia is present, tumor size, and impingement on the bronchial airways; this additional information is helpful in determining the cause of the patient's symptoms. Pulmonary angiography remains the gold standard in detecting PE, although it requires more dye than other contrast methods and has a greater risk of renal complications. The alveolar-arterial gradient (A-a gradient) from an arterial blood gas (ABG) can serve to corroborate the diagnosis of PE, but a normal A-a gradient does not rule out a PE. The upper limit of normal of an A-a gradient is equal to patient age/4 + 4, but this value can also increase when the patient is supine. In the PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis) study, ABGs were normal in 14% of patients with preexisting cardiopulmonary disease and in 38% of patients with no underlying cardiopulmonary disease despite the presence of pulmonary emboli⁽³⁸⁾ (Fig. 53-13).

The diagnosis of peripheral VTE can be made by Doppler ultrasound, impedance plethysmography, venography, nuclear venogram, or magnetic resonance (MR) venography (Fig. 53-14).

The D-dimer test can also be used in the evaluation of VTE; normal results are associated with a significantly lower likelihood of VTE than high values⁽³⁷⁾. D-Dimer has a high negative predictive value for pulmonary embolism in cancer patients, and a normal D-dimer can be used to exclude pulmonary embolism in cancer patients. Combining D-dimer with clinical symptoms and signs did not substantially change negative predictive value, positive predictive value, sensitivity, or specificity⁽³⁹⁾. Because D-dimer is commonly high in patients with cancer, an elevated D-dimer is not useful in diagnosing VTE.

First-line treatment for VTE consists of either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). Low-molecular-weight heparin has the advantage that factor Xa levels usually do not have to be monitored because protein binding is low. It also has a longer half-life than UFH and thus can be given less frequently (once or twice per day). The LMWHs enoxaparin, tinzaparin, and dalteparin are all different and cannot be used interchangeably. Monitoring may be required for patients with obesity and renal insufficiency, because LMWH is cleared by the kidneys. When monitoring is necessary, the Xa level should be measured 4 hours after the injection, with a target level ranging from 0.6 to 1.0 IU/mL for twice-daily dosing. For daily dosing, the Xa level should range between 1.9 and 2.0 IU/mL⁽⁴⁰⁾. For patients who will

be transitioned to warfarin treatment, there should be an overlap of at least 5 days with LMWH.

In a study, 672 cancer patients with VTE were randomized to dalteparin with oral anticoagulation (OA) versus dalteparin alone⁽⁴¹⁾. The OA group was given warfarin and dalteparin 200 IU/kg subcutaneously every day for 5 to 7 days until the international normalized ratio (INR) reached 2 to 3. At that point, dalteparin was discontinued and the warfarin continued for 6 months. In the OA group, the goal INR was 2.5. The dalteparin group was given dalteparin 200 IU/kg subcutaneously every day for 1 month and then 150 IU/kg subcutaneously every day for the remaining 5 months. The patients in the dalteparin group had a lower rate of recurrent VTE at 6 months (8.8%) than those in the OA group (17.4%). There were no significant differences in major or minor bleeding between the two groups. The study investigators concluded that the occurrence of recurrent VTE can be decreased by the use of dalteparin rather than warfarin⁽⁴¹⁾.

Although VTE can often be treated on an outpatient basis, patients not eligible for outpatient treatment are those with active bleeding, major comorbid illnesses, a history of heparin-induced thrombocytopenia, hypertensive emergencies, major surgery or trauma within the previous 2 weeks, recent GI bleeding, stroke or transient ischemic attack, severe renal dysfunction, or a platelet count below 100,000/ μ L⁽⁴²⁾. Table 53-2 shows the dosing schedule.

Most patients are treated for at least 3 to 6 months. Patients from whom the central venous catheter has been removed can undergo repeat testing using such techniques as Doppler ultrasound or nuclear venous flow study to determine whether the clot has resolved, so that cessation of anticoagulation therapy may be considered. For patients with small clots at the distal tip, manifested by the inability of the central line to work, tissue plasminogen activator (t-PA) can be given carefully provided that there are no contraindications.

Inferior vena cava filters can be used for patients who cannot tolerate anticoagulation therapy. Inferior vena cava filters do not decrease peripheral edema from deep venous thrombosis (DVT) and, in fact, can serve as a nidus for further clot formation. Inferior vena cava filters can prevent life-threatening pulmonary emboli. Patients with massive pulmonary emboli may require thrombolysis or embolectomy. See Table 53-3 for a synopsis of the relative and absolute contraindications for thrombolytic therapy and Table 53-4 for thrombolytic doses.

Patients with cancer and VTE should be treated indefinitely if the cancer remains active or for at least 3 to 6 months after resolution of the VTE if the cancer is no longer active^(43, 44). For patients who are treated with warfarin but who experience warfarin failure as evidenced by the recurrence or progression of clot formation, the INR range can be increased from 2 to 3, to

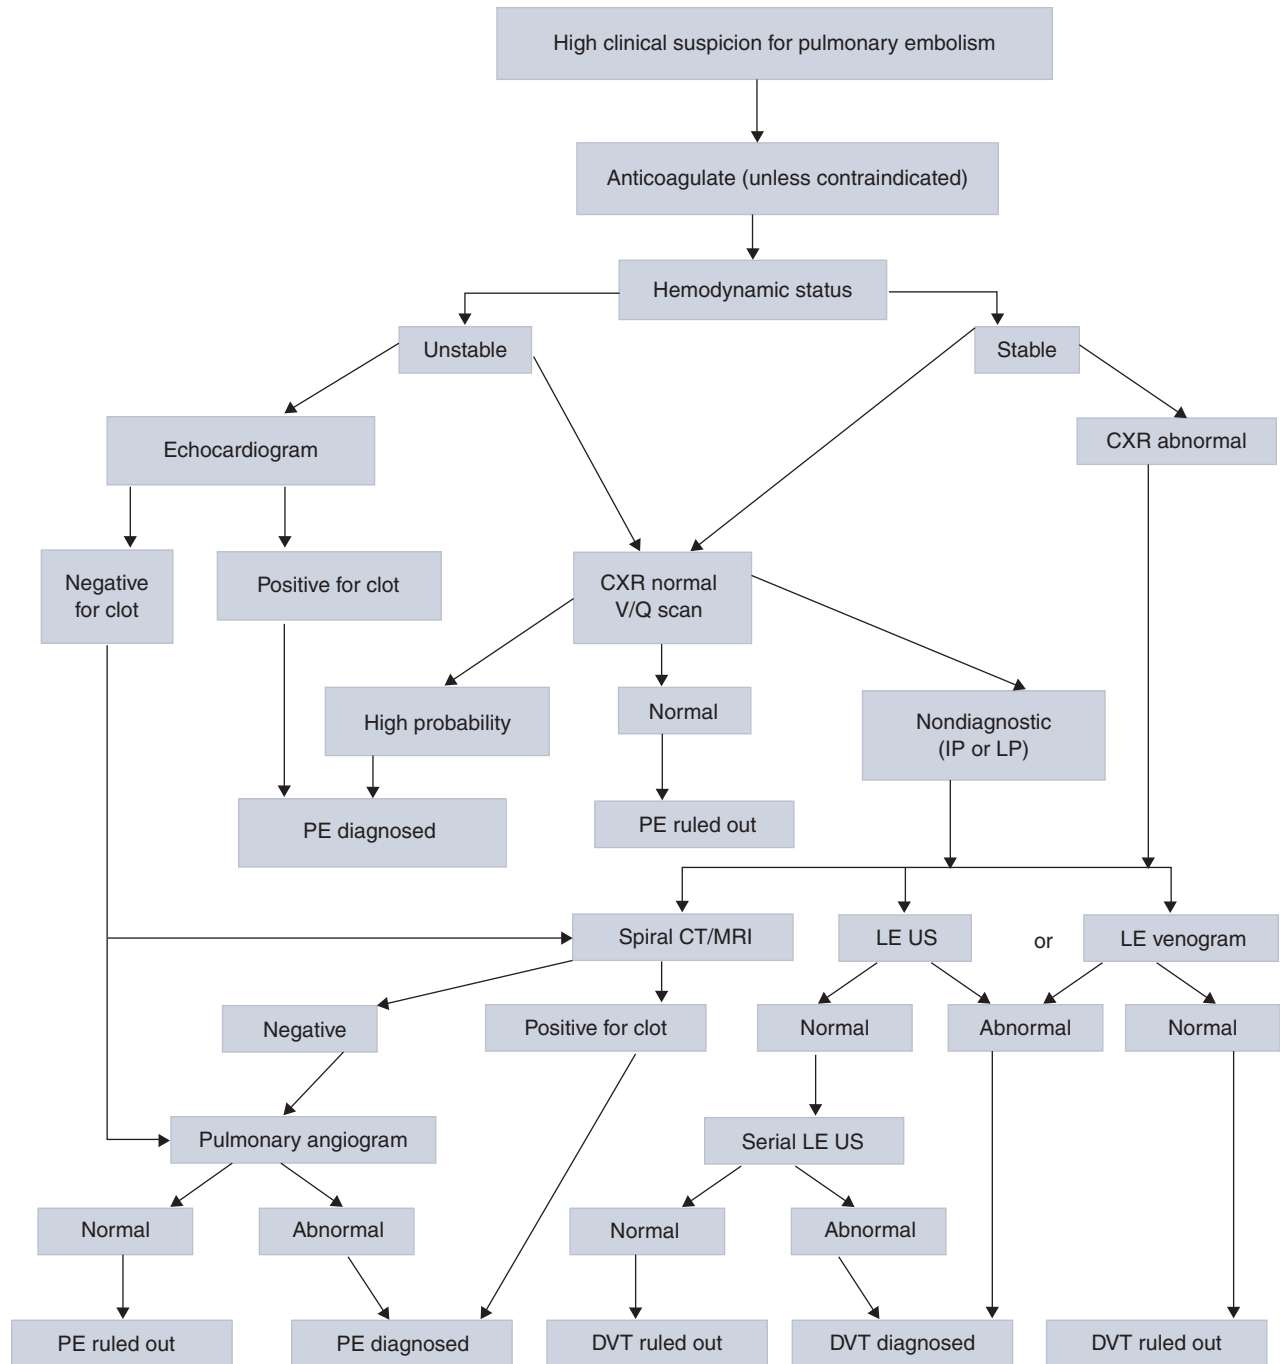

FIGURE 53-13 Suggested algorithm for the evaluation of pulmonary embolism. 3 to 3.5, the patient can be switched to twice-daily UFH, or the patient can be switched to LMWH⁽⁴⁵⁾. Thrombectomy should be used only for patients with massive PE who are hemodynamically unstable and who either have contraindications for thrombolytic therapy or have previously failed thrombolytic therapy⁽³⁷⁾.

Bleeding

Bleeding in cancer patients is most commonly due to thrombocytopenia induced by chemotherapy, marrow infiltration, disseminated intravascular coagulopathy (DIC), extensive radiation therapy, splenic

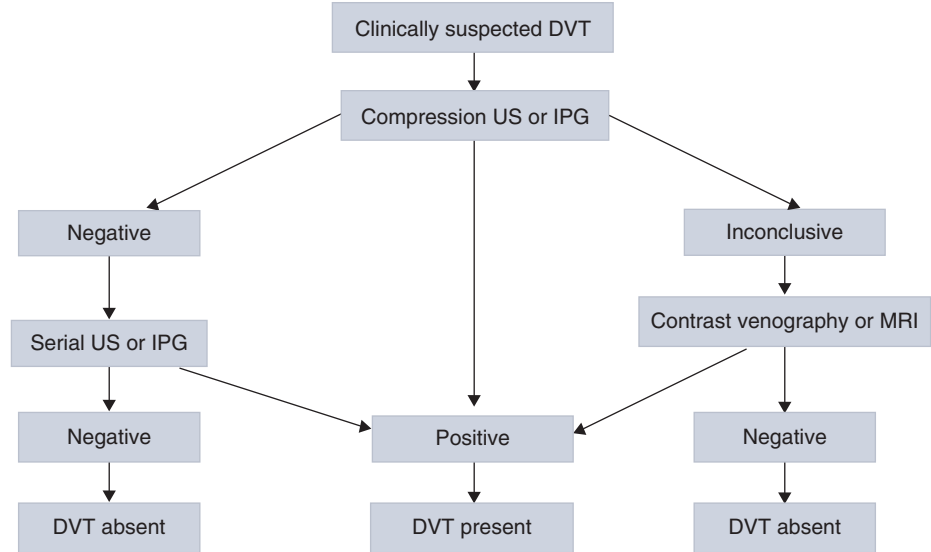

FIGURE 53-14 Diagnostic approach to patients with suspected acute deep venous thrombosis (DVT). IPG, impedance plethysmography; MRI, magnetic resonance imaging; US, ultrasound. (Adapted with permission from Yeung SJ, Escalante CP [eds]: *Oncologic Emergencies*. Hamilton, Ontario, Canada: BC Decker; 2002.)

sequestration, peripheral destruction, or infection. Thrombocytopenia usually manifests as mucocutaneous bleeding, such as gum oozing, epistaxis, and gynecologic or GI bleeding (37). At MDACC, all patients generally receive platelet transfusions if their platelet count falls to $\leq 10,000/\mu\text{L}$. If the patient has active bleeding and the platelet count is between $20,000/\mu\text{L}$ and $50,000/\mu\text{L}$, a platelet transfusion will also be given. A patient will also receive a platelet transfusion if an invasive procedure is planned and his or her platelet count is below $50,000/\mu\text{L}$. The American Society of Clinical Oncology (ASCO) recommends prophylactic platelet transfusions for patients being treated for

Table 53-2 Heparin Dosage Schedule for Venous Thromboembolism

Low-molecular-weight heparin	
Enoxaparin	1 mg/kg subcutaneously every 2 h or 1.5 mg/kg subcutaneously every 24 h
Dalteparin	200 IU/kg subcutaneously every 24 h or in a divided dose every 12 h; maximum dosage = 18,000 IU
Tinzaparin	175 anti-Xa antibody IU/kg subcutaneously every 24 h
Unfractionated heparin	
IV unfractionated heparin	80 IU/kg bolus, with a maintenance dose of 18 IU/kg/d; this should be adjusted to keep PTT at 1.5-2.5 \times the normal range

PTT, partial thromboplastin time.

Table 53-3 Absolute and Relative Contraindications to Thrombolysis

Absolute Contraindications to Thrombolysis
Major intracranial surgery or trauma within prior 2 months
Cerebrovascular hemorrhage within prior 3-6 months
Active intracranial neoplasm
Major internal hemorrhage within prior 6 months
Severe bleeding diatheses, including those associated with severe liver or renal disease
Relative Contraindications to Thrombolysis
Prolonged cardiopulmonary resuscitation
Pregnancy or postpartum period within prior 10 days
Nonhemorrhagic stroke within prior 2 months
Major trauma or surgery (excluding that of the central nervous system) within prior 10 days
Thrombocytopenia (platelet count $< 100,000/\mu\text{L}$)
Hemorrhagic retinopathy
Allergies to thrombolytic agents
Minor surgery to noncompressible vessels within prior 10 days
Tissue biopsy within prior 10 days
Peptic ulceration within prior 3 months
Infective endocarditis/pericarditis
Uncontrolled hypertension (systolic BP ≥ 200 mm Hg or diastolic BP ≥ 110 mm Hg)
Aortic aneurysm

BP, blood pressure. Adapted with permission from Yeung SJ, Escalante CP [eds]: *Oncologic Emergencies*. Hamilton, Ontario, Canada: BC Decker; 2002.

Table 53-4 Dosages of Thrombolytics

Streptokinase	250,000 IU intravenous load over 30 min, then 100,000 IU/h for 24 h for pulmonary embolism or 72 h for deep vein thrombosis
Urokinase	4,400 IU/kg intravenous load over 10 min, then 4,400 IU/kg/h for 12 h
Alteplase	100 mg intravenous infusion over 2 h; initiate heparin at the end of alteplase infusion

leukemia and those receiving bone marrow transplants if their platelet counts are below 10,000/ μ L. Transfusion thresholds may be higher for patients with fever, hyperleukocytosis, a rapid fall in platelet count, coagulation abnormalities, or active bleeding. In addition, ASCO recommends that patients with chronic stable thrombocytopenia who are not undergoing active treatment, such as those with aplastic anemia and patients with myelodysplastic syndrome (MDS), be monitored and given platelets only for active bleeding, even if their platelet count is below 10,000/ μ L. For patients with solid tumors, prophylactic platelet transfusions should be given if the platelet counts are below 10,000/ μ L unless the tumor is necrotic or is located in the bladder and undergoing treatment; in those cases, the threshold for transfusion should be 20,000/ μ L. According to ASCO's guidelines, platelet counts of 50,000/ μ L should be sufficient for invasive procedures, such as surgery. For lumbar puncture, the platelet count should be above 20,000/ μ L. Patients with AML commonly receive multiple transfusions and can develop alloimmunization against human leukocyte antigens (HLAs). Approximately 25% to 35% of patients with AML will become alloimmunized and refractory to nonhistocompatible platelet transfusions, predominantly through their exposure to leukocytes. Random-donor platelets are derived from pooled platelet concentrates from whole-blood donations, whereas single-donor platelets are obtained from one donor by platelet pheresis. The likelihood of alloimmunization can be decreased by using single-donor platelets, leukocyte-depleted platelets, leukocyte filters, and ultraviolet-irradiated platelets. The ASCO guidelines recommend that patients who are platelet refractory not receive platelet transfusions unless they are hemorrhaging or HLA-compatible platelets are available (⁴⁵).

Disseminated intravascular coagulopathy can cause bleeding and thrombosis. Disseminated intravascular coagulopathy should be suspected in a patient who has an unexplained elevation in PT, PTT, or thrombocytopenia with associated bleeding or thrombosis. Although bleeding is most often noted in patients with

DIC, it is the thrombosis of small (and occasionally large) blood vessels that leads to the most serious complications (⁴⁶). Collaborative laboratory findings are high D-dimer and fibrin split product levels, low levels of fibrinogen and thrombin-antithrombin III (TAT), or the presence of schistocytes (⁴⁶). It is important to remember that DIC is a clinical diagnosis based on the entire clinical scenario, and results for these laboratory tests might not be abnormal. Patients can also have mildly abnormal test results in cases of subclinical DIC, and these patients should be monitored closely for conversion to overt DIC.

Tumors can cause DIC, especially adenocarcinomas of the breast, prostate, stomach, lungs, and colon. In this instance, the disorder is believed to be stimulated by mucin produced from these cancers. Leukemia, especially acute promyelocytic leukemia (APL), is associated with DIC in up to 85% of patients because of a tissue factor in APL that has procoagulant activity. Other tumors associated with DIC are melanoma, lymphoma, and ovarian and pancreatic cancers. Other causes of DIC are sepsis, acidosis, extensive burns, the use of Denver catheters or LeVeen shunts in patients with malignant ascites, hemolytic blood transfusion reactions, polycythemia rubra vera, and amniotic fluid embolism (^{37, 46}).

Patients who have both DIC and bleeding can present with oozing from multiple sites, such as arterial or venous punctures or the mucous membranes, or with epistaxis. Thrombotic complications can be visible on the skin in the form of hemorrhagic bullae, acral cyanosis, or even gangrene (⁴⁶). Microvascular thrombosis most commonly affects the lungs, brain, and kidneys. The patient may develop shortness of breath, pleuritic chest pain, and ARDS. The kidneys can become clogged with microemboli, in which case patients often present with oliguria, anuria, hematuria, or proteinuria. The small vessels of the brain also can receive microemboli, causing strokes, seizures, altered mental status, or coma. As the patient deteriorates, hypotension, acidosis, and hypoxia can develop (⁴⁶).

The treatment of DIC should focus on reversing the underlying cause or trigger, such as treating an underlying infection. Acidosis, high catecholamine release, vasoconstriction, and corticosteroid use can exacerbate thrombosis associated with DIC (⁴⁶). Additional therapeutic measures for thrombosis can include heparin administration at 15 U/kg/h by continuous infusion. When the patient is bleeding, blood components (including platelets) can be transfused to correct coagulation abnormalities. Platelet transfusions are indicated to maintain platelet counts of at least 50,000/ μ L. Cryoprecipitate should only be used for severe hypofibrinogenemia <50 mg/dL, or <100 mg/dL if the patient is actively bleeding. Cryoprecipitate can be given at 0.2 bags per kilogram of body weight, and the fibrinogen

level should be tested 20 to 60 minutes after the infusion and every 6 hours thereafter until the bleeding has stopped. Fresh frozen plasma (FFP) can be transfused at 10 to 15 mg/kg to correct abnormalities in PT. Other products that might be needed are prothrombin complex, antithrombin concentrates, or washed RBCs. For patients with persistent bleeding, fibrinolytic inhibitors such as ϵ -aminocaproic acid (EACA) can be given. ϵ -Aminocaproic acid should always be given with heparin to prevent thrombosis; because EACA can cause hypotension, ventricular arrhythmias, and hypokalemia, it should be used with caution. Tranexamic acid is a newer fibrinolytic inhibitor that has fewer side effects and has been used successfully in DIC associated with APL.

GENITOURINARY EMERGENCIES

Hemorrhagic Cystitis

Hemorrhagic cystitis is inflammation or bleeding of the bladder; it can be due to radiation therapy, viral infection, or chemotherapy. Radiation-induced bladder bleeding can present as early as 3 months or as late as 5 years after the termination of radiation therapy. Chemotherapeutic agents associated with hemorrhagic cystitis are cyclophosphamide and ifosfamide (because of the liver metabolites secreted during use of these compounds, namely acrolein and chloroacetaldehyde). The mechanism by which cyclophosphamide and ifosfamide metabolites are toxic to the urinary bladder is not known, but they have been implicated as the cause of hematuria in some patients⁽⁴⁷⁾. Mesna is a thiol compound that binds acrolein, chloroacetaldehyde, and other metabolites of cyclophosphamide and ifosfamide; when it is administered before the patient receives the chemotherapeutic agents, the incidence of bladder toxicity can be decreased⁽⁴⁷⁾. Forced diuresis and adequate hydration complement mesna administration⁽⁴⁷⁾.

In addition to radiation therapy and chemotherapy-inducing hemorrhagic cystitis, the BK virus (a polyomavirus) can become activated in immunocompromised patients undergoing bone marrow transplantation and cause hematuria⁽⁴⁷⁾.

Treatment of hemorrhagic cystitis involves gentle bladder irrigation to remove any clots and decompress the bladder. Any coagulopathy, such as thrombocytopenia, should be corrected, as should manifestations of DIC, such as low fibrinogen levels or an elevated PT or PTT. For patients with persistent bleeding, prostaglandins E_2 or F_2 , 1% alum, or formalin can be instilled. Formalin instillation is painful and requires general or spinal anesthesia. To correct continued bleeding, some patients require surgery, hypogastric artery embolization, or open surgical intervention.

Urinary Tract Obstruction

Obstructive uropathy can be secondary to outflow obstruction or impingement on the ureters or kidneys; it can also be due to tumor invasion, radiotherapy-induced changes, or indirect effects of the tumor, such as ascites, lymphadenopathy, or fibrosis. A patient who is unable to urinate should have a small Foley catheter, such as a 14-F, placed. In patients with benign prostatic hypertrophy (BPH), a coudé catheter can often be inserted more easily⁽⁴⁷⁾. The catheter should not be forced, and if the bladder cannot be accessed, a suprapubic catheter can be used. A lack of residual urine in the absence of severe dehydration usually indicates either obstruction at a more proximal level in the urinary system or acute anuric renal failure. Patients who have residual urine may be unable to urinate because of a mechanical cause, such as BPH, urethral stricture, tumor impingement, or stone obstruction. Other possible causes of acute urinary retention are infection, spinal cord compression, viral radiculomyelitis, postsurgical effects interrupting bladder innervation, or medicines such as pain medications and antihistamines⁽⁴⁷⁾. In each case, the underlying disorder should be treated. Patients with BPH can undergo a trial of α -blockers, such as terazosin, prazosin, doxazosin, or finasteride, a type II 5- α -reductase inhibitor. Transurethral resection of the prostate can be considered for patients who do not respond to medical treatments.

Laboratory values are also useful in differentiating prerenal, postrenal, and renal failure. Patients with prerenal failure typically have a high ratio of BUN to creatinine of more than 20:1, although upper tract GI bleeding, corticosteroid use, and high protein intake can also increase the BUN-to-creatinine ratio. Acute urinary obstruction can present as flank pain, whereas chronic obstruction is often painless, with patients presenting with anuria or decreased urine output. The tumors most likely to cause ureteral obstruction are cervical, prostate, bladder, ovarian, breast, and GI cancers as well as lymphoma⁽⁴⁷⁾. Patients with infected urine and obstruction may also present with symptoms of urosepsis, including fever, confusion, and a high WBC count.

Computed tomography scanning of the abdomen is good for evaluating the cause of ureteral obstruction in that it can elucidate the nature of the obstruction. Other tests that can be used are MRI, renal ultrasound, IV urography, retrograde pyelography, and radionuclide renography⁽⁴⁷⁾. Helical CT scanning of the abdomen has the added benefit of avoiding the use of IV contrast. Urinary obstruction can be managed with ureteral stents or percutaneous nephrostomy tubes with or without internal stents; the stents or tubes are typically placed under guidance by interventional radiology. Many patients with stents develop infection,

which often requires hospitalization, IV antibiotics, and stent replacement. Other possible complications are stent clogging and stent migration. The “double J” stent, which is now most frequently used, is anchored in the bladder and the renal pelvis, so that stent migration is less common than it once was. Open surgical procedures are much less frequently performed now than in the past and are generally reserved for patients in whom endourologic procedures have failed (⁴⁷).

RESPIRATORY EMERGENCIES

Airway Obstruction

Airway obstruction can be caused by intraluminal tumor growth or compression of the airway by an extraluminal tumor. The oral cavity should be quickly visualized to exclude foreign body aspiration. In most cases of upper airway obstruction, the clinical examination provides the diagnosis. Computed tomography of the neck and/or chest is helpful in diagnosing obstruction by tumors. For lower airway obstruction, chest radiographs identify the obstruction in 75% of cases. Rigid or flexible bronchoscopy can be used to both diagnose and treat airway obstruction.

Patients with severe respiratory distress and airway obstruction should undergo endotracheal intubation distal to the obstruction before the obstruction is treated. Laryngoscope or bronchoscope may be used to guide intubation (⁴⁸). Once the airway has been stabilized, the obstruction can be treated. Patients with obstructions in the upper third of the trachea may need a low tracheotomy.

The methods that can be used to provide expedient relief of central airway obstruction include laser treatment, argon plasma coagulation (APC), electrocautery, endobronchial balloon dilation, and stent placement. Argon plasma coagulation can be achieved through flexible or rigid bronchoscopy at a relatively low cost and degrades the obstructive tissue by increasing its temperature. Electrocautery is also relatively inexpensive and can provide immediate relief of the obstruction, but side effects can include fire, hemorrhage, and electric shock. Rigid bronchoscopy can be used to treat extraluminal tumors by metal or silicone stent placement; this technique is most useful for tracheal or main bronchial disease. Metal stents can promote the growth of granulomatous tissue, whereas silicone stents are more likely to develop mucous plugging and to migrate. Laser therapy can also be used for endobronchial lesions, with the possible side effects of hemorrhage, pneumothorax, and pneumomediastinum. Laser therapy is more expensive than the other techniques and requires a skilled technician. Other methods that can be used for airway obstruction are

cryotherapy, external beam radiotherapy, brachytherapy, and photodynamic therapy, CT-guided radiofrequency ablation, and surgical debulking or resection.

Hemoptysis

Massive hemoptysis (about 5% of hemoptysis episodes) (⁴⁹) is defined as the expectoration of >100 mL of blood in a single episode or bleeding into the airway at a rate of >600 mL/d. Some 7% to 10% of patients with lung cancer will develop massive hemoptysis, which carries a poorer prognosis than massive hemoptysis associated with other cancers. In addition to structural abnormalities in the lungs, bleeding can be due to chemotherapy or other medications, sepsis, fungal infections, and thrombocytopenia. Death from this type of hemorrhage usually results from asphyxiation rather than anemia or blood loss.

The cardiopulmonary status should be initially supported by IV fluid and supplemental oxygen. The most important aspect of managing massive hemoptysis is protecting the airway. The American College of Chest Physicians guidelines recommend endotracheal intubation with a single-lumen tube and emergent bronchoscopy (⁵⁰). If the right lung is affected, the left lung can be selectively intubated through bronchoscopy. Use of a rigid bronchoscope allows removal of the tumor or clots, whereas flexible bronchoscopy allows access to the more distal airways. If the left lung is affected, the right lung should not be selectively intubated because inadvertent collapse of the right upper lobe can ensue. A single-lumen endotracheal tube is easier to place than a double-lumen tube and allows a larger area for evacuation of blood and clots. The patient should lie on the side of the bleeding lung to promote aeration of the unaffected lung. Any coagulopathy should be corrected, and cough suppressed with codeine or other agents. If a tumor is causing the bleeding and it can be localized, the patient can undergo bronchial artery embolization or tumor resection. If the tumor is unresectable, external beam radiation therapy can be used. If only the location of the bleeding can be determined, endobronchial interventions may also include administration of topical agents (thrombin), iced saline lavage, injection of epinephrine 1:20,000, laser treatment, electrocautery, APC, photocoagulation, or balloon tamponade.

Bronchial artery embolization is becoming increasingly important for massive or recurrent hemoptysis. An algorithm for management of massive hemoptysis has been proposed (⁵¹), in which CT angiography provides information about the tumor, bleeding site, and vascular anatomy for planning the embolization. The bleeding vessel may be embolized with Gianturco steel coils, isobutyl-2-cyanoacrylate, polyvinyl alcohol

foam, or absorbable gelatin pledgets. Failure of embolization to stop bleeding may require emergency radiotherapy or lung resection ⁽⁵²⁾.

CHEMOTHERAPY-INDUCED EXTRAVASATIONS

Extravasation injuries due to chemotherapy can produce a variety of symptoms ranging from skin irritation to skin ulceration, tissue necrosis, nerve damage, and (rarely) loss of limbs. Vesicant chemotherapy agents, including the alkylating agents (mechlorethamine, cisplatin, mitomycin C), DNA intercalating agents (doxorubicin, daunorubicin), and plant alkaloids (vinblastine, vincristine, vinorelbine), can cause the most severe reactions. Irritant chemotherapy extravasations are generally not severe, causing only pain, erythema, and inflammation at the extravasated site ⁽⁵³⁾.

The goal is to prevent chemotherapy extravasations. The patient should be told to inform the staff of any discomfort, swelling, or erythema over the infusion site. Nursing staff should evaluate the IV infusion site carefully by administering IV fluids before chemotherapy agents are infused, and they should monitor the patient frequently for any evidence of extravasation. Intravenous lines should be placed carefully; areas that have a poor blood supply or overlie a joint should be avoided. If an extravasation does occur, the infusion should be stopped immediately with the catheter left in place, and the staff should attempt to withdraw any remaining chemotherapy agents. Cold compresses should then be placed on the involved site except when the agents are plant alkaloids, in which case warm compresses should be applied ^(54,55).

Topical dimethylsulfoxide in a 50% solution can relieve extravasations when applied at a volume of 1.5 mL to the site every 6 hours for 7 to 14 days. Dimethylsulfoxide is commonly used to treat extravasations caused by mitomycin C and the anthracyclines ⁽⁵³⁻⁵⁷⁾. For extravasations caused by plant alkaloids (vinblastine, vincristine, vinorelbine) and epidophyllotoxins (etoposide, teniposide), a solution of 150 units of hyaluronidase in 1 to 3 mL of saline can be injected into the needle and subcutaneously around the extravasated site ^(54,55).

A 0.17-mol/L solution of sodium thiosulfate can be injected into mechlorethamine-induced extravasation sites. Sodium thiosulfate is thought to work by creating an alkaline-rich site to which the vesicant binds instead of the skin. The by-product is then excreted in the urine ⁽⁵⁵⁾. There is some evidence that sodium thiosulfate can also be used for extravasations caused by carmustine, cisplatin, carboplatin, cyclophosphamide, dacarbazine, and oxaliplatin ⁽⁵³⁾. **Table 53-5** lists selected chemotherapeutic agents and their antidotes.

If local measures fail to contain symptoms in all patients with anthracycline-induced extravasations, a plastic surgeon should be consulted. Surgery can consist of debridement, excision of dead tissues, and, in severe cases, skin graft placement. In patients with doxorubicin-induced extravasation, the drug remains in the tissue for a long period, perhaps being released by dying or dead cells and spreading over time.

Patients who have had previous extravasation reactions can also experience a “recall reaction” when the same chemotherapy is received later, causing ulcerations or burns to reappear at the previously affected area.

METABOLIC EMERGENCIES

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is a result of excessive tumor breakdown, causing hypocalcemia, hyperphosphatemia, hyperkalemia, elevated uric acid, and occasionally acute renal failure. Risk factors for TLS include high tumor burden, chronic renal insufficiency, and certain tumor types (Burkitt lymphoma, lymphoblastic lymphoma, diffuse large cell lymphoma, undifferentiated lymphoma, and leukemia) ⁽²⁾. Tumor lysis syndrome usually presents during chemotherapy, but it can also occur after radiation therapy, corticosteroid treatment for sensitive tumors, or administration of hormonal agents.

Patients with TLS can present with nausea and vomiting, diarrhea, constipation, low urine output, weight gain, acute renal failure, weakness, cramps, seizures, tetany, or arrhythmias.

A scoring system for predicting TLS has been derived from acute myelocytic leukemia patients ^(58,59). The score may guide prophylaxis for TLS. Preventive measures for patients at risk are hydration with IV crystalloid fluid up to 3 L/m²/d to maintain a urine output >100 mL/h and allopurinol (100-300 mg/d orally).

Alkalinizing the urine to increase uric acid solubility in the urine is no longer recommended for prophylaxis. To prevent TLS, patients with leukemia and high WBC counts may be treated with leukapheresis or hydroxyurea before chemotherapeutic agents are administered.

Once TLS is diagnosed based on the Cairo-Bishop definition ^(60,61) patients with severe TLS should be monitored in intensive care. Rasburicase is a highly soluble IV recombinant form of urate oxidase that converts uric acid to allantoin and is highly efficacious in prevention or treatment of hyperuricemia. Rasburicase (150-200 µg/kg IV daily or one-time dosing with a rescue dose as needed) may be used to prevent or treat

Table 53-5 Chemotherapeutic Extravasations and Their Antidotes

Chemotherapy Agent	Irritant/ Vesicant	Sodium Thiosulfate	DMSO	Hyaluronidase	Cool	Warm

DMSO, dimethylsulfoxide.

urate nephropathy (⁶²). Increased IV fluid hydration may be coupled with diuretics. Urinary alkalization by IV infusion of sodium bicarbonate or acetate should only be considered in cases of severe hyperuricemia when rasburicase cannot be obtained.

Hyperkalemia should be monitored closely and treated with insulin plus dextrose, calcium, and bicarbonate intravenously along with oral potassium ion exchange resins (sodium polystyrene sulfonate). In hyperphosphatemic patients with hypocalcemia, oral calcium compounds will reduce phosphate absorption and enhance calcium absorption. Some patients with refractory electrolyte abnormalities might require dialysis if conservative measures fail. An indication for dialysis is symptomatic hypocalcemia in the presence of hyperphosphatemia (serum phosphorus >3.3 mmol/L [>10.2 mg/dL]). Other indications for dialysis include persistent or refractory azotemia, volume

overload, hyperuricemia, acidemia, and refractory hyperkalemia. Dialysis should be continued until biochemical abnormalities resolve.

Hypercalcemia

Hypercalcemia is present in 10% to 20% of patients with advanced cancer (²). The most common cancers include squamous cell cancer of the lungs, breast cancer, multiple myeloma, and lymphoma (²). The two major mechanisms of hypercalcemia include the secretion of a parathyroid-related peptide (PTHrP) and abnormal 1,25-vitamin D production (which occurs in Hodgkin disease and non-Hodgkin lymphoma).

Symptoms of hypercalcemia are altered mental status, polyuria, polydipsia, nausea, vomiting, anorexia, constipation, and seizures (²). Measured serum calcium levels should be adjusted according to the albumin

level for accurate estimation. A low albumin level should be subtracted from 4, and the difference should be multiplied by 0.8. This product should be added to the serum calcium level to arrive at the estimated calcium. Alternatively, ionized calcium can be measured, which assesses the active calcium in the serum and is more accurate.

The choice of treatment for hypercalcemia depends on the patient's calcium level and symptoms. Calcium is a potent diuretic, and patients with mild hypercalcemia can be treated by IV fluids. Patients with a calcium level greater than 14 mg/dL should be treated with additional measures. Patients who have symptoms of hypercalcemia and a calcium level between 12 and 14 mg/dL should also receive additional treatment to lower the calcium level.

Bisphosphonates are the drugs of choice in treating hypercalcemia. Pamidronate can be given intravenously over 2 to 24 hours. A 60-mg dose corrects hypercalcemia 60% of the time, and a 90-mg dose does so 100% of the time (²). Bisphosphonates do not work immediately but have an onset of action after 12 to 48 hours (²). Zoledronic acid, a relatively new agent, can be infused more rapidly than pamidronate; the recommended dose is 4 mg intravenously over 15 minutes. Bisphosphonates are useful in not only reducing serum calcium levels but also helping to decrease bone pain and treat skeletal complications in cancer patients with bone metastases (⁶³).

Calcitonin can also be used to treat hypercalcemia; it has an onset of action of 2 to 4 hours, but its effects are transient because tachyphylaxis develops after 3 days. Patients may develop nausea, abdominal cramps, or hypersensitivity reactions to calcitonin (²).

Corticosteroids can be helpful in some patients with hypercalcemia—for instance, those with lymphoma and myeloma. Dialysis is reserved for patients who are unable to tolerate hydration. Furosemide can be used, but only after the patient has been hydrated adequately. Gallium nitrate and plicamycin are rarely used because of the high risk of toxic effects.

GASTROINTESTINAL EMERGENCIES

Gastrointestinal Bleeding

Patients with cancer can present with GI bleeding due to direct tumor invasion, effects of chemotherapy agents or corticosteroids, thrombocytopenia, coagulopathy, side effects of radiation therapy, or Mallory-Weiss tears from intractable nausea and vomiting. Other possible causes of GI bleeding are gastritis, peptic ulcer disease, duodenal ulcers, arteriovenous malformations, and diverticulosis. Patients who have

undergone bone marrow transplantation can present with GI bleeding as a manifestation of graft-versus-host disease, which typically presents as ulcerations in the small intestine. For patients bleeding from the upper GI tract, a nasogastric tube should be inserted and the tract lavaged with normal saline until the bleeding clears. If the bleeding does not clear, emergent upper GI endoscopy may be considered. Patients with small tumors rarely have significant bleeding, and patients with large tumors tend to ooze and bleed. However, relief of bleeding by endoscopic measures is usually temporary, and these tumors tend to bleed repeatedly. Endoscopic interventions can include electrocoagulation, epinephrine injections, and argon plasma laser treatment. For patients with persistent bleeding, arteriography and embolization are occasionally successful. If all other interventions have failed, surgery can be considered. Patients with bleeding should have any coagulopathy corrected, including deficits in the platelet count, which should be greater than 60,000/ μ L. Somatostatin or vasopressin can be used to control bleeding of esophageal varices. The patient should receive either an H_2 blocker or a proton pump inhibitor intravenously. Nausea should be controlled using IV antiemetics, and the patient should receive nothing by mouth. The patient should also receive maintenance IV fluid. If hypotensive, the patient should be volume resuscitated with IV crystalloid fluid and/or transfusion.

Typhlitis

Typhlitis is a syndrome of bowel inflammation, edema, and wall thickening involving the proximal large bowel in patients with neutropenic fever. It commonly affects the cecum but can also affect the ascending colon and occasionally the transverse colon. Typhlitis can occur in conjunction with any cancer but is most common in patients with leukemia (²⁶). The organisms most often isolated in cases of typhlitis are *Clostridium* and gram-negative bacilli (⁶⁴).

Patients with typhlitis present with fever, pain in the right lower quadrant of the abdomen, and sometimes diarrhea, which may be bloody. The patient with typhlitis is neutropenic, and plain abdominal x-ray films are often inconclusive. The diagnosis of typhlitis is made based on clinical suspicion and CT or MRI findings that reveal bowel inflammation, edema, wall thickening, and possibly air formation or, in severe cases, free air (Fig. 53-15).

Typhlitis is managed by bowel rest and IV administration of broad-spectrum antibiotics, including anaerobic coverage. Patients rarely require surgery unless they develop intractable bleeding or bowel perforation or do not respond to conservative measures.

INTRODUCTION

Onco-cardiology is a fast-growing medical subspecialty focused on the management of heart diseases in patients with cancer. Although cancer remains a leading cause of morbidity and mortality worldwide, the survival rate of patients with cancer has increased in the last 25 years. In the United States, the 5-year relative survival rate of patients diagnosed with cancer between 1975 and 1977 was 50%; it increased to 68% between 1999 and 2005. The US National Cancer Institute estimates that at least 13.7 million cancer survivors were alive in the United States in 2012 ⁽¹⁾. With the survival improvement, the long-term adverse treatment effects have also become more apparent. A survey of 1,807 cancer survivors with a 7-year follow-up found that 33% died of heart diseases and 51% died of cancer ⁽²⁾. Historically, since the late 1970s, the interest in chemotherapy-induced cardiotoxicity was focused on cardiomyopathy related to few chemotherapeutic agents. As the field of cancer therapies has expanded, so has the finding of other cardiovascular side effects such as transient left ventricular dysfunction, hypertension (HTN), cardiac arrhythmias, pericardial effusions, and arterial ischemia. Patients with known or subclinical cardiac disease are more susceptible to the cardiotoxic side effects of cancer therapy, and those with known cardiac disease often need to alter their cardiac management to allow for the treatment of cancer. This can be associated with significant cardiovascular risks. Onco-cardiology has evolved to address the cardiovascular needs of patients whose optimal outcome mandates close and collaborative

efforts between cardiologists and oncologists in a multidisciplinary approach. Involvement of cardiologists in cancer patients' care has changed from focusing on management of the cardiovascular complications of therapy to an overall assistance in the care of these patients from the initial cancer diagnosis to survivorship as outlined in [Fig. 54-1](#).

PATHOPHYSIOLOGY

Clinical knowledge and basic science discoveries in onco-cardiology have grown over the last decade. There is better understanding of molecular mechanisms of cardiac toxicity of several cancer drugs. An example is the observation that the Bruton tyrosine kinase receptor is expressed in the atria of human heart tissue ⁽³⁾. This tyrosine kinase receptor is the target of a novel drug, ibrutinib, used in certain hematologic malignancies including chronic lymphocytic leukemia. Ibrutinib has been associated with a significant incidence of atrial arrhythmias, potentially mediated by its on-target effect and more specifically by inhibiting the PI3K-Akt signaling pathway ⁽³⁾. Similarly, trastuzumab targets ErbB2 in breast cancer cells and has been shown to improve outcome and prolong survival in HER2+/ErbB2 breast cancer. The same receptors within the cardiac myocyte are responsible for normal cell function and myocyte repair. When affected by ErbB2 inhibitors like trastuzumab, secondary mitochondrial dysfunction can be observed ⁽⁴⁾. Other mechanisms of toxicities have recently been reported with older conventional chemotherapeutic drugs like

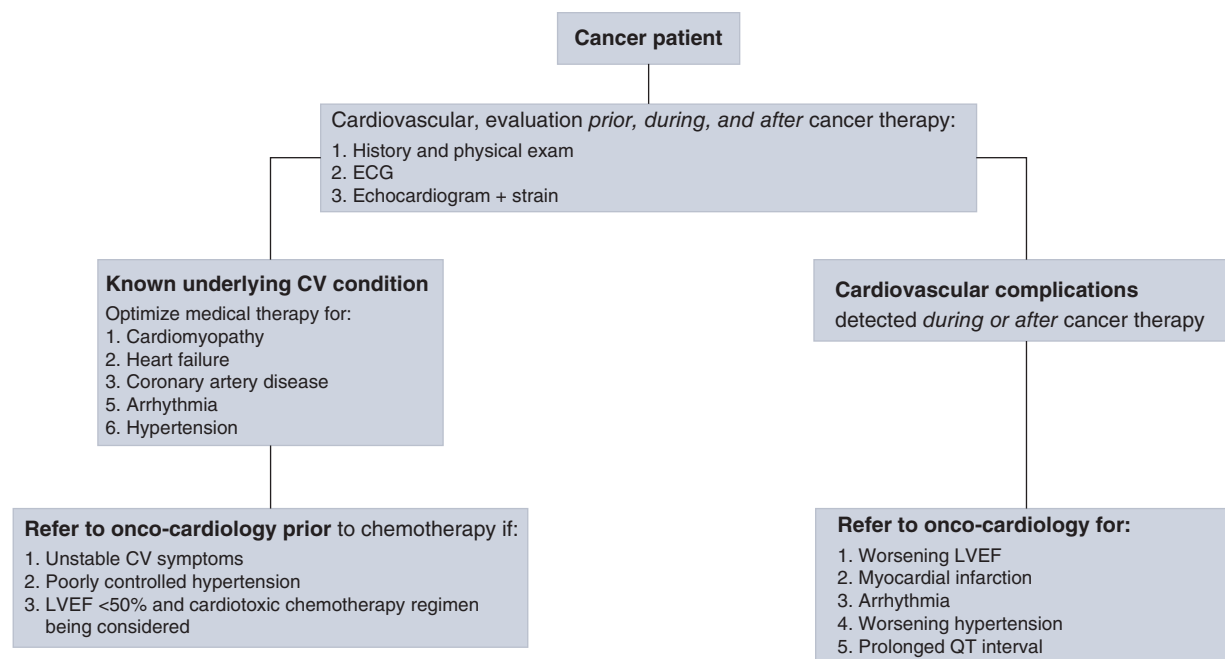

FIGURE 54-1 Algorithm for the general role of onco-cardiology. CV, cardiovascular; ECG, electrocardiogram; LVEF, left ventricular ejection fraction.

the anthracyclines; cardiovascular toxicity of this drug has been recently linked to inhibition of topoisomerase II β (°). This enzyme is responsible for normal myocyte function, and its inhibition partially explains the cardiovascular toxicity of doxorubicin. In addition to the benefit of improving strategies to prevent drug toxicities, a better understanding of these biologic pathways may also provide better understanding of certain heart diseases and their management. For example, the discovery of the key role of ErbB2 in normal cardiac function and its relation to trastuzumab toxicity was followed by the discovery of the benefit of an ErbB2 agonist called neuregulin-1 in the animal models of heart failure (°). Neuregulin-1 is currently being studied for the treatment of heart failure in humans.

CARDIOVASCULAR SYNDROMES OBSERVED IN CANCER PATIENTS

Aside from the direct cardiac toxic effect of certain cancer drugs (Fig. 54-2), many aspects of the cardiovascular system can be affected by cancer or cancer therapy (Fig. 54-3), resulting in a variety of cardiovascular syndromes.

Myocardial Dysfunction

Onco-cardiologists are often asked to assess patients with cancer and clinical heart failure (HF) symptoms. Although the most feared etiology is the progressive,

permanent, and irreversible myocardial damage related to anthracycline toxicity, this in fact constitutes only a small percentage of patients with clinical HF. The majority of patients with new-onset HF in the setting of cancer and cancer therapy have their symptoms triggered by mechanisms other than anthracycline toxicity. Despite some overlap, a clinically useful approach is to divide patients into two groups based on the initial clinical presentation (Table 54-1). The first group includes patients presenting with sudden and new-onset acute HF with associated systolic dysfunction. These patients include those with cardiomyopathy related to sepsis, stress cardiomyopathy, and myocarditis (toxic or infectious). The second group includes patients presenting with subacute or chronic HF symptoms and includes those with underlying structural heart disease, those with chemotherapy-induced cardiomyopathy, and those with infiltrative myocardial conditions related to their underlying malignancies or to cancer therapy (amyloidosis, iron overload). Evaluation of these patients typically includes obtaining a two-dimensional echocardiogram, brain natriuretic peptide, troponin, thyroid function tests, iron/ferritin level, ischemia assessment, and occasionally endomyocardial biopsy.

Acute Cardiomyopathy

Most of these cases are related to conditions referred to as reversible myocardial dysfunction or stress cardiomyopathy. This is a phenomenon typically

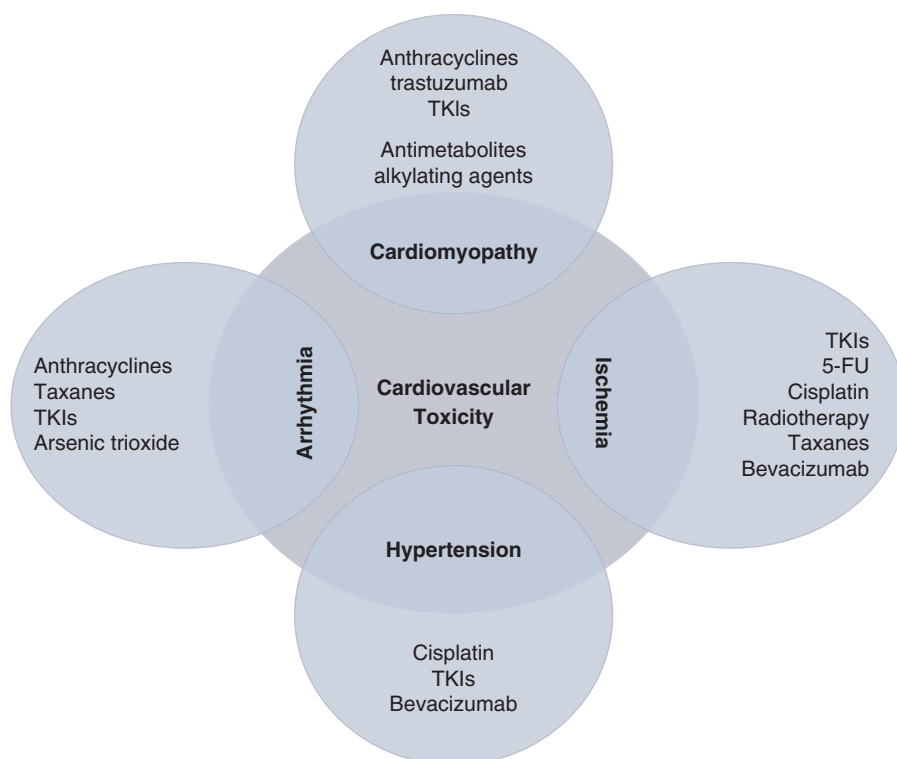

FIGURE 54-2 Cardiovascular syndromes associated with certain chemotherapy agents. 5-FU, 5-fluorouracil; TKI, tyrosine kinase inhibitor.

triggered by sepsis, but also occurs in a wide range of acute illnesses (see Table 54-1). Myocardial dysfunction has been documented in up to 40% of patients with sepsis and is a major predictor of mortality in this population (^{7,8}). During the course of the malignancy management, patients are at risk of these acute illnesses, especially during chemotherapy with

secondary neutropenic sepsis. Physiologically, both left and right ventricular systolic functions are diminished with variable degrees of myocardial depression. This is typically reversed within 7 to 10 days. The exact mechanism for myocardial dysfunction is not well defined, and multiple theories have been suggested including the possibility of altered

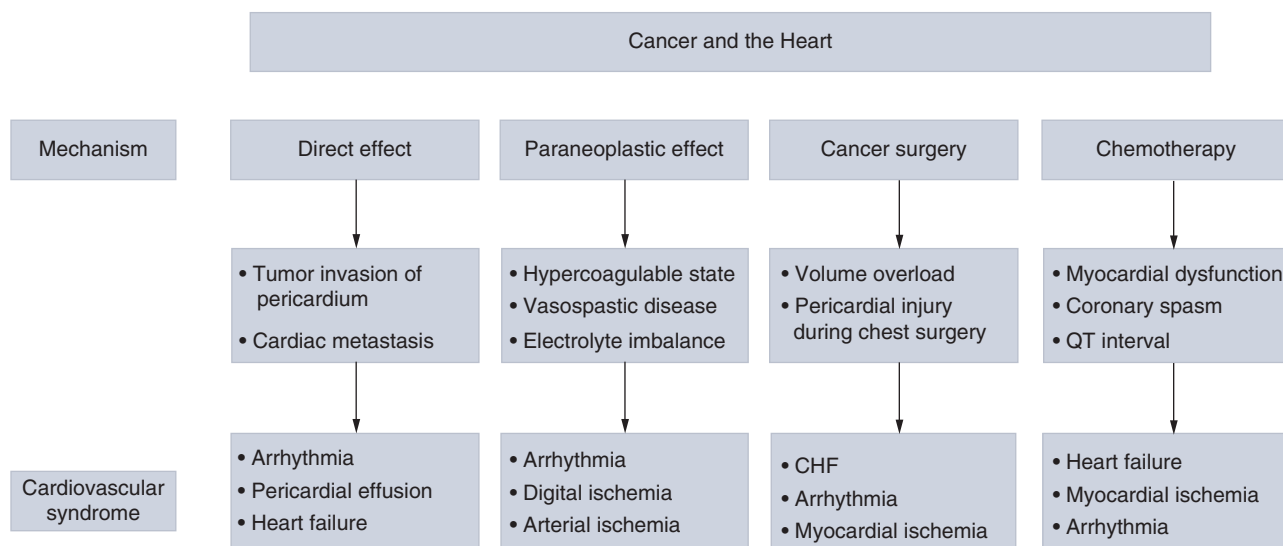

FIGURE 54-3 Mechanisms and etiology of some cardiovascular syndromes observed in cancer patients. CHF, congestive heart failure.

Table 54-1 Etiologies of Left Ventricular Systolic and Diastolic Heart Failure in Cancer Patients

Acute Left Ventricular Systolic Dysfunction	Subacute/Chronic Left Ventricular Dysfunction
Stress cardiomyopathy	Preexistent cardiomyopathy
Sepsis	Ischemic heart disease
Myocarditis	Nonischemic cardiomyopathy
Viral	Hypertensive heart disease
Chemotherapy	Chemotherapy
Myocardial infarction	Infiltrative cardiomyopathy
Metabolic derangement	Amyloid heart disease
Hypocalcemia	Iron overload

microcirculatory flow, mitochondrial dysfunction, myofibrillary dysfunction, autonomic dysregulation, altered calcium cellular transportation, and others (^{7,9}) (Fig. 54-4). Clinically, patients with reversible myocardial dysfunction/stress cardiomyopathy are recognized when evidence of new-onset left ventricular (LV) dysfunction is documented in the appropriate clinical setting (see Table 54-1). It is frequently associated with repolarization abnormalities on electrocardiogram (ECG) and minimal rise in cardiac troponins. Echocardiographic findings of severe LV dysfunction are typically out of proportion to the ECG changes and the cardiac biomarkers rise. The severity of LV dysfunction, however, correlates well with the brain natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) levels (^{7,9}). The management is focused on stabilizing the patient's blood pressure using vasopressors if shock is present and transitioning to cardioprotective drugs like angiotensin-converting enzyme (ACE) inhibitors and β -blockers after the patient is weaned off of pressure support and when blood pressure is stable for 24 to 48 hours. Improvement and recovery of myocardial dysfunction are typically observed within 7 to 10 days (⁷). Persistent LV dysfunction beyond 2 weeks should raise suspicion of possible underlying ischemic heart disease or viral myocarditis in these typically immunocompromised patients. These two conditions are associated with significant rise in cardiac biomarkers like troponin and creatine kinase (CK)-MB. Patients with suspected ischemic heart disease should undergo evaluation and management of coronary artery disease. The diagnosis of viral myocarditis is more challenging because viral cultures and antibody titers have limited diagnostic accuracy. Myocardial biopsy is the gold standard in the general population for diagnosis of viral myocarditis despite its limited diagnostic yield (60% and 80% sensitivity and specificity, respectively) (¹⁰). This can be more challenging and risky in patients with cancer because they often have

FIGURE 54-4 Acute severe cardiomyopathy with shock following chemotherapy for ovarian cancer complicated by severe hypocalcemia. Echocardiographic studies showing (A) baseline normal left ventricular systolic function and (B) severely depressed systolic function with small pericardial effusion 48 hours after developing severe hypocalcemia. (C) Severe hypocalcemia following chemotherapy.

coagulopathy with risk of procedure-related complications (bleeding, myocardial perforation). The use of empiric therapy with intravenous immunoglobulin for its antiviral and immunomodulatory effect in this setting is controversial, especially with the limited data to support the benefit of such intervention in the adult population (¹¹). It is also typically associated with high-volume fluid shift, which can exacerbate HF. Figure 54-5 summarizes a suggested algorithm for evaluation of new-onset cardiomyopathy and HF in patients with cancer.

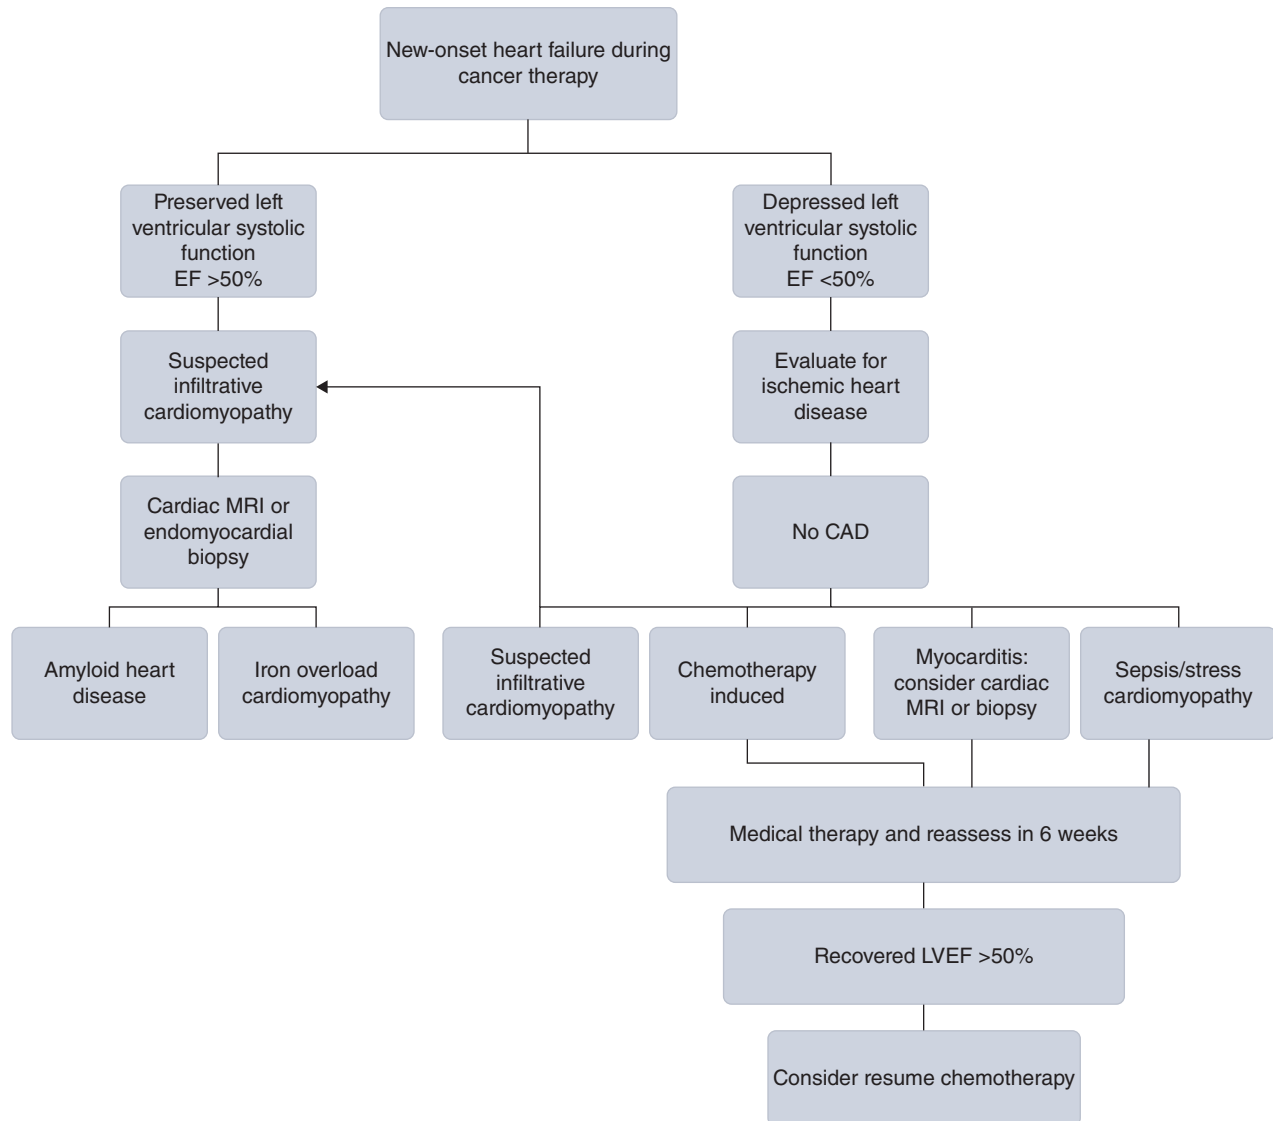

FIGURE 54-5 Algorithm for evaluation of patients with acute cardiomyopathy during cancer therapy. CAD, coronary artery disease; EF, ejection fraction; LVEF, left ventricular ejection fraction; MRI, magnetic resonance imaging.

Chemotherapy-Induced Cardiomyopathy

Definition

A large number of chemotherapeutic agents have been linked to cytotoxic myocardial injury. Table 54-2 lists several groups of chemotherapeutic agents known to be associated with LV systolic dysfunction or HF. The ones most commonly associated with cardiomyopathy include anthracyclines, alkylating agents, and tyrosine kinase inhibitors (TKIs). Cardiotoxicity in general is defined as a drop in LV ejection fraction (LVEF) by 5% or more, to less than 55% in the presence of HF symptoms, or an asymptomatic drop in LVEF by 10% or more to less than 55% (¹²). Myocardial toxicity is also classified into type I and type II based on the nature of myocyte injury.

Type I Myocardial Toxicity

Anthracyclines are the prototype of drugs causing type I, irreversible myocyte damage. Histologic findings include myofibrillar disarray, disruption of cellular organelles, myofibrillar loss, and myocyte death (¹³). Myocardial toxicity is dose dependent, with <5% chance of cardiomyopathy observed at a cumulative dose of <400 mg/m² in the case of doxorubicin (150 mg/m² for idarubicin and 900 mg/m² for epirubicin). This risk increases to 26% at a cumulative dose of 550 mg/m² (¹⁴). Anthracycline-related cardiotoxicity has also been classified as acute or chronic. The acute form manifests as nonspecific ECG changes, arrhythmia, myopericarditis, and transient LV dysfunction. The more feared chronic form is marked by LV systolic dysfunction occurring many months to years

Table 54-2 Most Commonly Used Chemotherapeutic Agents Known to Be Associated With Left Ventricular Systolic Dysfunction or Heart Failure

Chemotherapeutic Agent	Mechanism of Toxicity	Cardiomyopathy Incidence	Other Cardiovascular Toxicity
Anthracyclines <ul style="list-style-type: none"> • Doxorubicin • Epirubicin • Idarubicin 	Oxidative stress Inhibition of topoisomerase II β	5% at 400 mg/m ² 18% at 700 mg/m ² 4% at 900 mg/m ² 15% at 1 g/m ² 5%	Arrhythmia Pericarditis Arrhythmia
Anthracyclines analogues <ul style="list-style-type: none"> • Mitoxantrone 		2.6%	Arrhythmia Hypertension
Monoclonal antibodies <ul style="list-style-type: none"> • Rituximab • Cetuximab • Alemtuzumab • Trastuzumab • Bevacizumab 	No direct toxicity Hypomagnesemia-related arrhythmia Infusion-related hemodynamic effect ErbB2 receptor-mediated myocyte dysfunction VEGF inhibition Hypertension-mediated cardiomyopathy	<0.5% 2%-28% 1.7%-3%	Arrhythmia Hypotension Arterial thrombosis Hypertension
Alkylating agents (at high dose) <ul style="list-style-type: none"> • Cyclophosphamide (>1.5 mg/m²) • Busulfan • Ifosfamide (>1 g/m²) 	Myocarditis Myocardial fibrosis Myocarditis	3%-25% Rare 17%	Tamponade Pericardial effusion Myocardial infarction, arrhythmia
Antimetabolites <ul style="list-style-type: none"> • Gemcitabine • 5-Fluorouracil 	Noncardiogenic pulmonary edema	7.1% 2%	Ischemia
Antimicrotubule agents <ul style="list-style-type: none"> • Vinca alkaloids (vincristine, vinblastine) 	Impairment of myocardial metabolism	3%	Coronary spasm Hypertension
Oral tyrosine kinase inhibitors <ul style="list-style-type: none"> • Dasatinib • Lapatinib • Pazopanib • Sorafenib • Sunitinib • Vandetanib 	Mitochondrial toxicity Dysregulation of cellular energy Mitochondrial toxicity	1%-4% heart failure Up to 10%-28% left ventricular systolic dysfunction	Hypertension QT prolongation Arterial thrombosis Arrhythmia Fluid retention

VEGF, vascular endothelial growth factor.

following exposure and manifests as progressive HF. It is not clear whether the acute form of anthracycline cardiotoxicity is the prodrome of the more delayed cardiomyopathy form, because it has been shown that myocyte dysfunction can be observed even after the first dose of the drug. It is plausible that myocardial reserve allows normal cardiac function despite initial injury and until a second insult leads to further myocardial cell loss and subsequent systolic dysfunction. The long-term prognosis of chemotherapy-induced cardiomyopathy is much worse compared to other etiologies (¹⁵). For years, the understood mechanism has been based on the free radical and iron hypothesis.

The addition of an electron to the quinone moiety of anthracyclines within the cardiomyocytes leads to the generation of excess reactive oxygen species (ROS) and subsequent mitochondrial and intracellular protein damage. This toxicity is further increased when ROS interact with iron, generating a surge of oxidative stress (¹⁶). More recently, topoisomerase II β was found to be a key mediator of anthracycline-induced cardiomyocyte toxicity. Anthracycline-mediated inhibition of topoisomerase II β causes double-stranded DNA breaks, which can lead to cardiomyocyte death (⁵). The use of topoisomerase II β level in peripheral blood leukocytes has recently been reported to be of potential

benefit for risk stratification and as a surrogate biomarker for individual susceptibility for anthracycline-induced cardiotoxicity⁽¹⁷⁾. In a small study, the level of topoisomerase II β was significantly higher in the anthracycline-sensitive group. Close cardiac monitoring with early recognition and treatment of LV dysfunction using β -blockers and ACE inhibitors within the first 6 months of onset has been shown to be associated with stabilization and even recovery of cardiac function⁽¹⁸⁾. These observations are the basis for the current recommendations of routine cardiac monitoring during anthracycline therapy. Different diagnostic tools have been useful in monitoring these patients including the use of cardiac biomarkers and/or cardiac imaging studies⁽¹⁹⁾. There is no consensus regarding the best approach and optimal timing for testing. At the University of Texas MD Anderson Cancer Center (MDACC), we rely on serial imaging with two-/three-dimensional echocardiograms with myocardial strain to monitor these patients (Figs. 54-1 and 54-6).

Multiple primary preventive measures may be needed to lower the risks of anthracycline-induced cardiomyopathy. Continuous infusions instead of repetitive boluses are associated with a lower incidence of myocyte damage⁽²⁰⁾. Drug peak plasma level correlates with the degree of myocyte toxicity, whereas the area under the curve determines antitumor efficacy. Modified preparations of anthracyclines such as liposomal doxorubicin are associated with lower risk. Dexrazoxane is thought to lower risk through iron chelation and interference with the topoisomerase II β complex by preventing it from binding to anthracyclines. Finally,

the use of β -blockers and ACE inhibitors or angiotensin receptor blockers has been associated with mixed results in small prospective studies^(21,22). It is not clear if they exert a potential cell protection effect or if they only have a beneficial hemodynamic effect. Their role in primary prevention of chemotherapy-induced cardiotoxicity is uncertain.

Type II Myocardial Toxicity

This toxicity is associated with reversible disruption of myocyte contractile function. Trastuzumab is the prototype drug. Other targeted chemotherapy agents, including several small-molecule oral TKIs, are also suspected to exert type II cardiotoxicity. The mechanism involves disruption of signaling pathways responsible for tumor growth and also for cardiac cell repair (ErbB2 in the case of trastuzumab), resulting in myocyte dysfunction but not cell death⁽²³⁾. Up to a third of patients treated with trastuzumab develop evidence of LV systolic dysfunction or HF symptoms that are often reversible upon discontinuation of this agent⁽²⁴⁾. Re-initiation or continuation of trastuzumab after LV systolic function recovery is usually well tolerated. The US Food and Drug Administration (FDA) recommends monitoring LV function with imaging every 3 months during therapy. Not all patients are at the same risk, and several predisposing factors increase susceptibility for trastuzumab cardiotoxicity. These include concomitant use of anthracyclines, advanced age, and HTN or other underlying structural heart disease. There is an incremental increase in the incidence of LV systolic dysfunction or HF as the number of risk factors increases. For

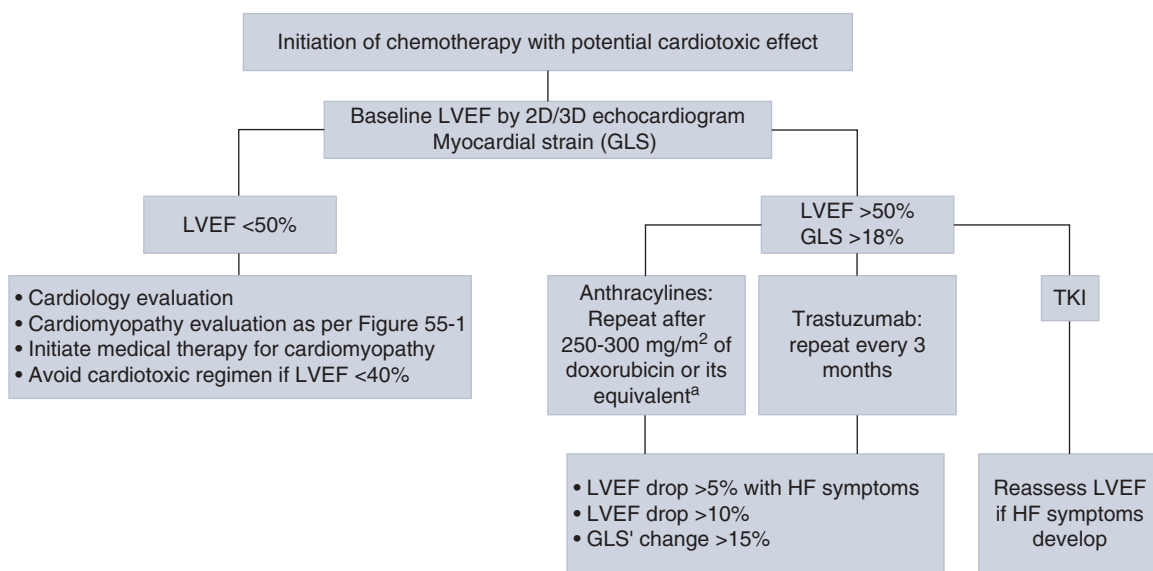

FIGURE 54-6 Algorithm for cardiac monitoring and management of patients receiving potentially cardiotoxic chemotherapy. 2D/3D, two-dimensional/three-dimensional; GLS, global longitudinal strain; HF, heart failure; LVEF, left ventricular ejection fraction; TKI, tyrosine kinase inhibitor. ªEquivalent cardiotoxicity dose to 300 mg/m² of doxorubicin = 150 mg/m² of idarubicin = 900 mg/m² of epirubicin.

example, the risk of myocardial dysfunction increases from <1% in young women with no risk factors to 27% in elderly patients receiving concomitant anthracyclines⁽¹²⁾. A clinical risk stratification model (National Surgical Adjuvant Breast and Bowel Project cardiac risk score) has been proposed to help risk stratify patients, but it needs to be validated⁽²⁵⁾.

Tyrosine kinase inhibitor-related LV dysfunction has been reported since early phase I and II studies. The mechanisms of toxicity are not fully understood, and several theories have been proposed, including apoptotic versus nonapoptotic cell death, dysregulation of cellular energy homeostasis through inhibition of 5-AMPK⁽²⁶⁾, mitochondrial toxicity, and HTN-mediated LV dysfunction⁽²⁷⁾. The incidence of TKI-related cardiomyopathy and HF varies widely with different drugs (mostly reported with sunitinib, sorafenib, imatinib, nilotinib, and ponatinib) and differs between studies by almost 10-fold. This is partially related to the fact that cancer trials typically do not have cardiovascular events as outcomes, and this likely leads to an underestimation of the incidence of such events. Also, the usual clinical HF symptoms of fatigue, dyspnea, and leg edema are nonspecific in patients with cancer, leading to limitations in clinical diagnostic accuracy. The incidence of symptomatic HF necessitating medical therapy varies between 1.5% and 15%, and the rate of reported drop in LVEF is between 7% and 28%⁽²⁷⁻³¹⁾. Time to onset of cardiomyopathy varies from a few weeks to several months after initiation of TKIs. Evidence of reversibility of significant LV dysfunction was seen in half of the patients after TKIs were discontinued.

Management

When clinical HF or LV systolic dysfunction is confirmed, patients typically are taken off of the TKI, and HF drugs are initiated (ACE inhibitors, β -blockers, and diuretics). Depending on the patient risk factors and clinical presentation, workup for other possible etiologies of cardiomyopathy should be performed when appropriate (ie, ischemic heart disease, HTN). In the absence of strong prospective data, there is not enough information to support the routine use of cardiac imaging to monitor asymptomatic patients. It is common practice to obtain a baseline two-dimensional echocardiogram study before initiating these drugs, with a low clinical threshold to obtain repeated echocardiographic studies if dyspnea or fluid retention symptoms develop on TKIs.

Preexisting Cardiac Dysfunction

This is usually observed in patients with underlying diastolic or systolic LV dysfunction including hypertensive heart disease, ischemic heart disease, or nonischemic cardiomyopathy. Decompensated HF symptoms

are often triggered by large amounts of intravenous fluids given during certain chemotherapy infusions (eg, cisplatin). Patients typically respond well to withholding fluids and using diuretics. Standard HF therapy, including β -blockers and ACE inhibitors, is indicated if LV systolic dysfunction is present⁽³²⁾.

Other Forms of Cardiomyopathies Observed in Cancer Patients

Infiltrative processes are another cause of cardiomyopathies commonly encountered. Examples include amyloidosis and secondary hemochromatosis. In patients with myelodysplastic syndrome, myocardial iron overload develops from frequent blood transfusions (ie, >100 units).

Ischemic Arterial Disease in Cancer

The association between malignancy and ischemic arterial diseases is well established. The clinical presentation and management of arterial ischemic events vary based on the arterial bed and the organ involved. The clinical spectrum includes stroke, myocardial infarction, and visceral and limb ischemia. In two large separate cohorts of patients with cancer, Khorana et al reported a 1.5% to 3.1% incidence of arterial ischemic events^(33,34). The most common events were cardiac, and less than 0.5% of events involved limb ischemia. The rate of arterial ischemic events is higher in specific cancer populations such as those with myeloproliferative disorders or hematologic malignancies with secondary amyloidosis. To assess the significance and outcome of these arterial events, Khorana et al prospectively followed 4,466 patients receiving active chemotherapy. Thromboembolism was a leading cause of death (9.2%)⁽³⁵⁾, with a higher rate of death from arterial events compared to venous events.

Etiology and Mechanisms

In addition to the usual causes and the traditional risk factors typically associated with arterial ischemia in the general population, patients with underlying malignancy have added increased risks for arterial ischemic events related to the inherent thrombophilia associated with the cancer and its therapy (Table 54-3). From the clinical perspective, it is useful to divide these cancer-related etiologies into two broad categories; the first category includes mechanisms, and the second group includes cancer etiologies.

Specific Mechanisms of Arterial Ischemia

Hypercoagulability

Multifactorial mechanisms have been implicated in the pathogenesis of hypercoagulability and thrombosis. As

Table 54-3 List of Potential Causes of Arterial Ischemic Events in Patients With and Without Malignancy

shown in Fig. 54-7, circulating and in situ cancer cells can enhance activity of tissue factor and other cancer procoagulant factors and can activate platelets. These mediators can then trigger coagulation in previously damaged vessels like the coronary arteries or peripheral arteries or even in previously healthy vessels⁽³⁶⁾. The end result is cancer-enhanced thrombosis, which manifests as (1) low-grade disseminated intravascular coagulation, (2) venous thrombophlebitis, (3) arterial thrombosis, (4) accelerated ischemic cardiac and peripheral vascular disease, and (5) nonbacterial thrombotic endocarditis. Another subgroup of patients with a hypercoagulable condition present with digital

ischemia with no evidence of large-vessel involvement (Fig. 54-8). The mechanism is thought to be due to capillary deposition of antigen-mediated antibody complexes from tumor cells. This paraneoplastic syndrome is usually very difficult to treat; symptoms do not respond to usual vascular therapy until the cancer is fully controlled⁽³⁷⁾.

Other Mechanisms

Other reported etiologies include radiation therapy, tumor embolization, arterial wall invasion by tumor, and paradoxical embolization. Often, a specific cause is never identified. In our cohort of 74 patients⁽³⁸⁾ with

**FIGURE 54-7** Suggested mechanism for the enhanced thrombosis observed in cancer patients. DIC, disseminated intravascular coagulation; IHD, ischemic heart disease; NBTE, nonbacterial thrombotic endocarditis; PVD, peripheral vascular disease.

FIGURE 54-9 Etiology of acute arterial ischemia at the University of Texas MD Anderson Cancer Center. (Data from Chow SF, McKenna CH. Ovarian cancer and gangrene of the digits: case report and review of the literature, *Mayo Clinic Proc* 1996 Mar;71(3):253-258).

acute arterial limb ischemia, 24 confirmed pathology samples were available. The majority of patients (67%) had thrombus, and 21% had associated underlying significant atherosclerotic disease. Tumor invasion of the artery was observed in two cases, and only one patient with leukemia had leukemic cell aggregates (Fig. 54-9).

Thrombotic Events Associated With Specific Malignancies and Cancer Therapy

Myeloproliferative Disorders

Myeloproliferative disorders, such as polycythemia vera and essential thrombocythemia, are associated with vascular events characterized by microcirculatory dysregulation and thrombosis in various central and peripheral terminal arterial beds leading to ischemic strokes and acute coronary syndrome^(39, 40). The incidence of thrombosis at diagnosis of polycythemia vera and essential thrombocythemia is 9.7% and 38.6%, respectively, in various studies, with 64% to 96.7% of these being arterial events⁽⁴¹⁾. Primary prevention of thrombosis in myeloproliferative disorder involves the use of aspirin⁽⁴²⁾.

Acute Leukemia

Although hemorrhage is the typical complication in acute leukemia, arterial ischemic events due to thrombosis can occur. De Stefano et al reported a 1.4% incidence of thrombosis at presentation in acute lymphoblastic leukemia and a 9.6% incidence in acute promyelocytic leukemia⁽⁴³⁾. Thromboembolism was reported as the presenting manifestation in more than half of the patients in this study, with 80% venous thromboembolisms and 20% arterial ischemic events. Options for management include leukapheresis, immediate chemotherapy, and sometimes revascularization of large-vessel occlusion.

Cardiac Amyloidosis

Primary amyloidosis, particularly AL type, has been associated with intracardiac thrombosis and

thromboembolic events despite preserved LVEF and absence of cardiac arrhythmias, with an incidence ranging from 26% to 33%^(44, 45) and arterial thromboembolism-related mortality of 26% in one study⁽⁴⁵⁾. A variety of mechanisms have been proposed for this phenomenon including endothelial dysfunction, endomyocardial damage⁽⁴⁶⁾, direct myocardial toxic effect⁽⁴⁷⁾, and hypercoagulability⁽⁴⁸⁾. In managing these patients, the benefit of prophylactic anticoagulation needs to be balanced against the risk of hemorrhage from fragile blood vessels with amyloid deposition⁽⁴⁹⁾.

Arterial Ischemic Events Related to Cancer Management and Therapy

Certain chemotherapeutic agents are known to have a stronger association with arterial ischemic events due to specific pathophysiological mechanisms. These drugs can be divided into two categories (Table 54-4). The first category includes several standard chemotherapeutic agents like L-asparaginase, cisplatin, 5-fluorouracil, capecitabine, and gemcitabine. In a study by De Stefano et al, the incidence of thrombosis in a population with acute lymphoblastic leukemia was shown to increase from 1.4% to 10.6% with L-asparaginase treatment⁽⁴³⁾. Cisplatin is known to induce thrombosis by causing endothelial damage⁽⁵⁰⁾ and increasing monocyte tissue factor activity and platelet activation with a reported 12% to 17.6%⁽⁵¹⁾ incidence of thrombosis, including strokes, recurrent peripheral arterial events, and aortic thrombosis⁽⁵²⁾. 5-Fluorouracil leads to a decrease in protein C and endothelial independent vasoconstriction via protein kinase C⁽⁵³⁾. Gemcitabine has been associated with vascular events including systemic capillary leaks, thrombotic microangiopathy with digital ischemia, and venous thromboembolism⁽⁵⁴⁾.

The second category of cancer drugs associated with arterial ischemia includes the group of angiogenesis inhibitors like thalidomide and several targeted therapy drugs also known as the vascular signaling

Table 54-4 Chemotherapeutic Agents Associated With Arterial Ischemic Events

L-Asparaginase
Fluorouracil
Gemcitabine
Capecitabine
Angiogenesis inhibitors:
Thalidomide
Bevacizumab
Sunitinib
Sorafenib
Ponatinib

pathway inhibitors. These include bevacizumab and several TKIs like sunitinib, sorafenib, axitinib, pazopanib, and ponatinib. Thalidomide is associated with a risk of vascular thrombosis due to its anti-angiogenic effects and modulation of adhesion molecules^(55, 56). In a prospective cohort of 195 patients with multiple myeloma, 11 patients developed an arterial ischemic event over a period of 522 patient-years (5.6%)⁽⁵⁷⁾. Several of these patients developed arterial thrombosis while receiving anticoagulation therapy. Bevacizumab has been linked to serious arterial ischemic events^(58, 59) through mechanisms such as endothelial damage and overexpression of proinflammatory genes⁽⁶⁰⁻⁶²⁾. In patients receiving concurrent bevacizumab and chemotherapy, Scappaticci et al reported the absolute rate of arterial events as 5.5 events per 100 person-years⁽⁶³⁾. Pereg and Lishner reported the efficacy of low-dose aspirin in preventing cardiovascular complications in patients 65 years of age or older who had a prior history of thromboembolic events and were receiving bevacizumab⁽⁵⁸⁾. The mechanism of vascular toxicities associated with TKIs is not well understood and is thought to be partially mediated by nitric oxide inhibition versus accelerated atherosclerosis and possible interference with platelet function. In a meta-analysis by Choueiri et al, the incidence of arterial ischemia was 4% with a three-fold increase in risk in patients treated with sunitinib or sorafenib⁽⁶⁴⁾. Arterial ischemia with ponatinib has been reported to be greater than 20%, leading to the implementation of major restrictions on indications and monitoring by the FDA⁽⁶⁵⁾.

Management

The management strategy should be tailored to the patient's clinical condition and the cancer type. Primary preventive strategies include life-long antiplatelet therapy and statins for radiation-induced and known underlying atherosclerotic disease, aspirin and/or hydroxyurea for myeloproliferative disorders⁽⁶⁶⁾, and aspirin for patients with a history of prior cardiovascular events or who are over age 65 and receiving bevacizumab⁽⁵⁸⁾. Treatment of the acute event varies by type of organ involved (cardiac, central nervous system, limb, or bowel ischemia) and is aimed at reversing ischemia and minimizing organ damage, followed by long-term therapy and secondary prevention. The decision to use medical therapy versus a surgical or percutaneous approach for revascularization is determined by the general condition of the patient and availability of local expertise. Management of these patients is often a challenge because of the bleeding risks, especially in the setting of associated thrombocytopenia. Although acute coronary intervention has been shown to be reasonably safe in these patients⁽⁶⁷⁾, there is a

Table 54-5 Therapeutic Interventions of Potential Benefit for Arterial Ischemic Events Observed in the Setting of Malignancy or Hematologic Disorders

Arterial Ischemic Events Associated With:	Treatment Options
Acute leukemia	Chemotherapy and leukapheresis Surgical thromboembolectomy
Radiation therapy	Antiplatelet therapy Statin therapy Percutaneous angioplasty with or without stenting Surgery
Paradoxical embolization	Systemic anticoagulation PFO closure for recurrent events
Myeloproliferative disorders	Aspirin (for primary and secondary prevention) Cell reduction therapy (ie, phlebotomy, hydroxyurea, anagrelide, interferon- α)
Cardiac amyloidosis	Systemic anticoagulation
Bevacizumab	Aspirin (for primary prevention in patients over 65 years of age or with a history of cardiovascular events)
NBTE	Systemic anticoagulation

NBTE, nonbacterial thrombotic endocarditis; PFO, patent foramen ovale.

significant concern regarding the need for dual antiplatelet therapy for an extended period of time. Drug-eluting coronary stents pose a special problem in this setting and should be avoided. We typically recommend using bare metal stents because many patients end up receiving more chemotherapy and/or surgery for the management of cancer. The type of long-term anticoagulation recommended for secondary prevention depends on the underlying mechanism and etiology. Table 54-5 summarizes some of the therapeutic interventions for arterial ischemic events observed in the setting of malignancy or hematologic disorders.

Cardiac Arrhythmia

Introduction

Patients with cancer have complex comorbidities that predispose to certain arrhythmias and limit the therapeutic options when using antiarrhythmic drugs. Patients with underlying malignancy can develop cardiac arrhythmia as a consequence of the malignancy

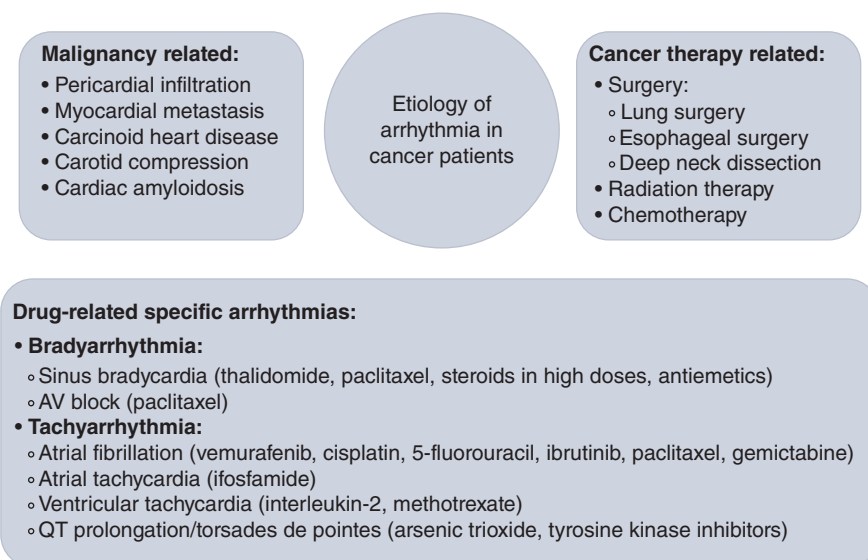

FIGURE 54-10 Etiology and mechanism of cardiac arrhythmia related to cancer and its management. AV, atrioventricular.

itself or its therapy (Fig. 54-10). When patients present with cardiac rhythm disturbances, they typically have associated complex comorbidities. The presence of a rapid heart rate or rhythm irregularity can be simply a sign of a more complicated and severe acute illness (eg, atrial tachycardia or fibrillation in the setting of acute pulmonary embolism, polymorphic ventricular tachycardia triggered by severe metabolic derangements and electrolyte imbalance while on a QT-prolonging agent). Adequate patient management necessitates accurate diagnosis and identification of the potential etiologies and mechanisms that triggered the arrhythmias.

Diagnosis and Management

The management of cardiac arrhythmia should follow the well-established standard-of-care guidelines^(68, 69). Treatment can sometimes differ slightly from those without malignancy. The difference is mainly related to the choice of antiarrhythmic drugs and atrioventricular-blocking agents and the timing and safety of anticoagulation. The choice of these drugs should take into consideration the possibility of drug-drug interactions. Cardizem and verapamil are potent cytochrome P inhibitors that can alter the pharmacokinetics of many chemotherapeutic agents. Several classes of antiarrhythmic drugs can potentiate QT prolongation observed with many cancer-targeted therapies. The decision for short- and long-term anticoagulation for atrial fibrillation or flutter should be tailored carefully in each case, because many patients face higher risks of bleeding in the setting of thrombocytopenia secondary to the malignancy or its therapy.

Bradyarrhythmias

Bradyarrhythmias can generally be categorized as sick sinus syndrome or heart block. The most common presenting symptoms of bradyarrhythmias include fatigue, lightheadedness, dizziness, or syncope. Many different causes have been linked to bradyarrhythmias. These include myocardial infiltration, atrioventricular nodal blocking drugs such as antiemetics, and certain chemotherapies, like paclitaxel and thalidomide. Possible suggested mechanisms include direct effect on the Purkinje system and extracardiac autonomic controls. The incidence of bradycardia with paclitaxel is as high as 30%. A less common but equally important cause of bradycardia is baroreflex failure. This is typically characterized by volatility of heart rate and blood pressure, including profound and severe bradycardia necessitating the use of a permanent pacemaker. This is most often seen in patients who undergo extensive head and neck surgery or receive neck radiation therapy causing dysregulation of the autonomic system at the level of the vascular baroreceptors, the glossopharyngeal or vagal nerves, or the brainstem⁽⁷⁰⁾.

Treatment

Treatment of bradyarrhythmias begins with identifying and removing any potentially offending agents that can exacerbate bradycardia. For severely symptomatic patients, urgent medical therapy with atropine or an intravenous inotrope, such as dopamine or epinephrine, may be used. In emergency situations, transcutaneous or transvenous pacemaker therapy may be required to maintain hemodynamic support. Long-term support with permanent pacing will depend on

the severity of the symptoms related to the bradyarrhythmia and whether it is reversible.

Tachyarrhythmias

These are typically classified into four different categories:

1. Irregular tachycardia: atrial fibrillation, atrial flutter, multifocal atrial tachycardia
2. Regular narrow QRS complex tachycardia: sinus tachycardia, atrial tachycardia, supraventricular tachycardia
3. Wide QRS complex tachycardia: ventricular tachycardia, supraventricular tachycardia with aberrancy, preexcited tachycardia
4. Polymorphic ventricular tachycardia

Sinus tachycardia is by far the most common cause of rapid heart rate. It is usually secondary to other concomitant acute illnesses (eg, infection, pneumonia, pulmonary embolism, surgery). Evaluation and treatment of the primary etiology and the precipitating causes are effective.

Atrial fibrillation has been shown in several epidemiologic studies to be more prevalent in patients with cancer compared to the general population⁽⁷¹⁾. Guzzetti et al reported a three-fold increase in the prevalence of atrial fibrillation in patients hospitalized with colon cancer compared to those admitted for nonneoplastic diseases⁽⁷²⁾. The highest incidence of malignancy-related atrial fibrillation has been reported in patients undergoing thoracic (6%-32%)⁽⁷³⁾ and esophageal (9.2%)⁽⁷⁴⁾ cancer surgery. Postoperative atrial fibrillation appears to be associated with higher in-hospital length of stay, intensive care unit admissions, and more importantly, higher short- and long-term mortality⁽⁷²⁾.

Acute management of atrial fibrillation follows the general recommendations of urgent cardioversion for the hemodynamically unstable patient and initial rate control for stable patients. Ventricular rate control can be achieved using atrioventricular-blocking agents like digoxin, β -blockers, or the nondihydropyridine calcium channel antagonists (diltiazem hydrochloride [Cardizem] or verapamil). Amiodarone can also be considered for rate control in patients with marginal blood pressure or LV dysfunction. For the subgroup of patients with previously known and documented permanent atrial fibrillation, controlling the heart rate and reversing the cause of acute decompensation should suffice.

The clinical decision for short- and long-term anticoagulation for atrial fibrillation is challenging and should be tailored individually because patients can be at high thromboembolic risk based on the standard risk scores used in cardiology and concomitantly at high risks of bleeding in the setting of thrombocytopenia secondary to the malignancy or its therapy. On the

other hand, a patient with low thromboembolic risks based on these same scores can still be at high risk secondary to an acquired hypercoagulable state related to cancer or its therapy. Figure 54-11 shows a suggested algorithm to help risk stratify patients for anticoagulation in the setting of atrial fibrillation, based on their thromboembolic and bleeding risk scores. (This algorithm has not been validated.)

Patients with cancer require special consideration due to the risk of QT prolongation and torsades de pointes from both chemotherapeutic agents and adjunctive medications. QT intervals as measured by ECG reflect the total duration of the action potential at the cellular level. QT prolongation is associated with increased risk for polymorphic ventricular tachycardia, also known as torsades de pointes, and subsequent sudden cardiac death. The corrected QT interval is considered prolonged when it is greater than 480 milliseconds in women and 470 milliseconds in men. The QT interval varies with the cardiac rate and is typically reported as corrected QT interval (QTc) after correction for the patient heart rate. Current ECG technology and digital diagnostic algorithms can generate immediate measurement of the QTc interval. It is important to recognize that an accurate measurement and interpretation of QTc is essential to minimize the chances of inappropriate drug discontinuation or overestimation of the true incidence of QT prolongation with these drugs.

In the cancer population, there are several risk factors predisposing to QT prolongation and subsequent torsades de pointes. These include electrolyte imbalance (hypomagnesemia, hypokalemia, hypocalcemia), metabolic derangements (hypothyroidism), and certain cancer therapies including chemotherapeutic agents (Table 54-6). It is of clinical importance to correct any concomitant contributing factors that may predispose to or worsen QT interval prolongation. Cancer treatment interruption is typically advised when a QT interval is above 500 milliseconds, and permanent treatment discontinuation is recommended if QT prolongation recurs or is associated with ventricular tachycardia or syncope. Figure 54-12 shows a useful algorithm to screen and monitor patients being considered for therapy with agents associated with potential QT prolongation or torsades de pointes.

Among TKIs, a high incidence of QT prolongation has been reported with several of these drugs, leading to an FDA black box warning mandating close ECG monitoring and management recommendations (Table 54-7).

Pericardial Diseases

Pericardial diseases are common in patients with cancer and can manifest as acute pericarditis, pericardial effusion, cardiac tamponade, or constrictive pericarditis.

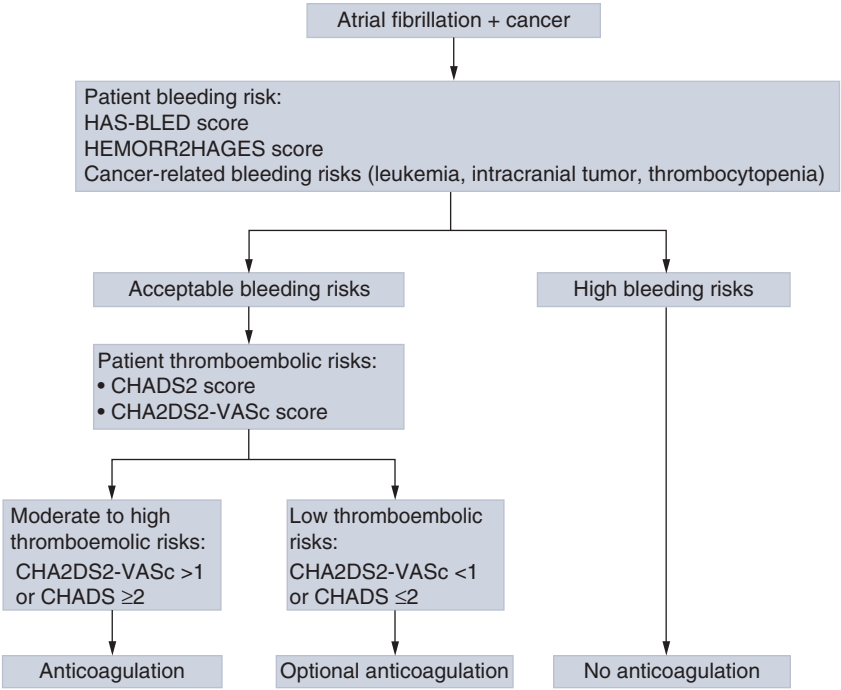

FIGURE 54-11 Algorithm for decision making regarding antithrombotic therapy in cancer patient with atrial fibrillation. Thromboembolic risk scores: CHA2DS2VASc is the acronym for congestive heart failure, age 2 (if >75 years), diabetes, stroke, vascular disease, age (65-74 years), sex category; CHADS2 is the acronym for congestive heart failure, age (if >75 years), diabetes, stroke. Bleeding risk scores: HAS-BLED is the acronym for hypertension, abnormal renal/liver function, previous stroke, prior major bleeding, labile international normalized ratio, elderly (age >65 years), drugs/alcohol use; HEMORR2HAGES is the acronym for hepatic or renal disease, ethanol use, malignancy, older age (>75 years), reduced platelets, rebleeding, hypertension (uncontrolled), anemia, genetic factor, elevated risk of fall, stroke.

Triggers of pericardial diseases include infections, tumor invasion of the pericardium, and cancer therapy, specifically chest radiation or chemotherapy (Table 54-8). The lack of randomized clinical trials makes the management of these syndromes mainly empirical, based

on expert opinion and limited data extrapolated from the few trials in noncancer populations (75,76).

Acute Pericarditis

The diagnosis of pericarditis is based on the findings of pleuritic chest pain, fever, and ST elevation detected by ECG. Patients are typically hospitalized after they present with acute pericarditis if they show evidence of high fever, suspected myopericarditis, and/or the presence of a large (>20 mm in diameter) pericardial effusion or have tamponade physiology detected by echocardiography. Nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin are the mainstay of therapy for acute pericarditis. Intermediate to high doses of NSAIDs are typically used for 10 to 15 days followed by a slow taper over an additional 1 to 2 weeks. Colchicine is often added to the regimen at a dose of 0.6 mg daily for 3 months to help minimize recurrence (77,78). It is a well-tolerated drug with few side effects. However, the few contraindications to the use of colchicine are common in patients with cancer, particularly in recent stem cell transplant recipients. Contraindications include significant interactions with several drugs, including antifungal agents, antibiotics, and immunosuppressants such as tacrolimus. These drugs can alter colchicine metabolism such that the level is significantly increased.

HDAC, histone deacetylase.

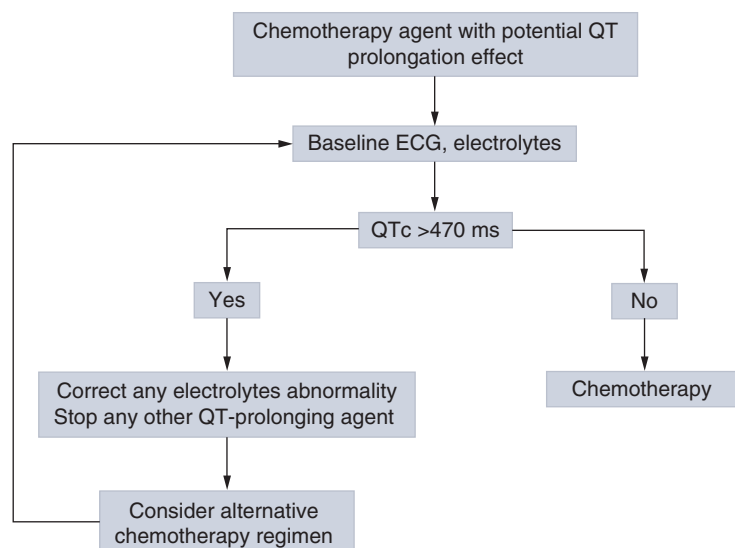

FIGURE 54-12 Suggested algorithm for the initial assessment and management of patients being considered for potential QT-prolonging chemotherapeutic agents. ECG, electrocardiogram.

The use of corticosteroids is typically discouraged in noncancer patients because of significant side effects and the association with an increased incidence of recurrent pericarditis. The situation is reversed in patients with cancer due to the numerous

contraindications to the use of aspirin and NSAIDs. Steroids are typically used in patients with low platelet counts or patients with blood dyscrasias when NSAIDs cannot be used. The evidence comparing the effectiveness of low-dose versus high-dose steroids is

Table 54-7 Monitoring Recommendations for Small-Molecule TKIs Associated With Prolonged QT Interval

Drug	Monitoring
Pazopanib (Votrient) Bosutinib (Bosulif) Crizotinib (Xalkori) Dasatinib (Sprycel) Lapatinib (Tykerb)	Use caution in patients at risk for QT prolongation, including patients with long QT syndrome; patients taking antiarrhythmic medications or other medications that lead to QT prolongation or potassium-wasting diuretics; and patients taking cumulative high-dose anthracycline therapy and with conditions that cause hypokalemia or hypomagnesemia. Correct hypokalemia and hypomagnesemia before initiation of therapy.
In addition to the general recommendations listed above, the ECG monitoring guidelines listed below must be followed when patients take certain TKI agents.	
Vandetanib (Caprelsa)	<ol style="list-style-type: none"> 1. Do not initiate treatment unless the Fridericia-corrected QT interval (QTcF) is <450 ms. 2. Order an ECG at baseline, at 2-4 weeks, at 8-12 weeks, and every 3 months thereafter. 3. During treatment, if QTcF >500 ms, withhold vandetanib and resume at a reduced dose when QTcF is <450 ms.
Nilotinib (Tasigna)	<p>Monitor ECG and QT_c at baseline, at 7 days, with dose change, and periodically.</p> <ol style="list-style-type: none"> 1. QTc >480 ms: Withhold treatment, monitor and correct potassium and magnesium levels; review concurrent medications. 2. If QTcF returns to <450 ms and to within 20 ms of baseline within 2 weeks, resume at prior dose. 3. If QTcF returns to 450-480 ms after 2 weeks, reduce dose to 400 mg once daily. 4. If QTcF >480 ms after dosage reduction to 400 mg once daily, discontinue treatment.
Vemurafenib (Zelboraf)	<ol style="list-style-type: none"> 1. Do not initiate treatment if baseline QTc >500 ms. 2. Monitor ECG at baseline, at 15 days, then monthly for 3 months, and then every 3 months and with dosage adjustments. 3. During treatment, if QTc >500 ms, temporarily interrupt treatment; may reinstate with a dose reduction once QTc falls to <500 ms. 4. Discontinue (permanently) if, after correction of risk factors, the QTc continues to increase >500 ms.

ECG, electrocardiogram; TKI, tyrosine kinase inhibitor.

Table 54-8 Etiologies of Pericardial Diseases in Cancer Patients

Infection
Tumor invasion
Radiation
Chemotherapy
Purine analogues (ie, fludarabine)
Antimetabolites (ie, capecitabine)
Anthracyclines (ie, doxorubicin)
Alkylating agents (ie, cyclophosphamide)
Histone deacetylase (HDAC) inhibitors (ie, mocetinostat)

weak. High-dose prednisone of 1.0 to 1.5 mg/kg (or its equivalent) over many weeks with a slow taper is associated with the lowest rate of recurrence but with a high rate of steroid-related side effects. A lower dose of prednisone of 0.2 to 0.5 mg/kg is associated with fewer side effects but a higher relapse rate. Because there are no strong data to support one option over the other, we typically use the protocol summarized in Fig. 54-13.

Pericardial Effusion

Pericardial effusion is a common finding and has been reported in up to 34% of autopsies performed

on patients with cancer. Its management is guided by three main factors: (1) clinical significance of the effusion (presence or absence of associated symptoms), (2) effusion size, and (3) etiology of the effusion

Etiology

Up to two-thirds of pericardial effusions are nonmalignant. The mechanism of effusion in this setting is likely related to loss of adequate lymphatic drainage of the pericardial sac secondary to lymphangitic spread of the malignancy or mediastinal irradiation. Other etiologies include infection, radiation, and certain drugs (see Table 54-8). Clarifying the specific etiology of an effusion not only helps to define the treatment modality, but also helps to determine prognosis because malignant effusions are associated with a dismal prognosis (1-year survival rate of 16% compared with 55% with nonmalignant effusions) (79).

Diagnosis

Patients with a pericardial effusion may be asymptomatic but may also present with mild symptoms of chest pain, cough, and/or dyspnea. Extreme cases can present with frank tamponade and shock. Clinicians should be very careful when relying on vital signs to guide the management in patients with a pericardial effusion. Stroke volume and cardiac output drop at an early stage (as the effusion builds up). Blood pressure (BP), however, is maintained by a progressive increase

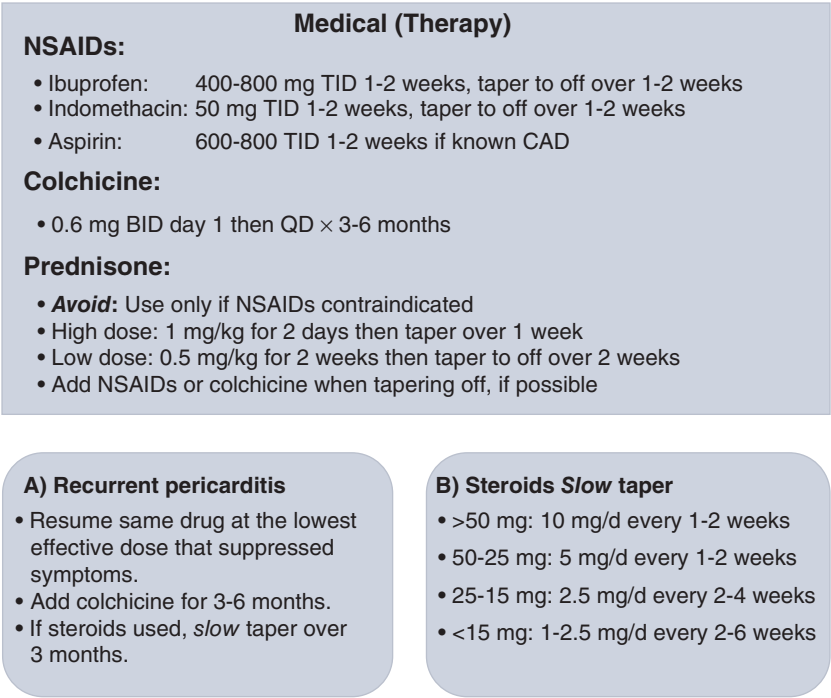

FIGURE 54-13 Medical management of acute pericarditis. BID, twice a day; CAD, coronary artery disease; NSAIDs, nonsteroidal anti-inflammatory drugs; QD, every day; TID, three times a day.

in heart rate until it reaches a plateau, after which a threshold is reached and a severe drop in BP follows. Waiting for these clinical findings to manifest (ie, rapid heart rate and drop in BP) may cause treatment to occur too late, and the patient can rapidly progress to shock. Echocardiography is the main diagnostic tool to confirm the diagnosis of a pericardial effusion and detect tamponade physiology. Pericardial effusion size is classified as small, moderate, or large (large effusions are >2 cm in diameter). Helpful echocardiographic findings to detect early tamponade physiology include the presence of chamber collapse and/or of significant respiratory variation in the mitral or tricuspid valve inflow; these features manifest much earlier than BP drop and heart rate increase.

Management

There is no evidence that medical therapy plays any role in the management of an effusion, except in the case of concomitant inflammation (ie, pericarditis). At MDACC, the three main indications for pericardial fluid drainage are large effusion (>2 cm in diameter), diagnostic purposes, and the presence of clinical or echocardiographic evidence of tamponade physiology. As shown in Fig. 54-14, the first step following the detection of a moderate to large pericardial effusion is to assess for clinical or echocardiographic evidence of tamponade. If there is no sign of tamponade, the effusion size dictates the next step in management. Small to moderate effusions (<2 cm in diameter) are monitored clinically and with serial echocardiograms; larger effusions (>2 cm in diameter) require drainage because about one-third of patients progress to tamponade⁽⁸⁰⁾.

Draining a pericardial effusion can be achieved percutaneously or surgically by creating a pericardial window and, in some centers, by thoracoscopy. Surgery is

preferred in the setting of recurrent effusions, purulent effusions, or high-output drainage (>100 mL/d for 5-7 days following percutaneous pericardiocentesis). The percutaneous approach is preferred in the majority of cases at MDACC, especially if the patient has hypotension or a coagulopathy. Following pericardiocentesis, pericardial fluid is sent for analysis (chemistry, microbiology, cytology, flow cytometry, and sometimes to check for tumor markers)⁽⁸¹⁾. A pericardial draining catheter is typically left in place for 5 days because this approach has shown to lower the effusion recurrence rate by two-thirds. Sometimes the catheter is removed early if drainage output is less than 25 mL over 24 hours and if there is no significant residual effusion on an echocardiogram. When performed by experienced teams, pericardiocentesis is safe with a low complication rate (<5%) and a high success rate (98%)⁽⁸²⁾. Recently, we demonstrated the feasibility and safety of this approach in a cohort of patients with severe thrombocytopenia related to leukemia or chemotherapy⁽⁸³⁾. Following initial pericardiocentesis, 25% of patients will develop recurrent effusions. Chemical pericardiodesis can be considered, but this approach can be complicated by severe pain, risk of infection, and long-term constrictive physiology, in addition to a 10% recurrence rate despite chemical pericardiodesis⁽⁷⁹⁾.

Hypertension and Cancer Management

Hypertension is known to be the most commonly diagnosed comorbidity in patients with cancer (37%). Its prevalence prior to chemotherapy exposure is similar to that reported in the general population (29%). A higher rate has been reported in association with certain cancer therapies including alkylating agents,

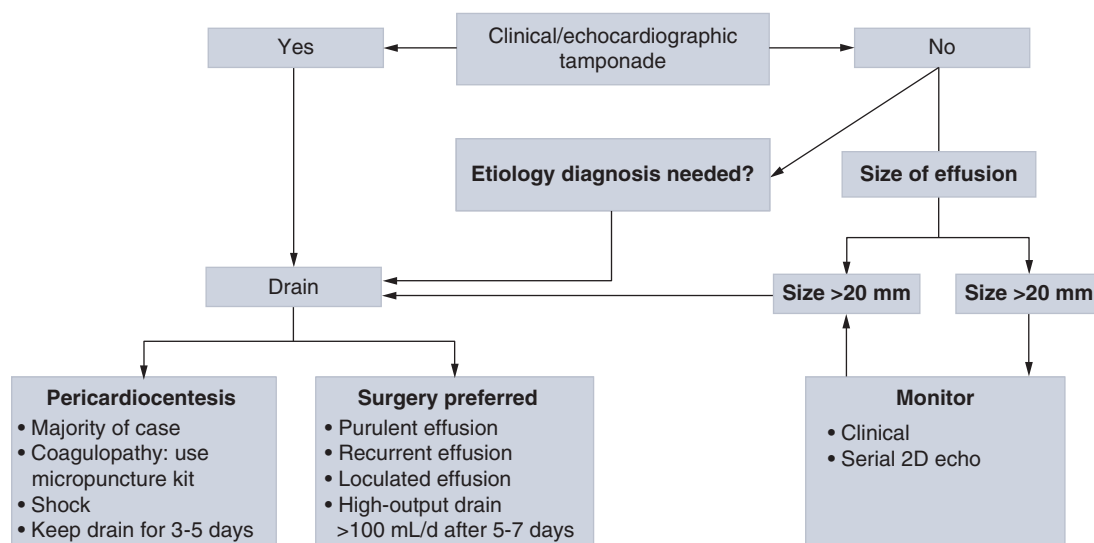

FIGURE 54-14 Management algorithm for pericardial effusion. 2D echo, two-dimensional echocardiography.

Erythropoietin	13.7-27.7

HTN, hypertension; mTOR, mammalian target of rapamycin; VEGF, vascular endothelial growth factor.

angiogenesis inhibitors, immunosuppressants, and hormones like steroids, erythropoietin, and some TKIs (eg, ponatinib) (Table 54-9) ⁽⁸⁴⁻⁸⁶⁾.

Etiology and Pathophysiology

The most common chemotherapeutic agents known to cause HTN include several of the angiogenesis inhibitors, also referred to as vascular signaling pathway (VSP) inhibitors. These drugs include anti-vascular endothelial growth factor (VEGF) antibody (bevacizumab) and several TKIs (sunitinib, sorafenib, pazopanib, vandetanib, and ponatinib). Hypertension is one of the most common side effects of these drugs. Vascular endothelial growth factor normally plays an important role in maintaining a balanced vascular tone by regulating nitric oxide (NO) production in endothelial cells. Hypertension develops when NO bioavailability is reduced, leading to vasoconstriction, increased endothelin production, capillary rarefaction, and increased peripheral resistance ^(86, 87). New-onset or worsening HTN with these agents can develop very early (within 24 hours) after initiation but is typically observed within the first few weeks. Blood pressure

usually returns to baseline shortly after therapy has been discontinued. Several previous limited observations raised the interesting concept of using HTN as a biomarker of cancer response to VSP inhibitors ⁽⁸⁸⁾. More data are needed to further clarify the clinical significance of such observation.

Other classes of chemotherapeutic agents are known to cause HTN. The incidence and time to hypertensive effect for the VSP inhibitors and other agents used in cancer therapy are provided in Table 54-9. Alkylating agents are commonly used in a large number of oncology protocols to treat various solid tumors and blood cancers. Hypertension is frequent with these agents and is commonly seen with cisplatin and busulfan and much less often with cyclophosphamide. Their effect has been observed both acutely as well as years after therapy has been discontinued. The mechanism is thought to be the result of endothelial dysfunction and arterial vasoconstriction ⁽⁸⁴⁾. Calcineurin inhibitors, used for the treatment of graft-versus-host disease, are also associated with a high incidence of HTN. Cyclosporine and tacrolimus are the major drugs in this class. Their effects are generally seen within the first 6 weeks of therapy and are thought to be the result of sympathetic system activation and an increase in endothelin-1 synthesis leading to vasoconstriction ⁽⁸⁶⁾. Following transplant, many patients receive immunosuppression with mycophenolate mofetil and the mammalian target of rapamycin inhibitor sirolimus. The mechanism by which these agents cause HTN is not well understood. Corticosteroids are frequently used and have been associated with variable rates of dose-dependent HTN. The mechanism by which they cause HTN is complex but likely involves increased production of angiotensinogen that induces salt and fluid retention, activation of the sympathetic nervous system, and an increase in patient sensitivity to vasoactive substances. Patients receiving erythropoietin for anemia are also at risk for experiencing severe HTN. The driving mechanism behind the HTN is complex and goes beyond just volume expansion. It is also the result of an activation of the renin-angiotensin system and an increase in endothelin-1 with a decrease in NO production due to changes in the erythropoietin receptor ⁽⁸⁶⁾.

Diagnosis and Management

Because HTN is a risk factor for chemotherapy-induced cardiotoxicity and poorly controlled HTN can lead to discontinuation of certain cancer therapies, a prompt and adequate intervention is essential to prevent potential irreversible damage. The Investigational Drug Steering Committee of the National Cancer Institute established a panel of experts to address the concern regarding VSP inhibitor-induced HTN. The recommendations published in 2010 focused on the

evaluation, surveillance, and management of BP problems in patients receiving VSP inhibitors⁽⁸⁹⁾. Treatment of HTN should begin at the time of diagnosis, without a concern of negatively impacting cancer treatment outcomes.

The choice of a pharmacologic regimen to manage HTN should take into consideration several factors. For example, the underlying pathophysiology leading to BP elevation in calcineurin-induced HTN is caused by excessive vasoconstriction that responds well to dihydropyridine calcium channel blockers. Diuretic agents can help relieve fluid retention associated with steroid-related HTN. Clonidine has been recommended for the management of severe BP swings in patients with baroreflex failure. Other important factors that need to be considered include the risk of drug-drug interactions. It is also important to consider agents that may have compelling indications in specific types of cancer. Several recent epidemiologic studies reported potential oncologic benefit of β -blockers in melanoma, breast, lung, and colon cancers with the mechanism suspected to be mediated by altering β -adrenergic signaling in cancer⁽⁹⁰⁾. It is also important to consider the risks and benefits of medications that target NO or angiotensin II production when determining management strategies for patients on specific agents like the VSP inhibitors. Because these anticancer agents cause vasoconstriction in part through a decrease in NO production, medications such as nitrates, phosphodiesterase-5 inhibitors, and nebivolol, an NO-producing β -blocker, would in theory seem beneficial. However, there is a theoretical concern that by targeting this pathway these anti-HTN medications might compromise the efficacy of the antitumor therapy.

Radiation Therapy–Related Cardiovascular Toxicity

Radiation therapy to the mediastinum, left breast area, and neck region is a risk factor for premature coronary and carotid atherosclerotic disease (Fig. 54-15). The risk of arterial ischemic events depends on the radiation dose, technique, extent of vasculature exposed, and type of cancer⁽⁹¹⁾. Radiation therapy can accelerate atherosclerosis by triggering oxidative stress leading to endothelial damage⁽⁹²⁾. The acute injury during therapy is sustained for a long period of time via activation of nuclear factor- κ B⁽⁹³⁾. Symptoms typically manifest after a long latent period of 5 to 10 years following exposure. Mediastinal exposure is also responsible for a spectrum of cardiovascular syndromes including acute pericarditis, chronic constrictive pericardial disease, valvular heart disease, and myocardial dysfunction with restrictive cardiomyopathy. There is no defined threshold level below which radiation therapy is safe to the cardiovascular system. Modification

FIGURE 54-15 Coronary angiogram showing critical near occlusion of the ostium of the right coronary artery in a 36-year-old patient with prior chest radiation for lymphoma at the age of 5. Pathology findings shown below are consistent with radiation arteritis.

of radiation protocols (including field planning and breath-holding techniques) is currently being done to reduce radiation dose to the cardiovascular system. The challenge in managing these patients is the long latency period between exposure and clinical manifestation, with many affected patients being no longer under the care of a treating oncologist. The 2013 expert consensus by the American Society of Echocardiography and the European Association of Cardiovascular Imaging recommends yearly clinical evaluation, with a history and physical exam, and echocardiogram studies in symptomatic patients. They also recommend a screening echocardiogram at 10 years after chest radiation and every 5 years thereafter. Primary prevention in patients with documented atherosclerosis following radiation therapy includes management of traditional atherosclerotic risk factors⁽⁴⁹⁾. Lifelong antiplatelet therapy and statin therapy are recommended for their anti-inflammatory and antithrombotic effects on the irradiated endothelium⁽⁹⁴⁾. Radiation-induced scarring makes surgical intervention difficult; hence

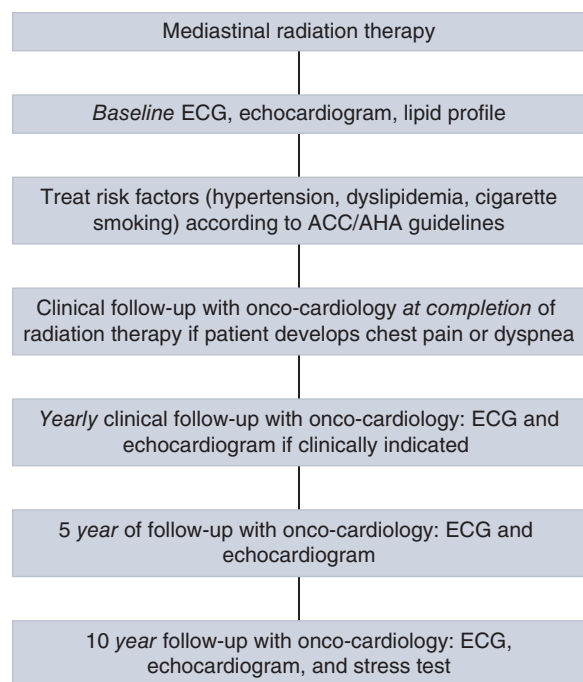

FIGURE 54-16 The University of Texas MD Anderson Cancer Center Department of Cardiology recommended algorithm for cardiac monitoring of patients following radiation therapy to the mediastinal area. ACC/AHA, American College of Cardiology/American Heart Association; ECG, electrocardiogram.

percutaneous angioplasty with or without stenting is becoming the preferred revascularization method with encouraging results for radiation-induced renal, iliac, and femoral arterial disease ⁽⁹⁵⁾. **Figure 54-16** shows our recommended algorithm for management and monitoring of these patients.

Pulmonary Complications of Cancer Therapy

Saadia A. Faiz
Horiana B. Grosu
Vickie R. Shannon

Chest medicine is inextricably intertwined with cancer medicine as a result of the propensity for cancer therapy or the disease itself to affect the lungs. Pulmonary complications in the cancer patient may manifest as injury to the pulmonary interstitium, alveolar-capillary membrane, pleura, pulmonary circulation, or airways, or, alternatively, may involve multiple intrathoracic structures. This chapter will review cancer-related pulmonary complications, including lung toxicities associated with aggressive chemotherapy and radiotherapy regimens, noninfectious lung disorders arising in the post-stem cell transplant setting, and cancer-related pleural disease, pulmonary vascular disease, and sleep disorders. The focus of this review is to identify, discuss, and provide practical algorithms for the diagnosis and treatment of these complications with emphasis on those issues in which early diagnosis may have a significant impact on patient management and outcome.

CHEMOTHERAPY-INDUCED LUNG INJURY

Injury to the lung due to cancer therapy results in stereotyped histopathologic disease patterns and syndromes (Tables 55-1 and 55-2). Lung toxicity has been described following exposure to conventional chemotherapy as well as molecularly targeted agents and immune modulators. Interstitial and alveolar lung injury patterns are the most frequent. Pleural effusions, pulmonary vascular disease, and, less frequently, drug-induced granulomatous disease and lymphadenopathy have

also been described. In addition to direct lung injury, chemotherapy-induced immune suppression may predispose patients to life-threatening pneumonias.

The diagnosis of drug-induced lung injury is hampered by the frequent use of multiagent and multimodality therapies. In addition, overlapping clinical, radiographic, and pathologic manifestations of lung injury caused by infections, aspiration, cancer relapse, radiation, and cancer-induced cardiac disease confound clinical distinctions between these entities and render precise estimates of drug-induced lung injury (DILI) difficult. Other conditions that may mimic DILI include pneumonia, aspiration pneumonitis, diffuse alveolar hemorrhage, and cardiogenic pulmonary edema (^{1,2}). Predisposing factors, such as older age, cumulative dose, concomitant or sequential radiotherapy, oxygen administration, prior lung injury, and the use of multidrug regimens, not only increase the risk of DILI, but also may shorten the latency period between drug exposure and the development of clinical symptoms.

The diagnosis of DILI is suggested by a temporal association between drug exposure and the development of compatible clinical, radiographic, and laboratory evidence of lung injury, coupled with the exclusion of competing diagnoses. Interstitial and mixed alveolar-interstitial opacities, manifested as ground-glass opacities, reticular lines, septal thickening, and mosaic attenuation, typically localize to the peripheral and lower lung zones on chest imaging studies. Upper lobe predominant disease may be seen with hypersensitivity reactions and be accompanied by skin rash and wheezing. Bronchoscopy with performance

ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans organizing pneumonia; DAD, diffuse alveolar damage; DAH, diffuse alveolar hemorrhage; DVT, deep venous thrombosis; IFN, interferon; IL-2, interleukin-2; NCPE, noncardiogenic pulmonary edema; TNF, tumor necrosis factor; VTE, venous thromboembolism.

of bronchoalveolar lavage (BAL) and/or transbronchial biopsies may be helpful in excluding infection or background disease. For example, findings of BAL eosinophilia of greater than 25% are supportive of drug-induced eosinophilic pneumonia. Increased numbers of hemosiderin-laden macrophages on BAL fluid and/or progressively bloody saline aliquots on sequential BAL samples is supportive of diffuse alveolar hemorrhage. A BAL lymphocytosis of greater than 50% with decreased CD4/CD8 ratios on BAL fluid is suggestive of interstitial lung disease; however, these findings are not sufficient to distinguish interstitial lung disease caused by drug toxicity from other causes. Although none of these histopathologic findings are pathognomonic of DILI, a few drugs produce characteristic patterns of involvement. For example, methotrexate, ipilimumab, everolimus, and interferon- γ may cause an acute granulomatous inflammation that mimics opportunistic infection. Histopathologic changes consistent with bronchiolitis obliterans with organizing pneumonia may be seen after exposure to several drugs, including bleomycin, cyclophosphamide, cetuximab, panitumumab, thalidomide, bortezomib, interferon- γ , and methotrexate (Table 55-3).

Clinical manifestations drug-induced interstitial lung disease include low-grade fever, dry cough, and dyspnea, which typically develop insidiously, usually within weeks to a few months after initiation of the first or subsequent cycles of therapy^(3, 4). Pulmonary fibrosis may immediately ensue or occur as a late manifestation of DILI months to years after exposure to some agents, such as bleomycin, busulfan, cyclophosphamide, gemcitabine, and carmustine (BCNU).

Bronchospasm and allergic reactions are common manifestations of infusion reactions, which typically occur within minutes to hours of therapy.

Evidence-based guidelines in the management of DILI are limited. In most cases, drug withdrawal is recommended once sufficient evidence to implicate the culprit agent with pneumotoxicity is established. Systemic corticosteroids have proven efficacy in the treatment of DILI patterns such as hypersensitivity pneumonitis, eosinophilic pneumonia, and bronchiolitis obliterans organizing pneumonia. In other entities (pulmonary fibrosis, bronchiolitis obliterans), no beneficial role has been established. Steroid therapy should be considered in patients with progressive, steroid-responsive, and/or advanced-stage lung injury patterns. No guidelines for corticosteroid management in DILI are currently available. General recommendations include starting doses of prednisone at 40 to 60 mg or weight-based dosing at 0.75 to 1 mg/kg daily with tapers over a 1- to 3-month time period, pending response to therapy. With few exceptions (see below), drug rechallenge is not recommended. Several of the specific drugs causing DILI deserve separate mention and are discussed below.

Interstitial Lung Disease

Nonspecific interstitial pneumonitis (NSIP) is the most common morphologic pattern of interstitial lung disease. Dry cough and progressive dyspnea develop insidiously, over weeks to months following drug exposure. Radiographic findings may include pleural-based, lower lobe ground-glass attenuations, reticular

Table 55-3 Cytologic and Histopathologic Changes on BAL or Lung Tissue Biopsies and Suggested Diagnosis

Suggested Diagnosis	Histopathologic Findings
Eosinophilic pneumonia	BAL eosinophilia (>25%)
Diffuse alveolar hemorrhage	Increased hemosiderin-laden macrophages (>20%)
Diffuse alveolar hemorrhage	Progressively bloody saline aliquots on sequential BAL samples
Hypersensitivity pneumonitis	Increased lymphocytes and plasma cell on BAL fluid; variable numbers of giant cells; small, noncaseating granulomas on biopsy specimens
Interstitial lung disease	BAL lymphocytosis (>50%) with decreased CD4/CD8 ratio; interstitial fibrosis, destruction of type I pneumocytes with proliferation of type II pneumocytes following some drug exposures
Bronchiolitis obliterans with organized pneumonia	Organized polypoid inflammatory granulation tissue in the small airways
Sarcoid-like reactions/ Granulomatous pneumonitis	Granulomatous inflammation without necrosis

BAL, bronchoalveolar lavage.

lines, mosaic patterns, and nodules. Injury to epithelial and endothelial cells leads to alveolar edema and diffuse alveolar damage early on, which may progress to end-stage fibrotic lung disease, despite drug withdrawal and corticosteroid therapy.

Bleomycin-induced interstitial pneumonitis (BIP) has been well studied. This cytotoxic antibiotic is widely used in the treatment of germ cell tumors, lymphomas, and a variety of squamous cell carcinomas, particularly those of head and neck and esophageal origin. The lungs and skin are targets of bleomycin-induced lung injury due to the lack of the inactivating enzyme, bleomycin hydrolase, in these two organ systems. Bleomycin-induced interstitial pneumonitis is the most common pattern of bleomycin lung injury, occurring in up to 20% of treated patients, typically 4 to 10 weeks after bleomycin administration (Fig. 55-1)⁽⁵⁾. Risk factors for BIP include age greater than 70 years, cumulative dose greater than 400 U, concomitant or sequential radiation therapy, uremia, multiagent therapy, and high inspired oxygen administration^(6, 7).

Evidence suggesting an association between hyperoxia and increased BIP risk and/or severity is largely anecdotal. Questions regarding the threshold dose of oxygen and duration of oxygen therapy that confer an increased risk of bleomycin lung toxicity are unknown. In addition, the latency period between bleomycin and high oxygen exposure that mitigates the risk of increased toxicity has not been established. Nonetheless, general recommendations regarding supplemental oxygen therapy in bleomycin-exposed patients includes titration to achieve oxygen saturations at or above 89% to 92%. Declining values of diffusing capacity of the lung for carbon monoxide (DL_{CO}) are thought to be early markers of bleomycin lung injury, although threshold cut-offs for drug withdrawal based on declining DL_{CO} have not been established. Pulmonary function tests (PFTs) with DLCO should be considered in patients with known lung disease and/or abnormal lung function at baseline. Serial monitoring of DL_{CO} is recommended as cumulative doses of bleomycin approach 400 U. Drug withdrawal is the mainstay of therapy with or without the institution of corticosteroids. The grade of pneumotoxicity should be used to guide the need for corticosteroid therapy. In patients with moderate (grade 2 or greater) interstitial pneumonitis, prednisone dosed at 0.75 to 1 mg/kg/d or its equivalent is recommended.

Rates of DILI following BCNU approach 50% among patients receiving cumulative doses of this drug in excess of 1,500 mg/m². Carmustine toxicity is unique in its predilection for middle and upper lobe disease, which may occur years after BCNU exposure. Late-onset pneumonitis and fibrosis have also been described following cyclophosphamide and busulfan administration. Gemcitabine and paclitaxel are also known causes of interstitial pneumonitis, which may be fatal in some cases. Among the molecular targeted therapies, the mammalian target of rapamycin (mTOR) inhibitors (everolimus, temsirolimus) and epidermal growth factor receptor (EGFR) inhibitors (gefitinib, erlotinib, cetuximab, panitumumab) are most frequently implicated in the development of interstitial pneumonitis⁽⁸⁻¹¹⁾.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP)-like reactions typically occur after repeated drug exposure to an offending agent. Associated symptoms of fever, dyspnea, dry cough, and rash typically occur over the first 3 to 4 weeks following drug exposure and may wax and wane without adjustments in therapy. Poorly formed granulomas and BAL lymphocytosis are common histopathologic findings. Upper lobe predominant disease is characteristic, particularly in chronic forms of the disease. Methotrexate is the prototype agent

FIGURE 55-1 Bleomycin lung injury. A 26-year-old woman with progressive shortness of breath, hypoxia, and decline in diffusing capacity of the lung for carbon monoxide on lung function testing following the fifth cycle of bleomycin-based chemotherapy for Hodgkin lymphoma. Sagittal (A) and standard (B) views on chest computed tomography imaging showed bilateral, lower lobe predominant ground-glass opacities and parenchymal consolidation. Bronchoalveolar lavage cultures showed no growth. The patient was treated with high-dose steroids for presumed bleomycin-induced lung injury but succumbed to respiratory failure.

associated with HP, which may develop following oral, intravenous, intrathecal, and intramuscular routes of methotrexate administration. Drug withdrawal and steroid therapy typically produce favorable outcomes, with complete resolution of clinical signs and symptoms in most cases.

Noncardiogenic Pulmonary Edema and Diffuse Alveolar Damage/Acute Respiratory Distress Syndrome

Drug-induced injury to the alveolar-capillary membranes may result in capillary leak and a permeability (noncardiogenic) pulmonary edema. Acute respiratory distress syndrome (ARDS) and its histologic hallmark, diffuse alveolar damage (DAD), may ensue as the disease progresses. These reactions may be unrelated to drug dosage or duration of therapy. Busulfan, bleomycin, cyclophosphamide, molecularly targeted agents (gefitinib, erlotinib, cetuximab), antilymphocyte monoclonal antibodies (rituximab, alemtuzumab, ofatumumab), and rapamycin inhibitors (everolimus, temsirolimus) are most often implicated in the development of drug-induced noncardiogenic pulmonary edema (NCPE). Noncardiogenic pulmonary edema leading to ARDS has been described following ruxolitinib, a novel JAK1/2 inhibitor, as a result of a cytokine rebound reaction. This reaction is mitigated with the preemptive use of corticosteroids and supportive therapy^(12, 13). Cytokine storm has also been described following all-*trans*-retinoic acid (ATRA) and arsenic trioxide therapies in the treatment of acute promyelocytic leukemia (APL). The so-called differentiation syndrome occurs in up to 25% of APL patients undergoing induction therapy, which is characterized

by potentially fatal NCPE and ARDS. Unlike many of the lung injury processes, in patients with ATRA- and arsenic-related differentiation syndrome, de-escalation of drug dose, rather than drug withdrawal, along with systemic steroid therapy has been associated with successful resolution of toxicity in patients with mild to moderate forms of this syndrome^(14, 15). Diffuse alveolar hemorrhage (DAH) is typically seen as sequela of alveolar-capillary membrane injury and, thus, in the setting of ARDS/DAD. Occasionally, bland alveolar hemorrhage has been described in the absence of DAD following rituximab and alemtuzumab therapy^(12, 16). Massive, and sometimes fatal, bleeding has been reported during bevacizumab therapy for treatment of central airway tumors⁽¹⁷⁾.

Pleural Effusions

Drug-induced pleural effusions may occur as an isolated toxicity to the pleura (following methotrexate, dasatinib, bosutinib, docetaxel, ATRA, or granulocyte colony-stimulating factor [G-CSF] administration) or as a manifestation of a generalized pleuroparenchymal abnormality^(18, 19). These small to moderate-sized effusions are typically exudative and lymphocyte predominant and may be unilateral or bilateral. Withdrawal of the offending agent may result in spontaneous resolution in some cases.

Pulmonary Vascular Disorders

The development of thromboembolic disease, pulmonary hypertension, and pulmonary veno-occlusive disease (PVOD) has been described following conventional chemotherapeutic, molecularly targeted,

and immune-modulating agents. Increased rates of venous thromboembolism (pulmonary embolism and deep venous thrombosis) have been reported with the ALK inhibitor crizotinib, the Bcr-Abl inhibitor ponatinib, and the vascular endothelial growth factor (VEGF) inhibitors bevacizumab, sunitinib, sorafenib, and pazopanib (^{17, 20-23}). In addition, the angiogenesis inhibitors (thalidomide, lenalidomide, pomalidomide) in combination with steroids, doxorubicin, or BCNU are associated with a 14% to 43% increased risk of thromboembolic events. Other agents, including hormonal therapies, growth factors, and erythropoietic agents, contribute to cancer-associated venous thromboembolism. The development of pulmonary arterial hypertension (PAH) has been associated with several drugs, including bleomycin, busulfan, BCNU, interferon, and dasatinib. Severe PAH following dasatinib, a multikinase Bcr-Abl tyrosine kinase inhibitor (TKI) is well described. Once dasatinib-associated PAH develops, drug withdrawal without rechallenge is recommended. There have been no reports of PAH following exposure to the more selective Bcr-Abl-targeted TKIs (imatinib and nilotinib), which may be safely used in dasatinib-induced PAH (²⁴⁻²⁷). Bleomycin and BCNU have also been implicated in the development of PVOD, an irreversible and often fatal form of pulmonary hypertension that is characterized by fibrous obliteration of pulmonary venules.

Drug-Induced Airway Disease

Virtually all chemotherapeutic and targeted agents may trigger an infusion reaction (IR), a sometimes life-threatening acute reaction that may be associated with dry cough, dyspnea, wheezing, chest pain, and hypoxia. Infusion reactions may manifest as IgE-mediated, type 1 hypersensitivity reactions (carboplatin, oxaliplatin, and L-asparaginase) or as anaphylactoid reactions, mediated by cytokine release. The latter reaction is often seen following the administration of many of the monoclonal antibodies (mAbs). Infusion reactions may be triggered by the drug itself or in response to the vehicle in which the drug is formulated. This is particularly true of the taxane class of drugs. For example, paclitaxel is formulated in Cremophor EL, a highly allergenic polyoxyethylated castor oil solvent. Docetaxel is formulated in polysorbate 80. Both vehicles may induce mast cell/basophil activation and subsequent hypersensitivity reaction. Other drugs that are formulated in Cremophor EL (cyclosporine, teniposide, ixabepilone) or polysorbate 80 (etoposide) may trigger similar reactions and should be avoided in patients with a history of IRs following taxane administration (^{28, 29}). Histamine receptor antagonists and steroids are recommended as standard prophylaxis prior to taxane administration, which has

reduced the incidence of taxane-induced bronchospasm from 30% to 2% (^{30, 31}). Infusion reactions may occur within minutes to several hours following drug exposure. Close monitoring during and immediately following drug infusion is critical, as breakthrough IRs may occur despite prophylaxis. Although vinca alkaloids are rarely associated with lung toxicity, severe bronchospasm has been described when these agents are given with concurrent or sequential administration of mitomycin therapy.

RADIATION-INDUCED LUNG INJURY

Clinically significant radiation-induced lung injury (RILI) is the most common dose-limiting complication of thoracic radiation therapy (RT), occurring in 5% to 20% of patients. Recent advances in radiation techniques and delivery systems, such as proton therapy, three-dimensional conformal RT (CRT), intensity-modulated RT (IMRT), and stereotactic body RT (SBRT), purport lower lung injury rates while delivering higher target doses of radiation to the lung. Factors associated with radiation delivery (total radiation dose, dose per fraction, volume of irradiated lung, and beam characteristics and arrangements) as well as clinical factors (preexisting lung disease, underlying poor pulmonary reserve, prior radiotherapy, multimodality regimens, rapid steroid withdrawal) all potentiate the appearance and severity of radiation pneumotoxicity. Radiographically apparent lung injury is common with total doses of radiation that exceed 40 Gy and is rare at doses below 20 Gy (^{32, 33}). Hyperfractionated radiation doses delivered to the smallest lung volume is recommended.

Acute clinical radiation pneumonitis, heralded by dyspnea, low-grade fever, and dry cough, develops insidiously over 1 to 3 months after completion of radiation. Radiographic changes typically precede clinical symptoms, appearing 3 to 4 weeks following RT. Discrete ground-glass opacities, ill-defined patchy nodules, or consolidation with air bronchograms and volume loss within the irradiated field are common early findings that evolve over the ensuing 6 to 23 months, leaving a linear scar. Regional fibrosis is seen in nearly all patients, including those without clinical symptoms, and is characterized by the appearance of a well-demarcated area of volume loss, linear densities, bronchiectasis, retraction of the lung parenchyma, tenting and elevation of the hemidiaphragm, and ipsilateral pleural thickening within the irradiated field (Fig. 55-2). Postradiation volume loss, bronchiectasis, and consolidation may occur following the newer modes of RT delivery, but typically are less extensive than injury patterns following conventional radiation.

Radiation recall pneumonitis (RRP) is a rare inflammatory reaction that develops within a previously

infections. Noninfectious pulmonary complications, however, remain a major cause of post-HSCT morbidity and mortality (^{39, 40}). Infectious and noninfectious pulmonary complications following HSCT are temporally related to immune recovery and the development of GVHD (Fig. 55-3).

Early-onset pulmonary complications occur within the first 100 days after transplant and include diffuse pulmonary edema, DAH, periengraftment respiratory distress syndrome (PERDS), idiopathic pneumonia syndrome (IPS), delayed pulmonary toxicity syndrome, and PVOD. Bronchiolitis obliterans syndrome (BOS),

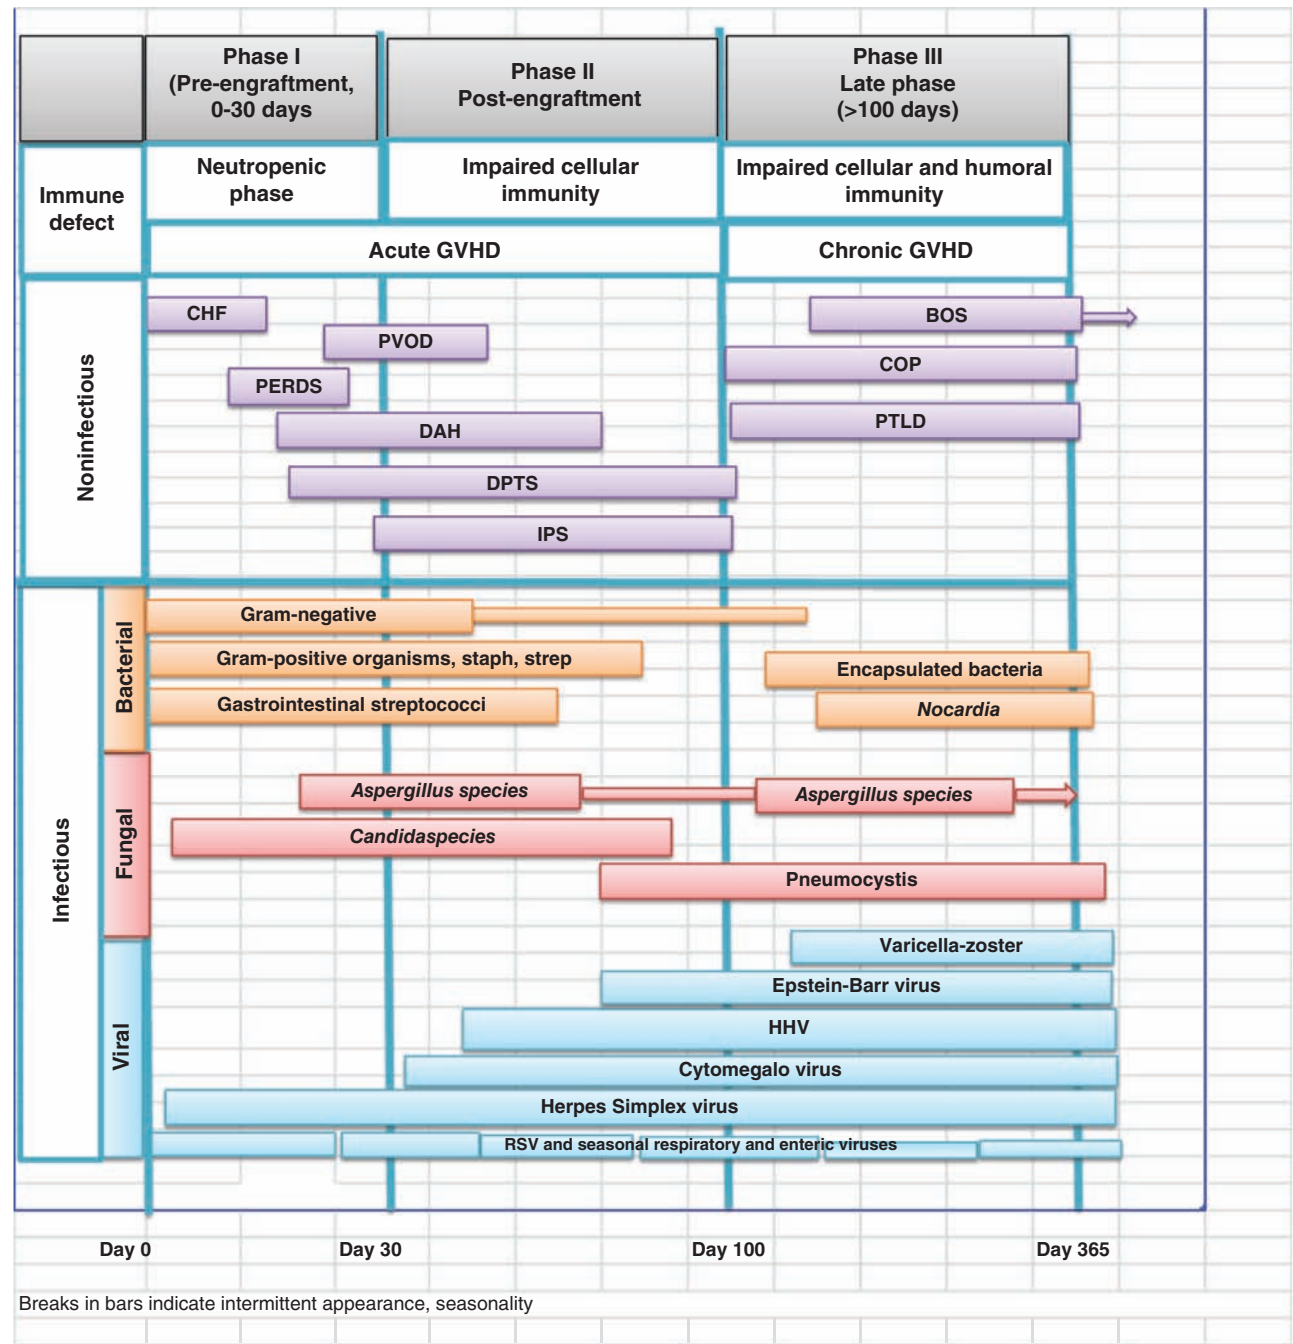

FIGURE 55-3 Temporal relationship of infectious and noninfectious complications following hematopoietic stem cell transplantation. BOS, bronchiolitis obliterans syndrome; CHF, congestive heart failure; COP, cryptogenic organizing pneumonia; DAH, diffuse alveolar hemorrhage; DPTS, delayed pulmonary toxicity syndrome; GVHD, graft-versus-host disease; HHV, human herpesvirus; IPS, idiopathic pneumonia syndrome; PERDS, periengraftment respiratory distress syndrome; PTLN, posttransplant lymphoproliferative disorder; PVOD, pulmonary veno-occlusive disease; RSV, respiratory syncytial virus. Breaks in bars indicate intermittent appearance or seasonality.

cryptogenic organizing pneumonitis, and posttransplant lymphoproliferative disorder (PTLD) compose the late-onset pulmonary complications, which typically occur more than 100 days after HSCT (Table 55-4). Each of these entities is briefly discussed below.

Early-Onset Noninfectious Pulmonary Complications

Early-onset pulmonary complications are characterized by nonspecific symptoms of acute dyspnea, cough, and fever with associated diffuse pulmonary infiltrates. The exclusion of a competing diagnosis such as infection, cardiac disease, and renal failure along with documentation of diffuse infiltrates are supportive findings. Diffuse pulmonary edema may develop as a result of increased hydrostatic capillary pressure or permeability pulmonary edema and is one of the most common early complications of HSCT. Hydrostatic and permeability etiologies of HSCT may coexist and overlap with other early-onset pulmonary complications, which confounds diagnosis. The diagnosis is supported by diffuse bilateral pulmonary infiltrates with or without bilateral pleural effusions and coupled with the absence of competing diagnoses, such as infection on diagnostic evaluation. Diffuse alveolar hemorrhage may occur as a result of widespread alveolar injury in association with PERDS, DAD, or IPS, or as a separate syndrome. Bronchoscopic findings of DAH include sequential aliquots of progressively bloody BAL fluid. Cytologic evidence of >20% hemosiderin-laden macrophages on BAL fluid is also supportive. Hemoptysis only occurs in approximately 20% to 25% of patients with DAH. Diffuse alveolar hemorrhage may develop independent of thrombocytopenia or coagulopathy. Supportive therapy is standard. The benefits of steroid therapy have not been definitely proven. Periengraftment respiratory distress syndrome may develop following both allogeneic and autologous transplants and is characterized by fever, hypoxemia, noncardiogenic pulmonary edema, erythematous skin rash, and weight gain arising during the periengraftment period. Diffuse alveolar hemorrhage complicates PERDS in approximately one-third of patients (⁴¹⁻⁴³). Growth factor administration, infusion of increased numbers of CD34⁺ cells, prolonged neutropenia, and peripheral blood source of stem cells all confer an increased risk of PERDS. Reductions in morbidity and mortality have been noted following steroid therapy in several small studies (^{44, 45}). Another early-onset diffuse lung disease, IPS, typically develops 14 to 90 days after transplant. The presence of GVHD, cytomegalovirus seropositivity, older age, total-body radiation, transplant type, human leukocyte antigen (HLA) disparity, and transplantation for malignancy other than leukemia are

possible risk factors (^{46, 47}). High-dose steroids, broad-spectrum antibiotics, and supportive care are the mainstays of treatment. Mortality rates may exceed 50% at 5 years, despite aggressive therapy. Pulmonary veno-occlusive disease (PVOD) is a rare complication of HSCT, which results in intractable dyspnea associated with severe pulmonary hypertension. Symptoms of dyspnea and fatigue develop insidiously, several weeks to month following HSCT. Treatment options are limited, with 2-year mortality approaching 100%. Delayed pulmonary toxicity syndrome occurs in 29% to 64% of autologous transplant recipients who received BCNU-, cyclophosphamide-, or cisplatin-based pretransplant conditioning regimens. This syndrome is heralded by dry cough, dyspnea, and bilateral pulmonary infiltrates, which typically occur 45 days after HSCT. Corticosteroid therapy leads to complete resolution of symptoms in 92% of patients (⁴⁸).

Late-Onset Noninfectious Complications

Chronic GVHD, an immunologic posttransplant disorder in which donor cells attack healthy host tissue, is the most common late complication of allogeneic HSCT (^{49, 50}). Involvement of GVHD in the lung results in BOS, a nonspecific lung injury causing inflammation, smooth muscle hypertrophy, and concentric intraluminal fibrosis of the small airways. The clinical hallmark of BOS is airflow limitation (^{49, 50}). Patients are often asymptomatic during the early stages of BOS, leading to delays in diagnosis. At presentation during late stages of the disease, wheezing, dry cough, and dyspnea on exertion predominate as airflow obstruction progresses. Recurrent sinusitis and antecedent “cold” symptoms are common prior to diagnosis. Hyperinflation may be seen on plain chest radiographs, which are otherwise normal (^{51, 52}). The lack of precise definition and uniform diagnostic criteria, along with a paucity of knowledge regarding the pathogenesis of BOS and delays in diagnosis, represent distinct challenges in management. The National Institutes of Health recently provided consensus guidelines in the diagnosis of BOS that require: (1) evidence of airflow obstruction (forced expiratory volume in 1 second [FEV₁]/forced vital capacity [FVC] <0.7 and FEV₁ <75% of predicted), with evidence of air trapping on PFT; (2) increased residual volume (>120% predicted); (3) air trapping, small airway thickening, or bronchiectasis on expiratory computed tomography (CT) or lung biopsy or pathologic confirmation of constrictive bronchiolitis; and (4) absence of any infectious process on radiographic, laboratory, or clinical testing (⁵³). The prognosis of BOS is poor, with 5-year survival estimates of only 13%. Immunosuppressive therapy with corticosteroids and calcineurin inhibitors composes the mainstay of treatment.

Table 55-4 Comparison of Early and Late Pulmonary Complications Following HSCT

	Early Complications (<100 days)					Late Complications (>100 days)	
	DAH	PERDS	DPTS	IPS	PVOD	BOS	COP
Incidence	5%-12%	33%	29%-64%	3%-15%	1%	2%-30%	2%
Transplant type	Autologous = allogeneic	Autologous	Autologous	Allogeneic	Allogeneic > autologous	Allogeneic	Allogeneic
Onset post HSCT	1-3 months	Within 5-7 days of neutrophil engraftment	5 weeks-3 months	1-3 months	3 weeks-3 months	4-24 months	3-12 months
Risk factors	Prolonged neutropenia	Growth factor use Infusion of CD34 ⁺ cell1s; Prolonged neutropenia; Peripheral blood HSCT source	Preconditioning regimens containing BCNU, cyclophosphamide and cisplatin radiotherapy?	GVHD, HLA disparity, CMV seropositivity; Increased age, TBI HSCT for cancer other than leukemia	Conditioning regimens containing cyclophosphamide?	GVHD	GVHD
Clinical symptoms/signs	Cough, progressive dyspnea, hemoptysis rare (<25%) Progressively bloody lavage fluid on BAL	Fever, dyspnea, dry cough, skin rash, weight gain, edema	Fever, dyspnea, dry cough,	Fever, cough, dyspnea, hypoxemia	Progressive dyspnea	Cough, dyspnea Progressive dyspnea, wheezing, obstructive findings on PFTs; DL _{CO} may be normal; Usually clinical diagnosis	Fever, dyspnea, dry cough, skin rash, weight gain, edema; Restrictive findings on PFTs; DL _{CO} reduced; Usually requires surgical lung biopsy for diagnosis
Histopathologic pattern	20% hemosiderin-laden macrophages in BAL fluid	BAL neutrophilia; Diffuse alveolar damage	Type II pneumocyte dysplasia, intra-alveolar edema, increased alveolar macrophages	Diffuse alveolar damage	Fibrous intimal proliferation of pulmonary venules and occasionally arterioles	Bronchiolitis obliterans (BO); cellular and constrictive bronchiolitis; Neutrophil-predominant BAL fluid	Organizing pneumonia intraluminal organizing fibrosis in distal airspaces; mild interstitial inflammation; BAL lymphocytosis

Radiographic findings	Diffuse infiltrates; may be central early on; ground-glass, linear, and nodular opacities may be seen	Bilateral infiltrates; pleural effusions; findings range from mild NCPE to ARDS	Ground-glass, linear, and nodular opacities may be seen	Bilateral interstitial infiltrates; ground-glass, opacities most common	Cardiomegaly, enlarged pulmonary arteries on CXR or CT	Hyperinflation on CXR; otherwise routinely normal; CT findings include mosaic attenuation (early) and air trapping, bronchiectasis (late)	Bilateral, patchy airspace disease with ground-glass appearance; may be nodular
Treatment	Supportive; response to steroids variable	Excellent; steroid responsive	Excellent; steroid responsive	Supportive; poor response to steroids	Supportive; no benefit from steroids	Supportive; immunosuppressive therapy; Variable response to steroids;	Steroid responsive disease
Prognosis	Less favorable prognosis when advanced; may progress to multi-organ system failure, sepsis and death	Favorable	Favorable	Poor	Poor	Poor; progressive disease with respiratory failure may occur	Favorable; potentially reversible disease

ARDS, acute respiratory distress syndrome; BAL, bronchoalveolar lavage; BCNU, carmustine; BOS, bronchiolitis obliterans syndrome; CMV, cytomegalovirus; COP, cryptogenic organizing pneumonia; CT, computed tomography; CXR, chest x-ray; DAH, diffuse alveolar hemorrhage; DLCO, diffusing capacity of the lung for carbon monoxide; DPTS, delayed pulmonary toxicity syndrome; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; HSCT, hematopoietic stem cell transplantation; IPS, idiopathic pneumonia syndrome; NCPE, noncardiogenic pulmonary edema; PERDS, perengraftment respiratory distress syndrome; PFT, pulmonary function test; PVOD, pulmonary veno-occlusive disease; TBI, total-body irradiation.

Recent studies have demonstrated stabilization of FEV₁ with high-dose inhaled corticosteroids. Other agents, including azithromycin, montelukast, azathioprine, sirolimus, and antithymocyte globulin, have been shown to have some benefit by PFT in small clinical trials and observational studies⁽⁵⁴⁻⁵⁶⁾. Early disease recognition is crucial to improvements in therapy and survival.

Cryptogenic organizing pneumonia, previously known as idiopathic bronchiolitis obliterans organizing pneumonia, is seen almost exclusively among allogeneic HSCT recipients with GVHD. Presenting symptoms of dry cough, dyspnea, and fever may be accompanied by a restrictive defect on PFTs and bilateral patchy infiltrates on chest imaging studies. Cryptogenic organizing pneumonia is typically steroid responsive, although no evidence-based guidelines regarding dosage and duration of corticosteroid therapy are currently available. Normalization of chest radiographs and PFTs may be seen within 1 to 3 months of therapy⁽⁵⁷⁻⁶⁰⁾.

Posttransplant lymphoproliferative disorder is a well-recognized complication of both solid organ transplantation and allogeneic HSCT. The disease is characterized by uncontrolled B-cell proliferation of donor-derived, Epstein-Barr virus-infected lymphocytes. Major risk factors include the use of T-cell-depleted donor stem cells, unrelated or HLA-mismatched related donor cells, and antithymocyte globulin. Posttransplant lymphoproliferative disorder complicates approximately 1% of allogeneic HSCTs, but may increase to 22% in patients with two or more risk factors. The lymph nodes, liver, spleen, and lungs are primary targets of PTLD. Dyspnea and fever typically develop 4 to 12 months following transplant, accompanied by interstitial and intra-alveolar infiltrates and ill-defined nodules. Reduction of immunosuppressive agents and administration of anti-CD20 (rituximab) therapy represent primary therapy^(50, 61). The prognosis is generally poor.

VASCULAR DISEASE

Venous thromboembolism (VTE) is a well-recognized complication of cancer and its therapy. The manifestations of VTE, pulmonary embolism (PE), and deep venous thrombosis (DVT) are seen in 20% of cancer patients. Cancer is associated with a four- to seven-fold increased risk of VTE. Evidence suggests that tumor type and stage as well as specific cancer therapies influence the absolute risk of thromboembolism. Furthermore, surgery, immobility, hormonal therapy, growth factors, angiogenesis inhibitors, erythropoietic agents, and central venous catheters all impact the overall likelihood of thrombotic complications^(62, 63). Rates of VTE as high as 28% to 43% have been reported in patients treated with combination antiangiogenic therapies, such as thalidomide and steroids or certain cancer chemotherapies (doxorubicin or BCNU). Unprovoked VTE may herald an impending diagnosis of cancer in patients without known malignancy. D-Dimer assays and scoring systems developed to estimate the pretest probability of VTE are neither sufficiently specific nor sensitive enough to rule out VTE⁽⁶⁴⁾. Computed tomographic pulmonary angiography (CTA) is the standard imaging technique for diagnosing PE and permits evaluation of competing diagnoses (Fig. 55-4). In unstable patients, echocardiography may provide rapid bedside assessment. Findings of right ventricle dilatation, right ventricle hypokinesis, tricuspid regurgitation, septal flattening, paradoxical septal wall motion, pulmonary artery hypertension, and lack of inspiratory collapse of the inferior vena cava are suggestive findings in the diagnosis of hemodynamically significant PE. Incidental PE is occasionally identified on CTAs performed for other reasons. Limited data support treatment of these asymptomatic PEs with full-dose anticoagulant therapy⁽⁶⁵⁾. Guidelines for VTE prophylaxis and treatment in the cancer setting have been established (Fig. 55-5). Low-molecular-weight heparin (LMWH)

FIGURE 55-4 Pulmonary embolism. A 25-year-old man presented to the emergency room with acute pleuritic chest pain and shortness of breath. Computed tomography angiogram confirmed a large saddle embolus with extension of clot into the left interlobar and lingular arteries (*). Subpleural ground-glass opacities (arrows) likely represent pulmonary infarction or hemorrhage.

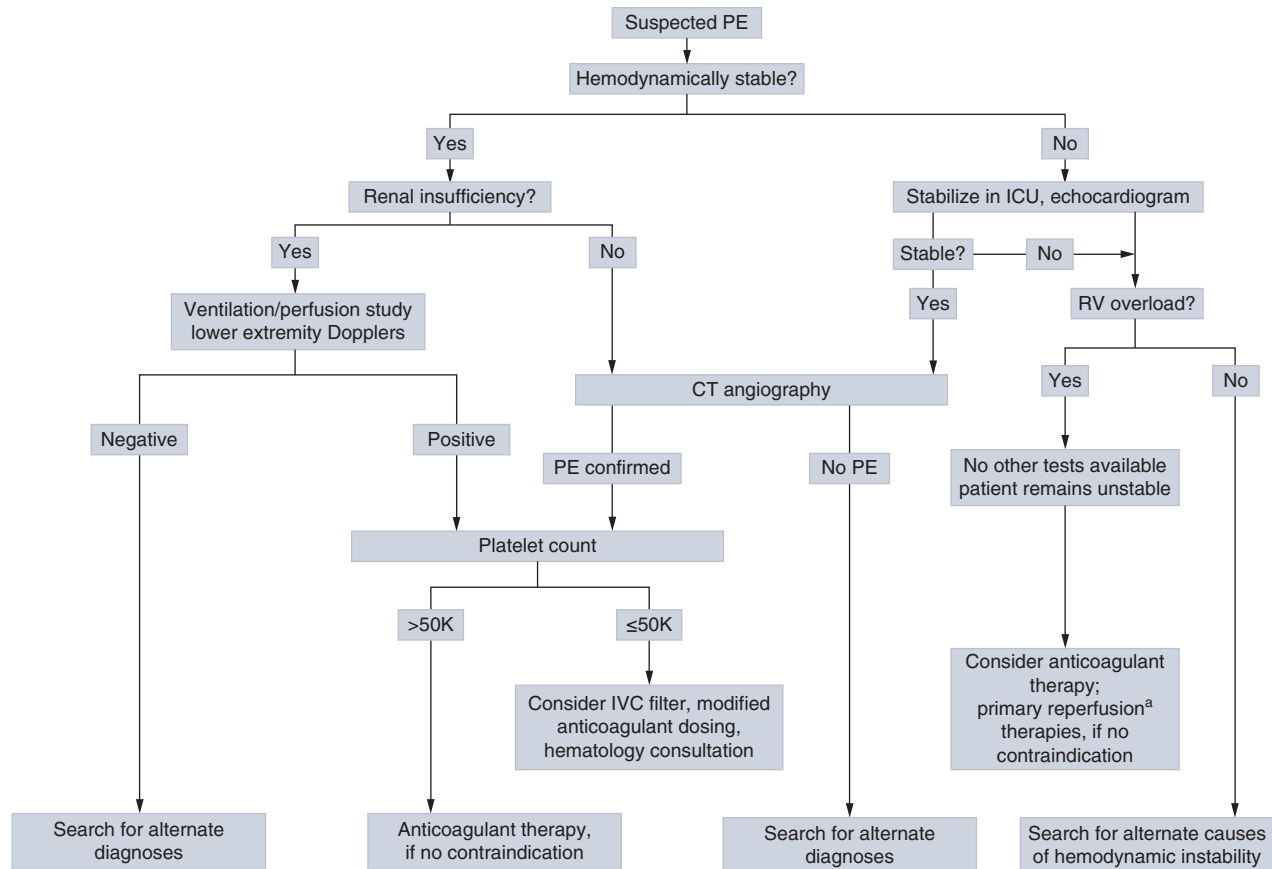

FIGURE 55-5 Algorithm for approach to assessment and management of pulmonary embolism (PE) in the cancer setting. CT, computed tomography; ICU, intensive care unit; IVC, inferior vena cava; RV, right ventricle. ^aSystemic thrombolytic therapy, surgical pulmonary embolectomy, percutaneous catheter-directed thrombolysis.

is the preferred agent, based on superior efficacy and safety data. In patients with impaired renal function, unfractionated heparin, or alternatively, fondaparinux should be considered. Recommendations include a 7- to 10-day course of LMWH for cancer patients undergoing surgery, which should be started preoperatively. Among patients at high risk for VTE, 4 weeks of LMWH are recommended. Thromboprophylaxis is not warranted in the routine management of the ambulatory cancer patient. This recommendation is based on analysis of the known risk of bleeding among patients with cancer and potential benefits of anticoagulant therapy in this setting. However, once hospitalized, VTE prophylaxis should be considered. Conversely, prophylactic LMWH is recommended for the ambulatory patient with multiple myeloma who is receiving thalidomide- or lenalidomide-based combination therapy. Prophylactic anticoagulation to prevent catheter-associated thrombosis is not recommended. Once established, full anticoagulant therapy should be initiated ⁽⁶⁶⁻⁷⁰⁾. Thrombolytic therapy for management of massive PE should be considered, although its efficacy and safety in the cancer setting have not been systematically studied. In all cases, contraindications

to anticoagulant therapy should be weighed against the potential benefits of therapy ⁽⁷¹⁾.

A variety of conditions in the cancer setting may be associated with pulmonary hypertension (PH), defined as an elevated mean pulmonary artery pressure (mPAP) ≥ 25 mm Hg at rest. These conditions are represented in all five categories of the revised 2013 World Health Organization classification scheme for PH ^(Table 55-5). For example, chemotherapeutic agents, such as dasatinib, and PVOD caused by chemotoxins, thoracic radiation, and stem cell transplantation are known causes of PAH (group 1). Cancer treatment-related left heart disease is a common cause of PH (group 2). Hypoxemic pleuroparenchymal disease due to tumor infiltration, infection, and chemotoxicity are well known sources of group 3 PH. Increased rates of acute and chronic PE as well as splenectomy in the cancer setting are associated with chronic thromboembolic PH (group 4). Finally, myeloproliferative disorders and entrapment/compression of large pulmonary vessels by infection and treatment-related mediastinal fibrosis, adenopathy, or neoplasms are recognized risk factors of group 5 PH ⁽⁷²⁻⁷⁶⁾. The development of significant PH in cancer portends a worse prognosis. Dyspnea, nonproductive

Table 55-5 Revised Classification of Pulmonary Hypertension

Class	Subclass
1. Pulmonary arterial hypertension (PAH)	1.1. Idiopathic PAH 1.2. Heritable PAH 1.3. Drug- and toxin-induced 1.4. Associated with 1.4.1. Connective tissue disease 1.4.2. HIV infection 1.4.3. Portal hypertension 1.4.4. Congenital heart diseases 1.4.5. Schistosomiasis 1.5. Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis 1.6. Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension due to left heart disease	2.1. Left ventricular systolic dysfunction 2.2. Left ventricular diastolic dysfunction 2.3. Valvular heart disease 2.4. Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. Pulmonary hypertension due to lung disease or hypoxia	3.1. COPD 3.2. Interstitial lung disease 3.3. Other pulmonary disease with mixed restrictive and obstructive pattern 3.4. Sleep-disordered breathing 3.5. Alveolar hypoventilation disorders 3.6. Chronic exposure to high altitude 3.7. Developmental lung diseases
4. Chronic thromboembolic pulmonary hypertension (CTEPH)	
5. Pulmonary hypertension with unclear or multifactorial etiologies	5.1. Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy 5.2. Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangiomatosis 5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders 5.4. Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure

COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus.

cough, and hypoxemia develop insidiously in cancer-related PH and may progress to respiratory failure and death. Supportive care and treatment of the underlying disease are the mainstays of therapy. The utility of pulmonary vasodilator agents, including treatment strategies that target nitric oxide, endothelin, and prostaglandin pathways in the management of cancer-related PH has not been definitively studied. Vasodilator therapy in the setting of cancer-related PVOD should be used with extreme caution, because fatal pulmonary edema precipitated by vasodilator therapy in this setting has been reported^(73,74,77).

MALIGNANT CENTRAL AIRFLOW OBSTRUCTION

Malignant central airway obstruction refers to obstruction at the level of the trachea, mainstem bronchi, and/or bronchus intermedius. Cough, stridor, wheezing,

dyspnea, atelectasis, and recurrent or persistent postobstructive pneumonia are common presenting symptoms. Hemoptysis, which can be massive and life threatening, may also occur. Stridor signals a more proximal level of obstruction at the level of the trachea or larynx, whereas focal wheezing is typically due to obstruction distal to the main carina. Tracheal stenosis resulting in airway narrowing of 50% or greater is associated with a 16-fold increase in flow resistance. Thus, obstructive symptoms typically develop with airway occlusions of 50% or more⁽⁷⁸⁾. Tracheal diameters of 8 mm are associated with dyspnea on exertion. Resting dyspnea occurs with tracheal diameters of 5 mm or less. Confounding factors, such as chronic obstructive pulmonary disease, mucosal edema, and increased airway secretions may precipitate inexorable dyspnea even in patients with only moderate tumor-related airflow limitation. Compromised airway caliber by tumor may be due to endoluminal tumor, extrinsic compression, or direct extension through the airway wall.

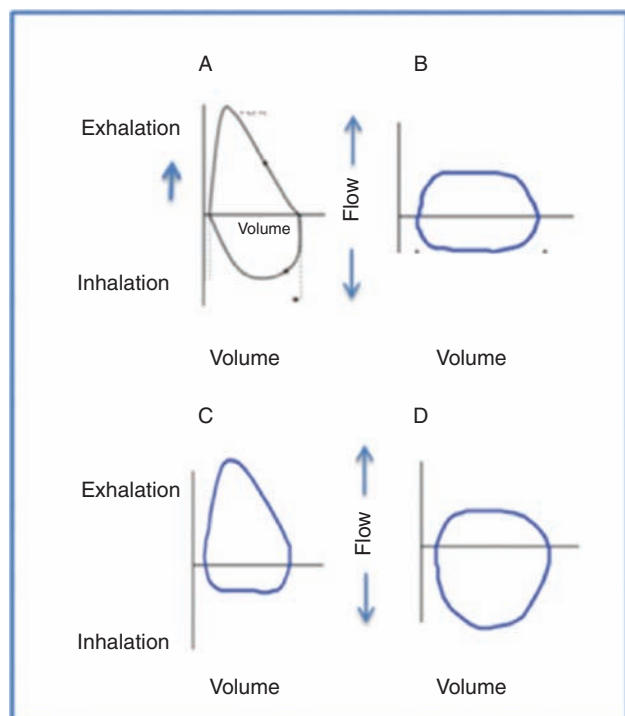

FIGURE 55-6 Flow-volume loops in upper airway obstruction. **A.** Normal. **B.** Flattening of both the inspiratory and expiratory limbs of the flow-volume loop, consistent with fixed upper airway obstruction with flow limitation. **C.** Flattening of the inspiratory limb consistent with dynamic (variable, nonfixed) extrathoracic obstruction with flow limitation. **D.** Flattening of the expiratory limb consistent with dynamic (variable, nonfixed) intrathoracic obstruction.

Optimization of therapy is predicated on the location and extent of airway disease and quantification of air-flow limitation. With the exception of rare findings of tracheal deviation on plain films, chest radiographs are of limited value in defining the anatomic extent of airway tumor. Blunting of the flow-volume loop on PFT is an insensitive signal of upper airway obstruction, which typically only occurs once tracheal caliber is reduced to less than 10 mm (Fig. 55-6) ⁽⁷⁹⁾. The use of spirometry in patients with severe airway obstruction is not recommended because it may precipitate frank respiratory failure.

Bronchoscopic examination is central to diagnosis and treatment of malignant central airflow obstruction. Characterization and histologic confirmation of the tumor as well as the extent of obstruction attributable to endoluminal and/or extraluminal disease at bronchoscopy are important findings that help to guide treatment decisions (Fig. 55-7). Therapeutic strategies for predominant endoluminal disease include surgical resection and mechanical debulking using the rigid bronchoscope. Balloon bronchoplasty and endobronchial argon plasma coagulation (APC) and/or laser

therapy, electrocautery, cryotherapy, brachytherapy, and photodynamic therapy are additional therapeutic options for predominant endobronchial disease and may be performed during rigid bronchoscopy. Stent placement and RT are reasonable treatment options for patients with predominant extraluminal disease. A multimodality approach that includes endobronchial debulking and stent placement is common, as many patients present with mixed endo- and extraluminal disease (Fig. 56-8). Treatment options are based on the type of obstruction.

PLEURAL DISEASES IN THE CANCER SETTING

Nearly 50% of all cancer patients develop pleural effusions. These may be malignant pleural effusions (MPEs) or paramalignant pleural effusions. The latter result from direct or indirect effects of tumor on the pleural space and include bronchial obstruction, infiltration of mediastinal lymph nodes, superior vena cava syndrome, trapped lung PE, and atelectasis. Paramalignant effusions occur on the involved side and are typically small to moderate in size, with negative pleural fluid cytology. Malignant pleural effusions rank second as the leading cause of exudative effusions, after parapneumonic effusions. Malignant pleural effusions may be quite large. In contrast to parapneumonic effusions, pleural fluid cytology is positive in more than 60% of patients with MPE ⁽⁸⁰⁾. Malignant pleural involvement may also occur in the absence of pleural fluid in patients with primary pleural tumors or metastatic disease to the pleura ⁽⁸¹⁾.

Fifty percent of all cancer-related pleural effusions are due to lung cancer. Breast carcinoma and effusions due to hematologic malignancies, including lymphoma and leukemias, are also common causes. Progressive dyspnea and dry cough are presenting symptoms in most patients, which may be accompanied by constitutional symptoms of malaise, anorexia, and weight loss with advanced disease. Preprocedure imaging is an important component in the diagnostic workup and treatment planning. Standard chest radiographs and bilateral decubitus films provide critical information regarding effusion size, position of the mediastinum and diaphragms, presence of fluid loculations, and characteristics of the underlying lung parenchyma. Patients with large pleural effusions and associated contralateral shift of the mediastinum should undergo prompt therapeutic thoracentesis. A centered or ipsilateral shift of the mediastinum with associated pleural effusion may signify frozen mediastinum, tumor encasement of the ipsilateral mainstem bronchus, or extensive parenchymal involvement due to lymphangitic spread of tumor, infection, or other infiltrative

FIGURE 55-7 Approach to malignant central airway obstruction using interventional bronchoscopic therapies.

lung diseases. Any of these diagnoses may cause ipsilateral opacification of the lung and simulate a large pleural effusion (Fig. 55-9). Pleural effusions in this setting should therefore be approached with caution⁽⁸²⁾.
Transthoracic ultrasonography is a well-established and validated imaging tool that has gained an

increasing role in diagnostic and therapeutic pleural interventions. Pleural ultrasonography is easy to learn and interpret and provides valuable information regarding optimal site localization for thoracentesis and other invasive pleural procedures, as well as information regarding pleural fluid characteristics such as

FIGURE 55-8 Complete occlusion of the right mainstem bronchus due to a large endobronchial bronchogenic carcinoma (A, B). The 2-cm tumor was removed using an electrocautery snare (C) followed by airway stent placement (D).

FIGURE 55-9 Large pleural effusion causing shift of the mediastinum to the contralateral side (A). Patient B also has a large effusion; however, the mediastinum is shifted ipsilaterally due to central airway obstruction caused by tumor, resulting in non-expandable lung.

the presence of loculations, fibrin strands, and pleural metastases (Fig. 55-10). Computed tomography provides valuable anatomic information of the visceral and parietal pleura, chest wall, lung parenchyma, and mediastinal structures and is particularly useful in characterizing the pleural fluid and identifying competing diagnoses⁽⁸³⁾. Findings on positron emission tomography (PET)-CT and conventional CT imaging, such as irregular, thickened, or nodular pleural surface, suggest malignancy. Pleural enhancement with intravenous contrast material is also suggestive of malignancy, although pleural inflammation may be associated with similar findings. Recent studies have shown that PET imaging with 18-fluorodeoxyglucose is useful in delineating pleural tumors and extrapleural extension

of disease in patients with malignant pleural mesothelioma (MPM). Magnetic resonance imaging (MRI) of the pleural space is also valuable in displaying pleural tumors. This imaging strategy provides excellent soft tissue contrast and delineation of extrapleural invasion of the chest wall, spine, nerves, and mediastinal vascular structures⁽⁸³⁾. This information is complementary to chest CT imaging and markedly enhances surgical planning for patients with MPM.

Nearly all MPEs are categorized as exudates using Light's criteria⁽⁸⁴⁾. The cytologic or histologic confirmation of malignant cells on pleural fluid or biopsy is key to diagnosis, although pleural cytology is only positive in 62% of patients⁽⁸⁰⁾. Flow cytometry with identification of tumor markers may improve

FIGURE 55-10 Coronal (A) and axial (B) views on computed tomography evaluation of a large multiloculated, left-sided pleural effusion in a patient with malignant mesothelioma. The loculations are caused by thick-walled adhesions (arrow), seen on ultrasound evaluation (C).

FIGURE 55-11 Positron emission tomography/computed tomography imaging (A) showing a fluorodeoxyglucose (FDG)-avid rind of thickened, nodular pleural deposits encasing the left lung. Extensive nodularity along the visceral pleural surface (*) was seen at pleuroscopy (B, C). Pathologic analysis of the biopsied nodules was consistent with malignant mesothelioma.

the diagnostic yield of cytologically negative effusions by 33%. This diagnostic strategy has proved particularly useful when pleural effusions associated with lymphoma, leukemia, or multiple myeloma are suspected^(85, 86). A definitive diagnosis is yielded after closed pleural biopsy in only 44% of patients, but increases to 77%⁽⁸⁰⁾ with the addition of pleural fluid cytology. More recent advances in pleuroscopic and image-guide biopsy techniques have improved the diagnostic yield as compared to traditional closed-needle biopsy in the diagnosis of pleural malignancy (Fig. 55-11). For example, pleuroscopy and CT-guided

pleural biopsies exhibit 95% and 87% sensitivity in the diagnosis of pleural malignancies, respectively. The addition of pleural fluid cytology to pleuroscopy offers only a marginal increase in the diagnostic yield⁽⁸⁵⁾.

With few exceptions, the presence of MPE portends a poor prognosis, with mean survival measured in months. Therefore, treatment is focused on palliation. Our approach to the management of MPEs is outlined in Fig. 55-12. Factors such as associated symptoms, performance status, volume of fluid evacuated, whether symptom palliation and lung reexpansion were achieved with prior thoracenteses, time course

Management of malignant pleural effusions (MPEE)

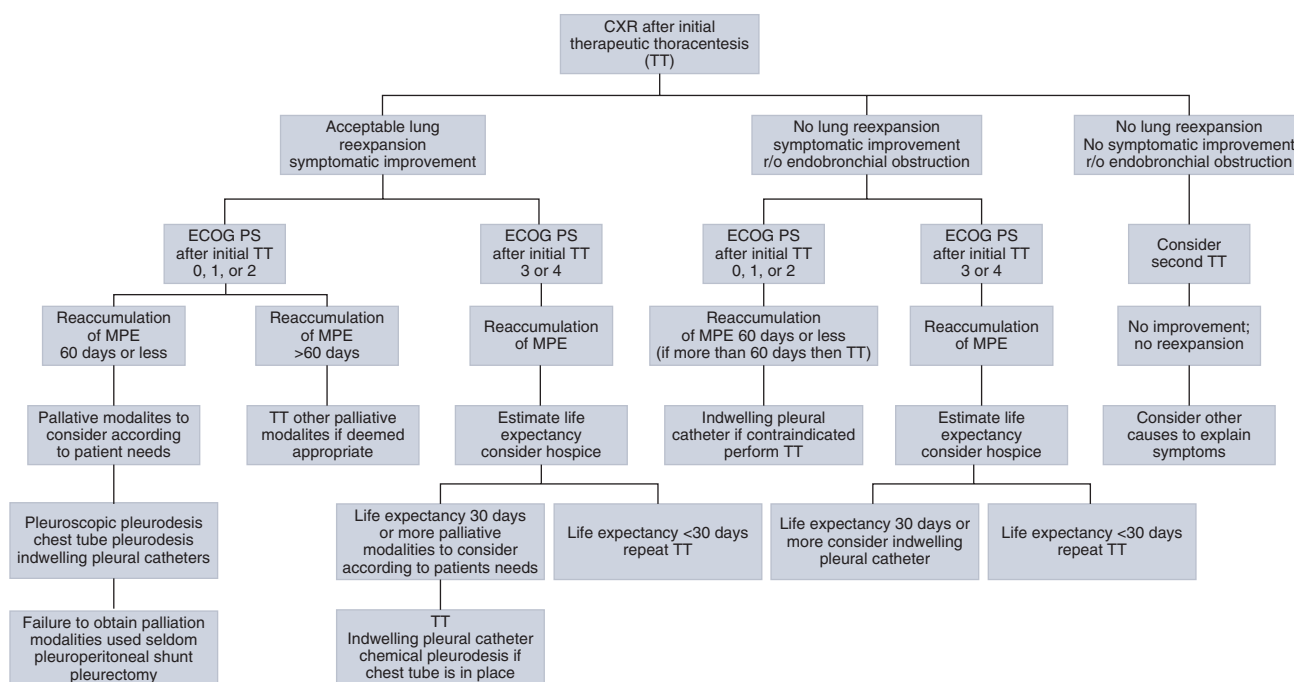

FIGURE 55-12 Management of malignant pleural effusions (MPEs). CXR, chest x-ray; ECOG PS, Eastern Cooperative Oncology Group performance status.

for recurrence, and tumor response to systemic therapy should be considered in management options. Among patients with newly diagnosed chemo- or radiosensitive tumors (lymphoma, breast, small-cell lung cancer, prostate, thyroid, germ cell), simple thoracentesis while awaiting response to definitive therapy is reasonable. Most MPEs will recur with 30 days of the prior thoracentesis. Repeated thoracentesis is also recommended in patients with slowly reaccumulating pleural effusions and short life expectancy (1-3 months). Poor performance status is predictive of limited survival among patients with recurrent malignant pleural effusions⁽⁸⁷⁾. Evacuation of pleural fluid is ideally ultrasound guided, which is associated with lower rates of pneumothorax. In a recent consensus statement, the American Thoracic Society and the European Respiratory Society endorsed symptom-limited pleural fluid evacuation, not to exceed 1.0 to 1.5 L of fluid in one sitting⁽⁸¹⁾. In our experience, symptom-limited evacuation of up to 2.0 to 2.5 L of pleural fluid in one sitting is safe among patients with contralateral mediastinal shift associated with a large pleural effusion. Chest pain, cough, and dyspnea are limiting symptoms that should prompt discontinuation of the procedure. Cautious evacuation of large volumes of pleural fluid is recommended in patients with centered or ipsilateral shift of the mediastinum. Pleural pressure measurements during thoracentesis have not been shown to be superior to symptom-limited pleural drainage in reducing the risk of procedure-related complications⁽⁸⁸⁾.

Indwelling pleural catheter (IPC) placement is an increasingly viable palliative option for patients with recurrent MPEs. Patients whose life expectancy exceeds 30 days and those in whom symptomatic improvement was achieved on prior thoracenteses are ideal candidates for IPC placement. Symptom improvement may occur without imaging evidence of lung reexpansion following thoracentesis due to other physiologic and mechanical changes that occur in the chest post large volume thoracentesis. Most catheters are placed in the outpatient setting. Designated family members and/or caretakers are then trained on the proper use of the catheter. Daily home drainage is recommended initially, followed by every other day drainage as pleural fluid volume decreases. In our experience, 94% of patients reported symptom relief, and in 52%, effective pleurodesis with subsequent removal of the catheter was achieved. The average time from catheter insertion to removal was 32 days. Empyema and persistent pain at the insertion site were rare complications of IPC placement in our review. Recurrent effusion has also been rarely described in a small group of patients following catheter removal⁽⁸⁹⁾.

Chemical pleurodesis using asbestos-free talc is a widely used strategy in the management of MPE. Several studies suggest that talc is superior to other

sclerosants (bleomycin, tetracycline) in achieving pleurodesis. Eligible patients for this procedure should have a good performance status (Eastern Cooperative Oncology Group performance status of 0 to 2) and report symptomatic relief and lung reexpansion following prior thoracentesis. Pleuroscopic talc poudrage and talc slurry instillation via small-bore chest tube are both viable methods of chemical pleurodesis.

The management of recurrent chylous effusions is a particular challenge because of the potential for severe lymphopenia, nutritional depletion, and water and electrolyte loss from prolonged loss of chyle. These effusions, when cancer-related, require treatment of the underlying malignancy. Parenteral alimentation, talc pleurodesis, and indwelling pleural catheter placement represent reasonable alternatives in the management of recalcitrant effusions⁽⁹⁰⁾. Pleuroperitoneal shunt placement is an attractive treatment option that permits reabsorption of chyle in the peritoneum, which mitigates the risk of malnourishment and immune suppression. However, small-volume shunt removal and increased potential for pump obstruction limit the utility of this treatment modality. Embolization of the thoracic duct has not been definitively studied but appears well tolerated.

SLEEP DISTURBANCES IN CANCER THERAPY

Nearly half of all patients with cancer develop sleep disturbances. Insomnia, poor sleep efficiency, early awakening, excessive daytime sleepiness, and restless legs may occur during all phases of cancer care and persist for many months to years after completion of cancer therapy. The biochemical changes inherent to cancer growth, anticancer therapies, and cancer-related symptoms of fatigue, pain, and depression may all adversely impact sleep quality.

Sleep disturbance may occur due to a myriad of causes and may have important implications in cancer treatment, prevention, and survivorship (Fig. 55-13). For example, sleep duration appears to influence cancer risk. Excess cancer prevalence has been demonstrated among insomniacs with sleep times of less than 5 hours per night and patients undergoing 9 or more hours of sleep nightly⁽⁹¹⁾. In the American Nurse Health Study, a relative increased risk of breast cancer was demonstrated among nurses working rotating shifts for many years^(92, 93). In another study, cancer mortality increased by five-fold among patients with a protracted history of severe sleep apnea⁽⁹⁴⁾.

A detailed history and physical examination may elucidate a single etiology or multiple etiologies for

FIGURE 55-13 Causes of sleep disorders.

sleep disturbance. Two frequent causes of sleep disturbance in the cancer setting include sleep-related breathing disorders and insomnia. The incidence of sleep-related breathing disorders may be increased in the cancer setting due to the cancer itself or as a sequela of cancer therapy. For example, higher rates of obstructive sleep apnea have been reported among patients with head and neck cancers ⁽⁹⁵⁾. Increased rates of central sleep apnea in the cancer setting have been attributed to the frequent use of opioid medications ⁽⁹⁶⁾. In addition, RT, pain medications, and chest wall deformities caused by cancer or its treatment may exacerbate sleep-related hypoventilation. Supplemental oxygen and positive airway pressure therapy are the mainstays of therapy for sleep-related breathing disorders. Cessation of sedating medications should be considered along with optimization of underlying pulmonary and cardiac disease.

Insomnia is a common problem in the cancer setting that impacts cancer treatment as well as survival. In one study, reported rates of insomnia among cancer patients completing their first cycle of chemotherapy were three-fold higher than the general population ⁽⁹⁷⁾. Sleep loss, and in particular rapid eye movement (REM) sleep deprivation, is hyperanalgesic. Thus, insomnia, which is common in the cancer setting, may confer an increased sensitivity to pain ⁽⁹⁸⁾. Insomnia is a major contributing factor to cancer-related fatigue, and the prevalence and association of these two disorders may vary greatly during the course of cancer care ⁽⁹⁹⁻¹⁰¹⁾. Cognitive behavioral therapy is the

mainstay of therapy, which may improve insomnia, optimize sleep hygiene, decrease sedative-hypnotic medication use, and improve quality of life among these patients. Treatment of other potential etiologies for cancer-related fatigue, including pain, anemia, and thyroid disorders, may also help to improve symptoms of insomnia.

Cancer-Associated Thrombosis

Rachel A. Sanford
Michael H. Kroll

VENOUS THROMBOEMBOLISM

Scope of the Problem

Pulmonary embolism (PE) and deep venous thrombosis (DVT) are manifestations of venous thromboembolism (VTE). Approximately 20% of all VTEs are associated with cancer, and cancer increases the risk for VTE four- to sixfold. Surgery, chemotherapy, hormonal therapy, growth factors, angiogenesis inhibitors, immunomodulators, erythropoietic agents, and central venous catheters (CVCs) contribute to cancer-associated VTE (¹). Risk of VTE is associated with the type of cancer and its clinical stage, with glioblastoma, stomach cancer, pancreatic cancer, lung cancer, gynecologic cancer, and leukemia frequently associated with VTE, and early-stage breast cancer, prostate cancer, and melanoma least commonly associated with VTE (¹). Cancer-associated VTE is rarely lethal within 6 months of diagnosis and treatment (²), but it is often undiagnosed, and its onset can be associated with considerable mortality. Venous thromboembolism was the death certificate–attributed cause of death for 0.21% of patients with cancer in a large population-based death certificate review (³), the cause of 3.5% of 141 deaths recorded among 4,466 community hospital–treated ambulatory patients with cancer (⁴), and the objectively documented cause of death among 1.5% of all patients with cancer managed by a single cancer center (⁵).

Diagnosis

Clinical presentations of VTE are not specific. Most patients with DVT have unilateral leg swelling and

tenderness, and most patients with PE have abrupt-onset dyspnea and pleuritic chest pain. These symptoms are nonspecific, especially in patients who have cancer. Scoring systems developed to estimate pretest probability of DVT and PE (like the Well's scores) can be used to rule out VTE in patients with cancer, but the likelihood of finding a normal D-dimer level among patients with cancer is less than 30%, and elevated D-dimers are of no positive predictive value (⁶). Doppler/compression ultrasound is the preferred method to diagnose DVT, although magnetic resonance imaging (MRI) and computed tomography (CT) may be required in special circumstances, such as internal iliac vein or vena cava thrombosis. High-resolution CT or CT angiography is the best method for diagnosing PE (⁷), and it offers the advantage of providing additional information regarding synchronous thoracic pathology that may confound the diagnosis of PE. Conversely, up to 5% of all chest CTs done for cancer staging, monitoring, and surveillance show asymptomatic incidental PEs (⁸).

Prevention

Pharmacological VTE prophylaxis should be considered in every hospitalized patient with cancer for whom there is no contraindication (⁹). Contraindications to pharmacological anticoagulation are absolute (recent central nervous system bleed, intracranial or spinal lesion at high risk for bleeding, or major active bleeding: more than 2 units transfused in 24 hours) or relative (chronic, clinically significant measurable bleeding >48 hours; platelets <50,000/ μ L; platelet dysfunction [uremia, medications, dysplastic hematopoiesis]; recent major operation at high risk for bleeding;

underlying hemorrhagic coagulopathy; high risk for falls; neuraxial anesthesia/lumbar puncture). Enoxaparin 40 mg, dalteparin 5,000 IU, or fondaparinux 2.5 mg subcutaneously once per day can be used for VTE prevention in patients with cancer.

Patients with cancer undergoing abdominal or pelvic surgery should receive low molecular weight heparin (LMWH) prophylaxis extended for 4 weeks (⁹). Routine pharmacological prophylaxis in ambulatory patients with cancer receiving chemotherapy is recommended only for patients with myeloma receiving thalidomide or lenalidomide as part of combination chemotherapy, although outpatient pharmacological prophylaxis can be considered in high-risk patients receiving systemic chemotherapy, such as those with pancreatic or gastric cancers (¹⁰).

Treatment

Routine VTE induction therapy is used to treat symptomatic VTE or incidental PE. Incidental PEs, including those found in the subsegmental branches of the pulmonary artery, appear to have a recurrence risk similar to symptomatic PE and should be managed similarly. Preference is for LMWH—for example, enoxaparin 1 mg/kg/12 hours or dalteparin 200 IU/kg/24 hours—but infused unfractionated heparin should be used for patients with renal failure or nonsevere hemorrhage. Thrombolysis can be considered in cases of massive PE (defined as associated with systolic blood pressure <90 mm Hg lasting for more than 15 minutes), and an inferior vena cava (IVC) filter should be placed when anticoagulation is contraindicated. If the contraindication is temporary, a retrievable IVC filter is preferred.

Maintenance therapy is different from that for patients without cancer, however, as it is with LMWH because LMWH is better than warfarin at preventing recurrences (²). When tolerated, maintenance therapy should be continued indefinitely for most patients with active cancer (^{8, 11}). The risk of recurrent cancer-associated DVT after stopping anticoagulation can be stratified by examining residual venous thrombosis 6 months into treatment: Only 3/105 patients without residual venous thrombosis had recurrent DVT after stopping LMWH anticoagulation. The recurrence rate among those with residual venous thrombosis was high (49/242), and continuing anticoagulation for 6 months did not significantly affect the risk of recurrence (¹²).

The reason why LMWH is better than warfarin for maintaining anticoagulation (and may be better than the new oral anticoagulants [NOACs]) in patients with cancer is not clear. Preclinical data indicate that LMWH, but not warfarin or fondaparinux, inhibits tumor procoagulant activity by blocking mucin binding to endothelial, leukocyte, and platelet selectins. The LMWH also stimulates endothelial cell release of the potent natural

anticoagulant protein *tissue factor pathway inhibitor* and binds to soluble inflammatory cytokines, thereby preventing their effect of shifting the endothelium toward an inflamed prothrombotic phenotype (¹³).

Recurrence

Recurrence of VTE on anticoagulation therapy is common in patients with cancer. The Comparison of Low-Molecular-Weight Heparin versus Oral Anticoagulant Therapy for the Prevention of Recurrent Venous Thromboembolism in Patients with Cancer (CLOT) trial from 2003 showed a best-case scenario of 9% recurrence at 6 months among those treated with LMWH maintenance (²). The more recent CATCH trial showed that we have not made great progress in the intervening decade: The recurrence rate was 6.9% at 6 months among patients receiving LMWH maintenance (¹⁴).

Optimal management of VTE recurrence remains uncertain. If the anti-FXa level drawn 4 hours after injection is not in the therapeutic range, the dose of LMWH should be adjusted, aiming toward the therapeutic peak anti-FXa level. If the anti-FXa level is therapeutic, one can increase the dose of LMWH by 20%, change to another anticoagulant, or place an IVC filter (¹¹).

Anticoagulation in Patient With Thrombocytopenia

Mild thrombocytopenia (platelets <50,000/ μ L) is presented as a relative contraindication for anticoagulation by the American Society of Clinical Oncology and the National Comprehensive Cancer Network despite the lack of data about the risk of anticoagulation in patients with thrombocytopenia. There are, however, fairly consistent data that thrombocytopenia preventing pharmacological prophylaxis is a critical factor in the large risk of VTE and its recurrence among patients with acute leukemia (¹⁵) and following stem cell transplant (SCT) (¹⁶).

To address this conundrum, the Subcommittee on Haemostasis and Malignancy for the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis has developed consensus guidelines (¹¹). One recommendation is that patients with chronic thrombocytopenia be given dose-adjusted LMWH, with full-dose LMWH when the platelet count is greater than 50,000/ μ L; half-dose LMWH when the platelet count is between 25,000 and 50,000/ μ L; and no anticoagulation when the platelet count is less than 25,000/ μ L. Such an approach can also be considered for patients with cyclical thrombocytopenia from chemotherapy.

Catheter Thrombosis

Catheter thrombosis may affect almost 50% of patients who have CVCs, although fewer than 5% of

catheters are associated with symptomatic occlusive DVTs (¹⁷). In addition to all the other risk factors for DVT development in patients with cancer, the catheter type (peripherally inserted central catheter > centrally inserted catheters > implanted ports) and location (femoral > jugular > subclavian) affect the risk of developing a catheter-related DVT.

There is no evidence that anticoagulation prevents catheter-associated thrombosis, and all guidelines currently recommend against it. The diagnosis and treatment of catheter-associated DVT are, however, similar to the diagnosis and treatment of lower-extremity DVTs, with two special considerations. The first is that the catheter can be maintained in place during anticoagulation if it is functional and useful. In this case, therapeutic anticoagulation should be maintained for as long as the catheter is in place. The second is how to manage anticoagulation when a catheter has been removed because it is infected or no longer needed. Clinical guidelines recommend 3 months of anticoagulation after catheter removal.

Bleeding Complications

Bleeding while on anticoagulation is common. During the first 6 months of treatment, about 3% of all

patients with cancer will have major bleeding (generally defined as a fall in hemoglobin of 2 g over 24 hours, the need for 2 units of packed red blood cell transfusion over 24 hours, or bleeding into a vital organ or eye), and another 10% will have nonmajor bleeding (¹⁴). These rates may double during the next 6 months of anticoagulation. After the first year, they appear to stabilize (¹⁸).

Bleeding often develops unexpectedly at the beginning of treatment when LMWH unmasks a previously unrecognized bleeding threat (⁸). When major bleeding occurs, it is essential to stop anticoagulation, reverse it when appropriate (Table 56-1), and place an IVC filter.

Direct Oral Anticoagulants

The use of the DOACs—rivaroxaban, apixaban, and dabigatran—for cancer-associated VTE is generally discouraged, as few patients with cancer were included in the major trials of these agents, and there are no established procedures for monitoring or reversing their effects (¹⁹). Clinical trials are ongoing to determine the therapeutic index of these agents when they are used to prevent or treat cancer-associated VTE.

Table 56-1 Rapid Reversal of the Effects of Low Molecular Weight Heparins (LMWHs)

LMWH	Reversal Agent	Dosage	Comments
Enoxaparin (Lovenox®) ½ life: 4.5-7 h	Protamine % Xa activity neutralized: Enoxaparin 54.2% Dalteparin 74%	Administer 1 mg of protamine for each 1 mg of enoxaparin or 100 IU of dalteparin IV slowly over 10 min or as a continuous infusion over 30 min. Rate should not exceed 5 mg/min. If enoxaparin/dalteparin was used greater than 8 h ago, then reduce dose by half (0.5 mg/1 mg enoxaparin)(0.5 mg/100 units of dalteparin). A second dose (0.5 mg/1 mg enoxaparin)(0.5 mg/100 IU dalteparin) of protamine may be given 2-4 h after the completion of the first dose. Single dose of protamine should not exceed 50 mg. Half-life is 10 min so repeat dosing may be needed.	Hypersensitivity reactions may occur in patients with known hypersensitivity to fish Monitoring: aPTT and anti-Xa Possible side effects of protamine: severe hypotension, anaphylaxis, dyspnea, bradycardia, flushing, a feeling of warmth especially when given too rapidly
Dalteparin (Fragmin®) ½ life: 4-8 h	Recombinant factor VIIa (Novo-Seven®): ½ life: 2.6-3.1 h	For life-threatening bleed that persists despite protamine administration: 20-30 µg/kg IV times 1 dose Repeat in 2 hours if needed Round to the nearest 1 mg	Monitoring: monitor for evidence of hemostasis A "normal" INR may not mean successful reversal Accepted by most Jehovah's Witness patients

Rapid reversal of the effects of low molecular weight heparins can be accomplished in bleeding patients using protamine and, if necessary, recombinant activated factor VII.

^aPTT, activated partial thromboplastin time; INR, international normalized ratio.

THROMBOTIC MICROANGIOPATHIES

Cancer-associated thrombotic microangiopathies (TMAs) are a group of disorders identified mainly by descriptive clinical characteristics, always involving the presence of circulating schistocytes associated with intravascular hemolysis (elevated lactate dehydrogenase LDH and indirect bilirubin), anemia, and when the bone marrow is healthy, elevated reticulocytes. Anemia and thrombocytopenia are the principle clinical manifestations, but there may also be end-organ dysfunction from microvascular thrombosis, particularly in the kidneys. Cancer-associated TMAs are distinguished from disseminated intravascular coagulation (DIC) by normal coagulation studies and D-dimer levels.

Pathogenesis of Cancer-Associated Thrombotic Microangiopathy

The molecular pathogenesis of cancer-associated TMAs is barely understood, and ignorance about pathophysiological mechanisms is coupled to inadequate diagnostic measures and a paucity of effective evidence-based clinical therapeutics. Most of the approaches utilized derive from those used to manage patients with two of the well-characterized TMAs: de novo thrombotic thrombocytopenic purpura (TTP) and hereditary complement-mediated TMA (also referred

to as familial atypical hemolytic uremic syndrome [aHUS])⁽²⁰⁾. Because some forms of cancer-associated TMA almost certainly result from an overlap of pathophysiological elements present in TTP and complement-mediated TMA (Fig. 56-1), a brief overview of each is presented.

De Novo Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is an autoimmune disorder leading to severely deficient (<5%) activity of the primary von Willebrand factor (VWF) cleaving protease ADAMTS-13 (the thirteenth member of the protein family designated “a disintegrin and metalloproteinase with thrombospondin-type 1 motif”). Anti-ADAMTS-13 antibodies cause its dysfunction or rapid clearance, and this results in absent cleavage of ultralarge VWF multimers that are synthesized and secreted by vascular endothelium. The ultralarge VWF multimers are adhesive, and when they circulate systemically, they attach to platelet glycoprotein Ib in the microcirculation, leading to in vivo platelet activation and aggregation, microvascular thrombosis, and end-organ ischemia accompanied by microangiopathic hemolytic anemia. This is a hematological emergency with considerable mortality when it is unrecognized and untreated. Treatment targets the antibody (immune suppression with corticosteroids and urgent plasmapheresis) and restoring normal ADAMTS-13 activity (immediate plasma

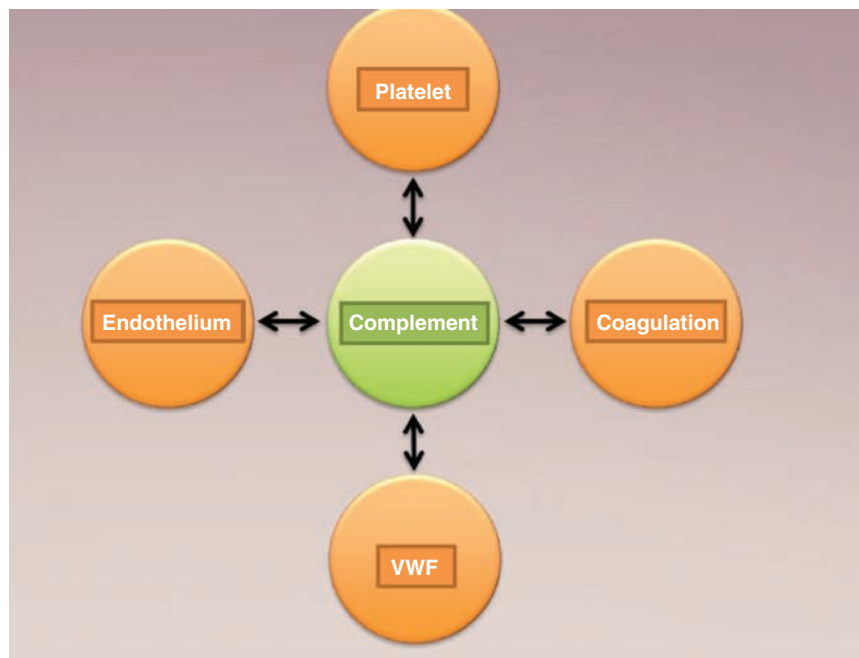

FIGURE 56-1 Cancer-associated thrombotic microangiopathies represent a pathophysiological nexus involving von Willebrand factor (VWF), platelets, the soluble coagulation system, perturbed vascular endothelium, and the complement system. Identifying and ranking the major predisposing and triggering elements is the clinical challenge that one must confront with each individual case.

infusion). Factors separate from ADAMTS-13 deficiency (eg, numerous infections) are involved in triggering the onset and relapse of TTP, suggesting that there is more than a single pathophysiological element driving the development of this TMA ⁽²¹⁾.

Complement-Mediated Thrombotic Microangiopathy

The aHUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal impairment. It is distinguished from typical hemolytic uremic syndrome by the absence of infection with Shiga-like toxin-producing bacteria ⁽²²⁾. The most common etiological element in both inherited and sporadic aHUS is a deficiency of the alternative complement pathway regulatory protein factor H. Factor H binds indirectly to endothelial surfaces and engages C3b, serving as an essential allosteric cofactor for C3b cleavage by factor I. Factor I cleavage of C3b shuts down the proteolytic cascade of complement activation, thereby preventing the formation of the membrane attack complex on intact vascular endothelium. In the absence of factor H, there is unregulated complement activation and deposition of the membrane attack complex on the vascular endothelium, leading to endothelial injury and its shift from an antithrombotic to a prothrombotic surface. The reason why the renal compartment is the primary target for thrombosis in aHUS is poorly understood, although one hypothesis is that the fenestrated endothelium of the glomerulus makes the kidney particularly vulnerable to complement attack ⁽²²⁾. The aHUS is treated with the anti-C5 antibody eculizumab.

Cross Talk Between von Willebrand factor, ADAMTS-13, and Complement

A story relevant to the pathogenesis of cancer-associated TMAs is rapidly developing: Recent data indicate that de novo TTP involves complement activation, and that aHUS involves abnormalities in the VWF/ADAMTS-13 axis ^(23, 24). Furthermore, mechanisms of cross talk between these two prototypical pathogenic elements have been identified and include direct interactions between factor H, VWF, and ADAMTS-13 ^(25, 26). These molecular interactions provide a conceptual framework from which to explore mechanisms of cancer-associated TMAs. Innovations in diagnosis and treatment will only become possible when pathogenic elements can be identified and their clinical significance elucidated and ranked.

Syndromes of Cancer-Associated Thrombotic Microangiopathy

There are rare but predictable clinical associations between TMA and some malignancies and their

treatments. These may provide general clarity about pathogenesis, and their recognition often provides a useful management strategy for patients with microangiopathic hemolytic anemia and thrombocytopenia, particularly when the TMA is due to a drug that can be replaced with an effective alternative agent.

Drugs

Several antineoplastic drugs have been repeatedly associated with TMA ⁽²⁷⁾. These include mitomycin C, gemcitabine, interferons, pentostatin, sunitinib, bevacizumab, oxaliplatin, and docetaxol. Also, TMA is predictably associated with drugs used routinely in the management of SCT: the calcineurin inhibitors cyclosporine and tacrolimus and the m-TOR inhibitors sirolimus and everolimus. End-organ injury, should it occur, mainly involves the kidneys and is reversible after stopping the drug ⁽²⁸⁾.

Hematopoietic Stem Cell Transplantation

Perhaps 25% of all recipients of SCT develop TMA ⁽²⁹⁾. Risk factors include conditioning programs (total body irradiation, busulfan, fludarabine, and platinum compounds); graft-versus-host disease; infections (especially *Aspergillus*, cytomegalovirus, and adenovirus); and medications (especially calcineurin inhibitors). The pathogenesis of post-SCT TMA focuses primarily on vascular endothelial injury (directly from drugs or irradiation or indirectly by inflammatory cytokines) as the trigger (see Fig. 56-1). Genetic or acquired abnormalities of the VWF/ADAMTS-13 axis or complement are theorized as predisposing factors that drive the development of overt TMA in susceptible individuals suffering a triggering event.

Diagnosis is based on scoring systems that have been weakly validated, only one of which includes acute renal failure, which is the primary and most threatening clinical consequence of post-SCT TMA ⁽²⁹⁾. Renal biopsy, while diagnostic, is rarely employed because comorbidities increase risks—especially bleeding—associated with it. Treatment with plasma exchange or any other active intervention is rarely effective, but discontinuing a calcineurin inhibitor can often arrest (and sometimes reverse) kidney injury. The long-term prognosis of post-SCT TMA is unfavorable; there is an increased risk of hypertension, chronic kidney disease, end-stage kidney disease, cardiac disease, and death.

Paraneoplastic Thrombotic Microangiopathy

Thrombotic microangiopathy may develop in patients with solid tumors. The most likely development pattern for patients is gastric > breast > prostate > lung > lymphoma > unknown primary cancer. Paraneoplastic TMA almost always develops in patients with

bone marrow metastases and can involve a DIC-like coagulation picture. It rarely involves any end-organ injury and appears to be treatable only with effective chemotherapy, although plasma infusion followed by plasma exchange (if needed because of TMA progression despite plasma infusion) is often employed along with anticancer therapy⁽³⁰⁾.

Summary

In patients with cancer, TMAs are a heterogeneous group of diagnoses, almost all of which have common clinical correlates and a final common pathway of microvascular thromboses that threaten or injure the kidneys. Dissecting established pathophysiological elements of de novo TTP (VWF and ADAMTS-13) and aHUS (complement over activity); putative pathophysiological elements of chemotherapy and post-SCT TMA (direct endothelial toxicity and cytokine “storms”); and vague pathophysiological elements of paraneoplastic TMA (myelophthisis and coagulation system activation) may someday allow clinicians to establish diagnostic criteria and treatments that are based on a hierarchy of pathophysiological factors driving each individual case.

VASCULAR SYNDROMES

Chemotherapy-Induced Thrombosis

A number of medications used to treat cancer have been documented to increase the risk of venous thromboembolic events. These are reviewed individually. It is worth noting, however, that the use of any chemotherapeutic agent has consistently been demonstrated to increase thrombotic risk. In 2008, Khorana et al developed a predictive model for chemotherapy-associated thrombosis. In their derivation cohort of 2,701 patients, 60 patients (2.2%) developed VTE; of these events, 75% of the VTEs occurred within the first two cycles of chemotherapy⁽³¹⁾. A 2009 review identified systemic chemotherapy as carrying a two- to sixfold increased risk of VTE⁽³²⁻³⁴⁾.

The most common oncologic medications that carry an increased risk of thrombosis include thalidomide and its derivatives when combined with steroids or chemotherapy; bevacizumab and other angiogenesis-inhibiting tyrosine kinase inhibitors (TKIs); L-asparaginase; and tamoxifen. Tamoxifen raises the risk of thromboembolic events particularly in the first 2 years of use; its procoagulant effect is amplified by coadministration with chemotherapy^(35,36). The 2011 meta-analysis of the Early Breast Cancer Trialists' Collaborative Group found a small but real increase in VTE, including fatal PE, in patients with estrogen

receptor-positive breast cancer treated with tamoxifen who were followed for 10 years. This risk was higher in patients over 55 years of age (14 fatal VTEs in 2,386 women >55 years treated with 5 years of tamoxifen and followed for 10 years versus 1 fatal VTE in 2,289 women >55 years who did not receive tamoxifen)⁽³⁷⁾. In a premenopausal patient with breast cancer, a history of VTE may be an indication to consider alternative antiestrogen therapy with ovarian suppression and an aromatase inhibitor.

Bevacizumab and other angiogenesis-inhibiting TKIs have been associated with an increase in arterial thrombotic events; there are mixed data on whether the risk of venous thrombotic events is also increased⁽³⁸⁾. Mechanistically, it is thought that these drugs disturb the endothelial lining of the vasculature, providing a nidus for thrombus formation. Given the risk for both thrombotic and hemorrhagic complications with these medications, prophylactic anticoagulation is not recommended.

Thalidomide and its derivatives (lenalidomide, pomalidomide) increase the risk of VTE when administered in combination with steroids or chemotherapy; the highest risk is when thalidomide is combined with doxorubicin. This is thought to be due to direct endothelial damage caused by both thalidomide and doxorubicin, in addition to alterations in the coagulation cascade⁽⁹⁾. Thalidomide alone does not raise the risk of VTE. Patients with multiple myeloma treated with combination therapy containing thalidomide have a risk of VTE approaching 20%. Therefore, pharmacologic VTE prophylaxis is indicated with aspirin, LMWH, or warfarin. The Myeloma Working Group has proposed a risk stratification model including factors such as obesity, recent surgery, history of VTE, and type of therapy to help determine which agent to use for VTE prophylaxis. Patients with no or one risk factor should receive aspirin (81 mg or 325 mg), and patients with two or more risk factors should receive LMWH (enoxaparin 40 mg subcutaneous daily)⁽³⁹⁾.

Myeloproliferative Neoplasm–Associated Thrombosis With Attention to Portal Vein Thrombosis and Budd-Chiari Syndrome

The Philadelphia chromosome-negative myeloproliferative neoplasms (Ph⁻ MPN), including polycythemia vera (PV), essential thrombocythosis (ET), and primary myelofibrosis (PMF), are clonal disorders of myeloid lineage stem cells associated with *JAK2*, *MPL*, or *CALR* mutations. These disorders carry an increased risk of both arterial and venous thrombotic events, as well as increased risk of hemorrhagic events. The mechanism of thrombophilia in Ph⁻ MPN is complex. Proposed factors include increased total volume of erythrocytes,

activated/adhesive platelets and erythrocytes, inflammation leading to endothelial damage, inhibition of anticoagulant pathways, and secretion of procoagulant factors⁽⁴⁰⁾. Thrombotic events contribute significantly to disease-specific morbidity and mortality, causing 45% of all disease-specific fatal events⁽⁴¹⁾. Venous thrombosis in an unusual location (ie, portal vein thrombosis [PVT]) may be the presenting symptoms of Ph⁻ MPN, and *JAK2* mutation testing should be strongly considered in a patient presenting with a first thrombosis in an unusual location.

A number of studies have sought to stratify patients with PV and ET into those with high- versus low-risk of thrombotic events, with conflicting results. Patients over age 60 or with a history of thrombosis are considered high risk. High-risk patients should be managed with low-dose aspirin, phlebotomy to a goal hematocrit of less than 45%, and cytoreduction with hydroxyurea or interferon alpha to normalize platelet count (for ET) or if phlebotomy alone is unable to produce the target hematocrit level (for PV)⁽⁴²⁾. Additional factors to be considered in evaluating the individual patient include *JAK2* mutation status and allele burden, leukocytosis, inflammatory markers, and any history of bleeding, particularly the presence of an acquired von Willebrand syndrome. Traditional risk factors for arterial and venous thrombotic events (smoking, hyperlipidemia, and diabetes and immobility, respectively) should be managed aggressively⁽⁴³⁾. The role of ruxolitinib and other *JAK* inhibitors in the prevention of thrombotic events is uncertain at this time.

Management of the acute VTE in a patient with Ph-MPN includes anticoagulation with LMWH, heparin, fondaparinux, warfarin, or a new oral anticoagulant (NOAC); LMWH is the preferred agent. The duration of anticoagulation remains controversial; a minimum of 3 to 6 months is required, with longer duration to be guided by the clinician's estimate of risk of recurrence. Risk of recurrence is influenced by MPN disease burden, advanced age, and prior history of VTE. Bleeding complications must also be considered. If the decision is made to continue anticoagulation beyond 3 to 6 months, the risk and benefit of anticoagulation should be reassessed frequently. Aggressive management of the MPN, with attention to achieving goal complete blood cell count values, is an integral component of the management of VTE in the patient with MPN. Concurrent use of anticoagulation and antiplatelet therapy increases the risk of bleeding events⁽⁴⁴⁾. After VTE, monotherapy with an antiplatelet agent reduces the risk of both recurrent venous and arterial events; therefore, a reasonable course of action for the patient with MPN and a new VTE is 3 to 6 months of LMWH followed by long-term low-dose aspirin with optimal cytoreduction. Patient-specific factors

(a life-threatening VTE or life-threatening bleeding) must always be considered.

As noted, the diagnosis of MPN may be heralded by development of a VTE in an unusual location, including the portal vein or the hepatic vein; the latter may result in venous congestion and hepatocyte damage (Budd-Chiari syndrome). The management of portal vein thrombosis (PVT) is dictated by the acuity of the thrombus. Acute PVT, in which symptoms precede the diagnosis of PVT by less than 60 days and there is no evidence of cirrhosis, is managed with therapeutic anticoagulation. The diagnosis is made with abdominal ultrasound, which has a 98% negative predictive value⁽⁴⁵⁾. Chronic PVT, and patients with PVT and cirrhosis, should not be anticoagulated as the likelihood of recanalization of the blood vessel in this setting is low, and the sequelae of PVT-related portal hypertension (gastric and esophageal varices) increase the risk of life-threatening bleeding with anticoagulation. Making the diagnosis of MPN at the time of chronic PVT diagnosis may be hindered by portal hypertension causing gastrointestinal blood loss or hypersplenism resulting in platelet sequestration, falsely suppressing hematocrit and platelet levels; a high index of suspicion is required.

Budd-Chiari syndrome can be classified as fulminant, acute, sub-acute or chronic. Unless there are clear contraindications, anticoagulation should be started promptly upon diagnosis and continued indefinitely. Although a stepwise approach is warranted with medical management alone first, a number of interventions for patients with MPN-associated Budd-Chiari syndrome are available including endovascular stenting, transjugular intrahepatic portosystemic shunt (TIPS procedure), and even orthotopic liver transplant for patients with good-prognosis ET and PV⁽⁴⁶⁾.

Trousseau's Syndrome

Trousseau's sign is the appearance of superficial thrombophlebitis heralding the diagnosis of malignancy, named after the French physician Armand Trousseau, who noted the phenomenon in 1865. Trousseau's syndrome is used more broadly to describe the hypercoagulable state associated with malignancy. The pathogenesis of Trousseau's syndrome is multifactorial and likely to involve all three components of Virchow's triad (stasis of blood flow, activation of the coagulation cascade, and damage to endothelial cells of the blood vessel)^(47, 48). Mouse models of *MET* oncogene-driven hepatocellular carcinoma have demonstrated a relationship between *MET*-driven malignancies and the development of a thrombohemorrhagic phenotype similar to Trousseau's syndrome, mediated by cyclooxygenase-2 (COX-2) and plasminogen activator type 1 (PAI-1) genes⁽⁴⁹⁾.

ARTERIAL THROMBOSIS

The management of patients with malignancy-associated thrombocytopenia and acute coronary syndrome (ACS) poses a unique challenge; the cardioprotective effect of antiplatelet agents must be balanced with the increased risk of bleeding. A retrospective analysis of 70 patients demonstrated marked improvement in seven-day survival in patients with ACS and thrombocytopenia who received aspirin. Patients with ACS and thrombocytopenia who received aspirin had a 90% survival rate at seven-days, compared with only 6% for those with ACS and thrombocytopenia who did not receive aspirin ($P < 0.0001$). Platelet counts in the thrombocytopenic group ranged from 4,000 to 100,000, and no major bleeding events (defined as major gastrointestinal bleeding, intracranial bleeding, or fatal bleeding) were reported⁽⁵⁰⁾. In an appropriately monitored setting and in the absence of clear contraindications, aspirin should not be withheld from the patient with malignancy-associated thrombocytopenia and acute coronary syndrome.

THE NEED FOR PALLIATIVE CARE

Despite significant progress in our understanding of cancer biology and the development of novel therapeutics, most patients with advanced cancer still die of their disease (¹). In addition to the significant mortality, cancer contributes to significant morbidity for cancer patients and their families.

The growth of cancer can result in multiple symptoms by direct invasion, obstruction, compression, inflammation, effusions, and paraneoplastic syndromes. Moreover, cancer predisposes patients to various complications, such as infections, bleeding, thrombosis, and fractures. Cancer treatments such as surgery, radiation, chemotherapy-targeted agents, and immunotherapy can also cause multiple adverse effects involving the cardiac, pulmonary, gastrointestinal, hematologic, musculoskeletal, neurological, endocrine, and dermatologic systems. Living with cancer also means that patients not only have to face their own mortality but also have to deal with many psychosocial stresses related to the uncertainties along the disease trajectory. They have to cope with changes in their bodily function, body image, ability to engage in daily activities, and family dynamics. Finally, many patients and families express significant existential issues and financial concerns. Taken together, the direct cancer effects, cancer treatments, and psychosocial issues all contribute to a large number of physical and psychological symptoms, resulting in a decrease in quality of life and increase in caregiver burden (²).

The literature has consistently demonstrated that cancer patients, particularly those with advanced

disease, experience an average of 8 to 12 symptoms (^{3,4}), suggesting that many symptoms are underrecognized, underdiagnosed, and undertreated. In addition to physical, psychological, and existential concerns, patients and families often have informational and decision-making needs (⁴).

Over the past few decades, palliative care has matured as a discipline that specializes in addressing the multidimensional care needs of patients and their families. Palliative care

is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual. ... Palliative care is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications. (⁵)

The key domains of palliative care include the following: building relationships and rapport, assessing and managing symptoms, addressing coping, establishing illness understanding, discussing cancer treatments, discussing end-of-life planning, and engaging family members (⁶).

Multiple studies have demonstrated improved patient outcomes associated with palliative care. In a meta-analysis, Higginson et al found that palliative care was associated with a significant improvement

in pain (odds ratio [OR], 0.38; 95% CI, 0.23-0.64) and other symptoms (OR, 0.51; CI, 0.30-0.88) (⁷). Recent randomized controlled trials also demonstrated that palliative care involvement was associated with improvement in health-related quality of life compared to routine oncologic care (^{8,9}). Evidence also supports the role of palliative care in enhancing patient satisfaction (¹⁰) and caregiver satisfaction (¹¹). Through facilitating end-of-life discussions, providing spiritual care, and offering an alternative to aggressive care, palliative care also contributes to improved quality of end-of-life care (¹²⁻¹⁴). This in turn leads to a reduction in the cost of care in the last days of life (¹⁵).

Setting of Palliative Care

Specialist palliative care is provided in four care settings: inpatient consultation teams, acute palliative care units, outpatient clinics, and community-based palliative care. Inpatient consultation teams represent the backbone of palliative care in the United States, with 92% of cancer centers designated by the National Cancer Institute (NCI) and 74% of non-NCI-designated cancer centers reporting their presence (¹⁶). Acute palliative care units provide intensive symptom control for patients and families in severe distress and facilitate transition of care (¹⁷⁻¹⁹). The mortality rate varies widely, but the average is approximately 30% (²⁰). Outpatient clinics are present in 59% of NCI-designated cancer centers and in 22% of non-NCI-designated cancer centers (¹⁶). They are key to early palliative care access and provide longitudinal supportive care concurrent with active cancer treatments (²¹). There is growing emphasis to increase the availability of these programs. Finally, the community branch of palliative care is tailored for patients as they approach the end of life (ie, 6 months or less) (²²), when they often have decreased ability to travel back and forth to the hospital. These individuals may benefit from outreach by the palliative care team in the form of home palliative care or a transition to home-based or inpatient hospice programs.

Evidence to Support Early Palliative Care

In the 1990s, several first-generation randomized controlled trials compared palliative care interventions to usual care; however, they did not consistently demonstrate improved outcomes (²³⁻²⁵). A systematic review revealed significant methodological limitations among these studies, such as contamination, underpowered sample size, attrition, and poor adherence (¹¹). The variable timing of introduction of palliative care, the lack of standardization of palliative care programs, the heterogeneous study duration, and the inconsistent outcome measures all made it difficult to clearly

identify the intervention effect associated with palliative care.

Over the past decade, second-generation studies with improved designs have provided more evidence to support not only the need for specialist palliative care but also the early involvement for patients with advanced cancer. We review the key studies supporting involvement of palliative care early in the disease trajectory.

Temel et al conducted a landmark randomized controlled trial involving 151 patients with stage IV non-small cell lung cancer comparing routine oncology care with or without early palliative care referral (⁸). Patients were eligible if they were within 8 weeks of diagnosis of metastatic cancer and had an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 2. Early palliative care involvement was associated with significant improvement in the primary outcome Trial Outcome Index in the Functional Assessment of Cancer Therapy-Lung (FACT-L) scale at 12 weeks (59 vs 53, $P = .009$). The secondary outcomes, including the Lung Cancer Subscale (21 vs 19, $P = .04$); FACT-L total score (98 vs 92, $P = .03$); Hospital Anxiety and Depression Scale (HADS) depression (16% vs 39%, $P = .01$); Patient Health Questionnaire 9 (PHQ-9) (4% vs 17%, $P = .04$); aggressive end-of-life care (33% vs 54%, $P = .05$); documentation of resuscitation preferences (53% vs 28%, $P = .05$); and overall survival (11.6 months vs 9.8 months; hazard ratio 0.59, $P = .01$) also improved significantly. Largely based on this study, the American Society of Clinical Oncology published a provisional clinical opinion in 2012 supporting the integration of palliative care into standard oncologic care (²⁶).

Bakitas et al examined the effect of a nurse-led palliative care intervention in a randomized controlled trial (⁹). A total of 322 patients within 8 to 12 weeks of their diagnosis of advanced lung, gastrointestinal, genitourinary, or breast cancer were randomized to the intervention arm or usual care arm. Specifically, the study intervention was led by advanced practice nurses and consisted of four structured educational and problem-solving sessions followed by monthly telephone follow-up sessions addressing various aspects of care, such as symptom management, crisis prevention, communication strategies, advance care planning, and timely referral to palliative care and hospice teams. Over time, palliative care was associated with a significant improvement in health-related quality of life (Functional Assessment of Chronic Illness Therapy for Palliative Care [FACIT-PC], $P = .02$), depression (Center for Epidemiological Studies Depression Scale [CES-D], $P = .03$). However, symptom burden (Edmonton Symptom Assessment Scale [ESAS], $P = .06$), resource use at the end of life (intensive care unit admission, $P > .99$; emergency room visits, $P = .53$), and palliative care team referral ($P = .32$) were not significant different between the intervention and control groups. Because

the study intervention was primarily nursing based, the lack of involvement of other disciplines, such as medicine, may have contributed to the lack of a significant difference in some observed outcomes.

Zimmermann et al randomized, using a cluster randomized design, 461 patients in 24 medical oncology clinics to either early involvement of palliative care or routine oncology care (¹⁰). Unlike the two previous clinical trials that enrolled patients from time of diagnosis, patients in this study had stage III/IV lung, gastrointestinal, genitourinary, breast, or gynecological cancer with an estimated survival of 6-24 months. The primary outcome, Functional Assessment of Chronic Illness Therapy–Spiritual Well-Being (FACIT-Sp) at 3 months, improved in the early palliative care arm (1.6) and decreased in the control arm (–2.0), although the difference was not statistically significant (3.6, $P = .07$). At 4 months, a significant improvement was observed (2.5 vs –4.0, difference = 6.4, $P = .006$). Secondary outcomes also favored early palliative care by 4 months, including Quality of Life at the End of Life (QUAL-E) scale (3.0 vs –0.5, difference = 3.5, $P = .003$), symptom burden measured by the ESAS (–1.3 vs 3.2, difference = –4.4, $P = .05$), and patient satisfaction with care assessed by FAMCARE-P16 (3.7 vs –2.4, difference = 6.0, $P < .0001$). The median survival in the early palliative care arm was 340 days, suggesting that these patients accessed palliative care relatively early in the disease trajectory.

Because the studies mentioned compared early palliative care to routine oncologic care, it was unclear if late palliative care was as effective as early palliative care. This question was partly addressed in a recent retrospective cohort study examining the quality of end-of-life care indicators in the last 30 days of life

among patients who died of advanced cancer at MD Anderson Cancer Center (¹⁴). Patients referred to palliative care 3 months or more before death had significantly lower rates of emergency room visits (39% vs 68%, $P < .001$), hospital admission (48% vs 81%, $P < .001$), and hospital death (17% vs 31%, $P = .004$) compared with a patient seen by the same palliative care team less than 3 months before death. Similar differences were also reported using 6 months as the cut-off. Moreover, outpatient palliative care consultation was associated with significantly improved outcomes compared with inpatient palliative care consultation (Table 57-1). In multivariate analysis, improved quality of end-of-life care was associated with female gender (OR, 1.63; $P = .027$), palliative care outpatient referral (OR, 2.4; $P < .001$), and nonhematologic malignancies (OR, 2.6; $P = .02$).

Taken together, these studies suggest that early outpatient palliative care is associated with improved health-care outcomes. Table 57-2 summarizes some key questions related to palliative care delivery.

Access to Palliative Care

The delivery of palliative care can be categorized as primary, secondary, and tertiary (^{27, 28}). Primary palliative care is the provision of basic symptom management and psychosocial care by oncology teams and primary care clinicians. Because these clinicians see patients in the frontline setting, it is crucial that they are all equipped with core palliative care competencies. Secondary palliative care refers to consultation services provided by interdisciplinary specialist palliative care teams. Often, patients have more complex supportive care needs, such as severe pain not relieved

Table 57-1 Outpatient Palliative Care Consultation Is Associated With Improved Quality of End-of-Life Care^a

Within the Last 30 Days of Life	Outpatient Referral, n = 169 (%)	Inpatient Referral, n = 199 (%)	P Value
Any emergency room visit	80 (48)	135 (68)	<.001
2 or more emergency room visits	18 (11)	51 (26)	<.001
Any hospital admission	87 (52)	171 (86)	<.001
2 or more hospital admissions	17 (10)	47 (24)	.001
More than 14 days of hospitalization	14 (8)	40 (20)	.002
Hospital death	30 (18)	67 (34)	.001
Any ICU admission	7 (4)	28 (14)	.001

Table 57-2 The Delivery of Palliative Care

Question	Answer
Who should receive palliative care?	According to the National Comprehensive Cancer Network guideline, all patients with significant physical, psychological, social, or spiritual concerns should be considered for referral to a palliative care team. Additional triggers include comorbidities, caregiver distress, and professional distress ⁽⁴⁹⁾ .
When should palliative care be provided?	The literature supports early introduction of palliative care from the time of diagnosis of advanced cancer.
Who should deliver palliative care?	All oncologists and primary care teams should be prepared to provide core palliative care skills. At the same time, specialized interdisciplinary palliative care teams should be available to provide further support and guidance, particularly for patients with significant distress.
How should palliative care be delivered?	Comprehensive palliative care interventions, including outpatient and inpatient components, should be used.
Where should patients receive palliative care?	Outpatient palliative care facilitates early involvement and is ideal for initial consultation and longitudinal follow-up. Inpatient palliative care is appropriate for hospitalized patients who are acutely ill. Community-based palliative care is particularly helpful for patients who are too frail to make repeated visits to the hospital.

by first-line strong opioids. A growing number of countries, such as the United Kingdom, the United States, and Canada, have formal board accreditation for palliative medicine ⁽²⁹⁾. Tertiary palliative care denotes the situation when palliative care becomes the primary coordinating team. For example, patients admitted to acute palliative care units are followed by tertiary palliative care teams. Tertiary palliative care teams are often actively involved in education and research.

In delivering primary palliative care, oncologists generally feel the need for their active involvement in the provision of symptom management and supportive care ⁽³⁰⁾. A 1998 survey of 3,227 medical, radiation, surgical, and pediatric oncologists revealed that 90% learned palliative care by trial and error. A majority also reported that they had inadequate coaching in discussing prognosis and symptom control ⁽³¹⁾. In another survey of 895 medical oncologists in Europe, only 36% agreed that a palliative care specialist is the best person to coordinate palliative care of patients with advanced cancer; however, only 37% reported that most medical oncologists they know are expert in symptom management ⁽³⁰⁾. A more recent survey of US oncology trainees showed they still received limited core palliative care training, with less than half reporting having explicit training in the management of depression at the end of life and opioid rotation ⁽³²⁾. To date, only approximately 25% of oncology fellows have routine palliative care rotations ^(16,32). To enhance the level of primary palliative care delivery, oncology fellowships should incorporate a greater degree of didactic and clinical training related to palliative care, ideally with role modeling and clinical rotations. Recognizing this important gap in knowledge, multiple organizations, such as the American Society of Clinical Oncology (ASCO) and the European Society of

Medical Oncology (ESMO), are taking active measures to increase the level of core palliative care skills among oncology professionals through conferences, continuing medication education, and web-based learning ⁽³³⁾.

For secondary and tertiary palliative care, access to specialized teams can be measured in several ways: (1) What is the level of availability of palliative care in cancer centers? (2) Among cancer centers that offer palliative care programs, how many patients with advanced cancer see palliative care before they die? (3) Among patients who have had a palliative care consultation, when was the time of referral?

Although most US cancer centers reported having a palliative care service, the infrastructure of these programs varied widely, ranging from a single nurse practitioner to a comprehensive interdisciplinary team ⁽³⁴⁾. Cancer center executives, particularly in NCI-designated cancer centers, generally supported the expansion of palliative care in their centers. On a global scale, the development of palliative care has recently been outlined in the Worldwide Hospice Palliative Care Alliance (WPCA) Global Atlas of Palliative Care, demonstrating higher level of development in developed nations and areas for improvement in developing nations ⁽³⁵⁾.

The proportion of cancer patients who had palliative care consultations is another measure of access, although the denominator is not easily defined because not all patients may benefit from palliative care. We examined the timing of referral for patients who died of advanced cancer at MD Anderson Cancer Center during a 6-month period and found that only 366 of 816 (45%) had a palliative care consultation ⁽³⁶⁾. The percentage of referral varied significantly among tumor types. Over 60% of patients with gynecology malignancies had a palliative care consultation before death compared to only slightly over 30% in patients

with hematologic malignancies. Older patients and those who were married were more likely to have a referral ⁽³⁶⁾. The timing of palliative care referral was also examined in this study. A majority of patients were referred to palliative care late in the disease trajectory, ranging from 1 to 2 months before death for patients with solid tumors to 0.4 months before death for hematologic malignancies ⁽³⁶⁾. In a US national survey, the median time from referral to death was 90 days for outpatient palliative care clinics and 7 days for inpatient palliative care programs ⁽¹⁶⁾.

Overcoming Barriers to Palliative Care Access

Despite the evidence to support early palliative care, there remain significant barriers to accessing specialist palliative care. These barriers can be categorized as oncology team–related barriers, patient-related barriers, and health-care system–related barriers (Table 57-3) ⁽³⁶⁻³⁹⁾. In particular, the lack of emphasis of supportive care needs and the stigma associated with palliative care represent barriers common to both patients and oncology teams. A number of interventions, such as routine symptom screening, use of the goals of car analogy (discussed further in the chapter), and name change to supportive care may facilitate early palliative care access early in the disease trajectory.

To increase the awareness of supportive care needs, routine symptom screening using validated questionnaires in the oncology setting is essential. The ESAS examines 10 symptoms (pain, fatigue, nausea, depression, anxiety, drowsiness, appetite, well-being,

dyspnea, and sleep). The intensity of each symptom is documented using a one-item numeric rating scale that ranges from 0 to 10 (0 is no symptom, 10 is worst possible intensity) ^(40, 41). Other symptom batteries include the Memorial Symptom Assessment Scale and Palliative Care Outcome Scale ^(42, 43). Routine symptom screening allows the oncology team to obtain patient-reported outcomes, which would help bring significant symptoms to their attention that would otherwise be missed. Once symptoms are identified, the oncology team may initiate treatments or make a referral to specialist palliative care. Repeat screening in future visits allows symptoms to be monitored longitudinally and symptom response to be assessed ⁽⁴⁴⁾.

Another approach to increase the awareness of supportive care needs is to educate patients using the analogy of the goals of the use of a car (Fig. 57-1) ⁽⁴⁵⁾. Some patients focus on seeking cancer treatments and do not want to worry about addressing their supportive care issues, such as symptom management, psychological distress, and advance care planning. This is similar to a hopeful and unrealistic driver who only wants to get to the destination without worrying about the potential hazards on the road and the possibility of accidents. In contrast, a hopeful and realistic driver knows the need to prepare for the road trip ahead—seat belts, insurance policies, suspensions, and cushions are essential to help arrive at the destination comfortably and safely. Because patients with advanced cancer inevitably develop symptom burden along the disease trajectory, it is important for the hopeful and realistic patient to maximize supportive care while receiving cancer treatments. Optimal supportive care would help to maximize symptom control and function, which may

Table 57-3 Barriers to Palliative Care Referral

Types of Barriers	Examples
Oncology team related	<ul style="list-style-type: none"> • Oncology professionals' perception that they should be the team providing most of the supportive care to their patients • Oncology professionals' misconception that palliative care should only be delivered late in the disease trajectory • Stigma associated with palliative care (a referral denotes hopelessness) • Lack of routine symptom screening leads to lack of recognition of supportive care needs • Lack of time to discuss palliative care referral
Patient related	<ul style="list-style-type: none"> • Unaware that palliative care is available as a service • Misconception that palliative care should only be received late in the disease trajectory • Stigma associated with palliative care (a referral denotes hopelessness) • Unwillingness to discuss symptom burden to maximize chances to receive cancer treatments • Lack of time to discuss symptom concerns • Financial constraints (eg, insurance copay, transportation, parking)
Health-care system related	<ul style="list-style-type: none"> • Lack of resources to support palliative care teams • Fragmentation of health-care system means patients with supportive care needs receive heterogeneous referral • Financial barriers for patients (eg, parking, transportation)

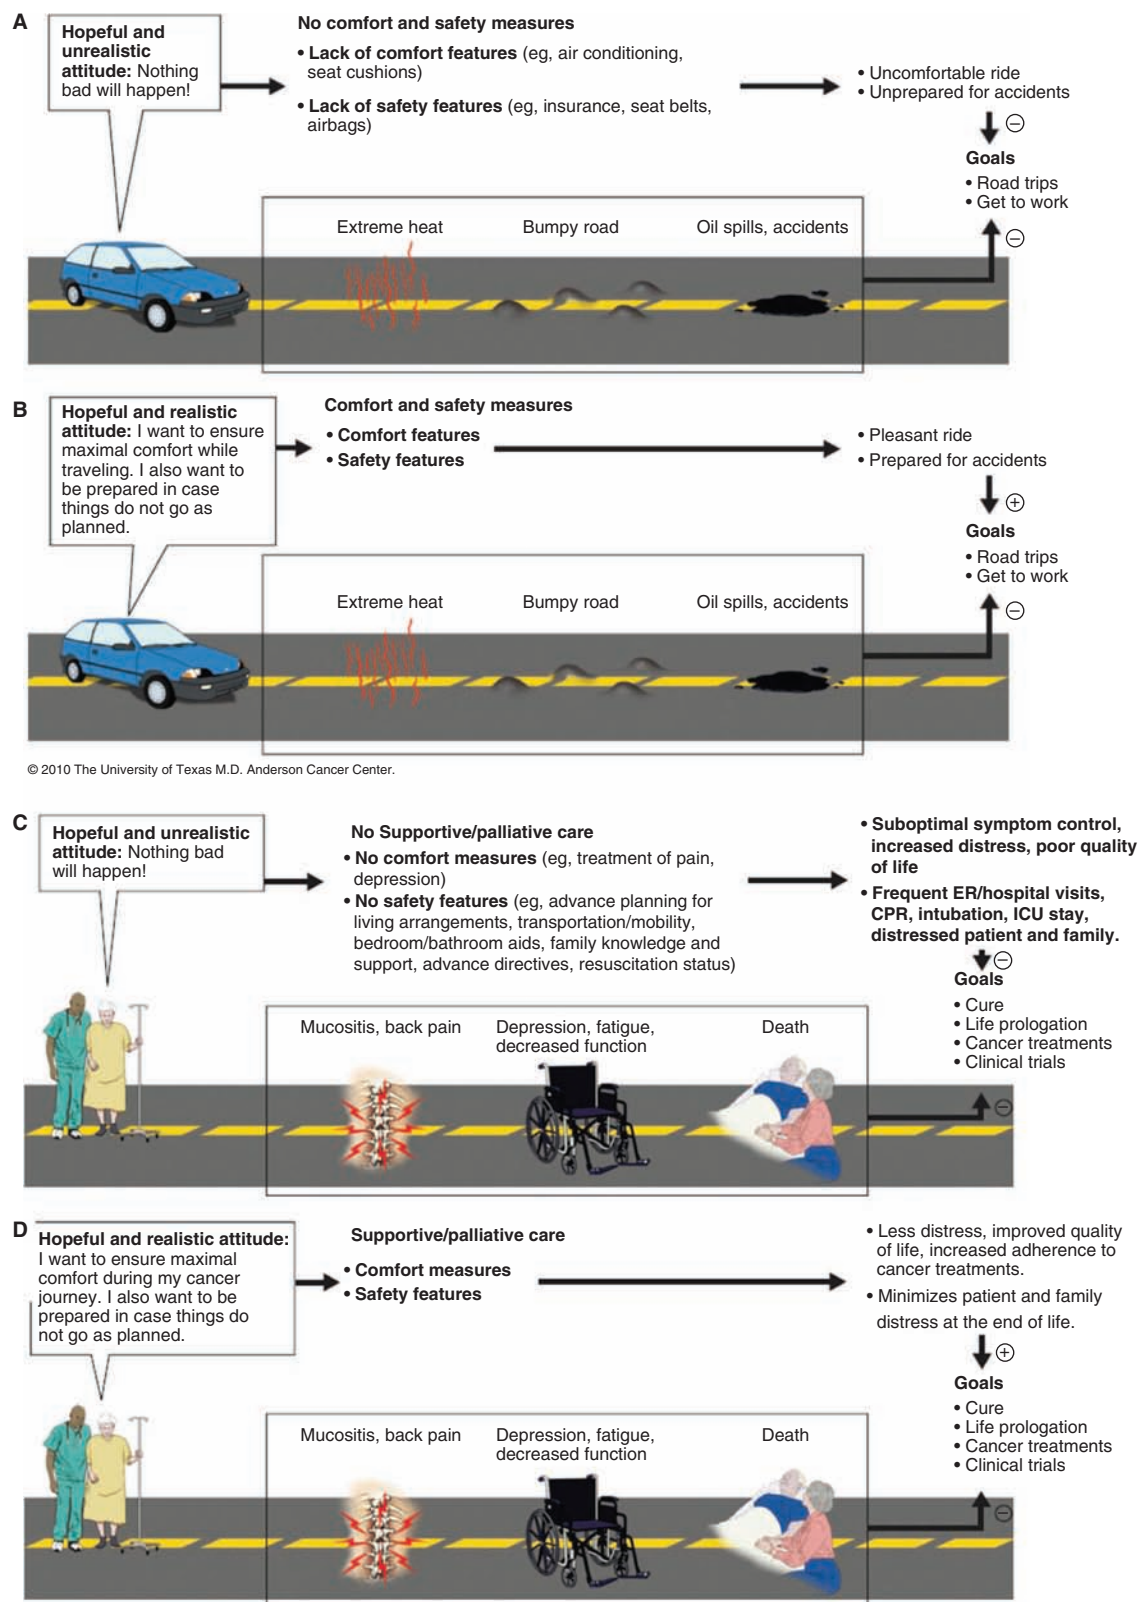

FIGURE 57-1 Goals of care. The use of a car is an analogy for setting goals of care. (A). A hopeful and unrealistic driver wishes that nothing bad will happen on the road. This is in contrast to (B), the hopeful and realistic driver who knows the importance of comfort measures and of being prepared for the trip ahead. (C). A hopeful and unrealistic patient focuses on cancer cure and life-prolongation measures without paying attention to her symptoms and advance care needs. This results in unnecessary distress for patients and families. This is in contrast to (D), a hopeful and realistic patient, who has the same goals for cancer control but is better equipped to manage symptoms and prepared for crisis because of the concurrent use of supportive/palliative care. Table 57-4 Perception of the Names Palliative Care and Supportive Care^a

Perception	Supportive Care, n (%)	Palliative Care, n (%)	P value
Service name is a barrier for me to refer patients	9 (7)	32 (23)	<.0001
Service name is synonymous with hospice and end of life	21 (15)	78 (57)	<.0001
Service name can decrease hope in patient and families	15 (11)	61 (44)	<.0001
Service name is associated with treatment of chemotherapy side effects	85 (61)	20 (15)	<.0001

^aAdapted with permission from Fadul N, Elsayem A, Palmer JL, et al. Supportive versus palliative care: what's in a name?: a survey of medical oncologists and midlevel providers at a comprehensive cancer center, *Cancer* 2009 May 1;115(9):2013-2021.

help in tolerating cancer treatments and deriving a treatment response.

Because palliative care is often felt to be synonymous with hospice care and end-of-life care, many clinicians and patients may have the impression that palliative care is not compatible with early referrals. To overcome this misconception, the term *supportive care* has been proposed to facilitate early palliative care referral. Supportive care is defined as “the provision of the necessary services for those living with or affected by cancer to meet their informational, emotional, spiritual, social or physical needs during their diagnostic, treatment, or follow-up phases encompassing issues of health promotion and prevention, survivorship, palliation and bereavement”⁽²⁸⁾. Thus, palliative care is, by definition, supportive care for patients with advanced diseases. We previously conducted a survey of oncology specialists at our cancer center to examine clinicians’ beliefs toward the palliative care and supportive care. Compared to supportive care, oncology specialists were significantly more likely to feel that the service name palliative care decreases hope in patients and families, is synonymous with hospice and end of life, and is a barrier for referral (Table 57-4)⁽⁴⁶⁾. This led our program to change its name from Palliative Care to Supportive Care in 2007. We found an increased number of referrals and earlier referral among outpatients after the name change, supporting the hypothesis that supportive care facilitates palliative care access (Table 57-5)⁽⁴⁷⁾.

Finally, it is important to help oncologists understand how integration of palliative care with oncology can help them care for their patients. The everyday oncology practice consists of management of cancer, such as diagnosis, staging, and treatment decisions, as well as management of supportive care issues such as pain, fatigue, anxiety, and care planning. There are three approaches to address these increasingly complex issues (Fig. 57-2). In the solo practice model, the oncologist manages all the issues. Because of lack of time to conduct routine symptom screening, inability to keep up with the growing literature on supportive care, and absence of an interdisciplinary team, those in solo practice may not provide the optimal level of supportive care. In the congress model, the oncologist focuses on cancer-related issues and involves many different services, each focusing on one particular aspect of supportive care. This could potentially result in fragmentation of care, sometimes-conflicting recommendations, and added care costs. In the integrated care model, the oncologist addresses cancer management and involves the supportive/palliative team early in the disease trajectory. Patients thus would receive timely and comprehensive supportive care. A study showed that consultation to palliative care saves the oncologist on average 170 minutes of patient encounter⁽⁴⁸⁾.

In summary, cancer patients experience significant symptom burden and have information and decision-making needs. Palliative care is now an accredited

Table 57-5 Growth in New Patient Activity Before and After Name Change^a

Program	Before Name Change (January 1, 2006, to August 31, 2007), n	After Name Change (January 1, 2008, to August 31, 2009), n	% Change
Supportive care program	1,950	2,751	41%
Division of Cancer Medicine	17,009	21,325	25%
Hospital overall	58,540	66,608	14%

discipline that addresses these issues to improve patients' quality of life. There is a growing body of evidence to support that early referral to palliative care improves patient outcomes, including symptom control, quality of life, quality of end-of-life care, patient and caregiver satisfaction, and possibly survival. However, there remain many barriers to palliative care access. Innovative models and approaches are needed to overcome these barriers and to maximize patient outcomes.

Pain Management and Symptom Control

Kaoswi Shih
Rony Dev
Suresh K. Reddy

INTRODUCTION

Cancer is frequently associated with a host of distressing physical and psychosocial symptoms that can occur throughout the disease trajectory (¹). Access to a multidisciplinary supportive care service is imperative for patients with cancer experiencing distressing symptoms, including fatigue, pain, anorexia, nausea, dyspnea, anxiety, depression, and weight loss, to improve the quality of life of patients. Without optimal symptom control, administration of anticancer therapies may be delayed or discontinued (Table 58-1).

CANCER PAIN

Uncontrolled pain has been reported by 42% of patients seen in the outpatient cancer center (¹) and 50% of hospitalized patients with cancer (²). Pain was the most common symptom (82%) among patients with cancer referred to a palliative care service (³). In patients with cancer, pain may be the only symptom present prior to diagnosis and can indicate the recurrence or spread of the disease.

As many as 30% to 50% of patients receiving active anticancer therapy experience pain (¹). Pain resulting from the tumor burden occurs in approximately 65% to 85% of patients with advanced cancer (⁴). In addition, treatment-related pain is reported by approximately 15% to 25% of patients, and 3%-10% of patients with cancer develop chronic nonmalignant pain syndromes similar to the general population

(eg, low back pain associated with degenerative disk disease).

Pathophysiology

The pathophysiologic classification of pain forms the basis for therapeutic choices. Pain may be broadly divided into those associated with ongoing tissue damage (nociceptive) and those resulting from nervous system dysfunction (neuropathic). Nociceptive pain can be classified as either somatic or visceral and results from the activation of nociceptors in cutaneous or deep tissues. Nociceptive pain is described by patients as localized aching, throbbing, and gnawing discomfort. Visceral pain is the result of activation of nociceptors resulting from distention, stretching, and inflammation of internal organs. It is often poorly localized discomfort, described as a deep aching or cramping or a pressure-like sensation. An example of visceral pain is abdominal pain due to pancreatic cancer. Breakthrough pain is defined as a transitory exacerbation of discomfort that occurs on a background of stable persistent chronic pain. Causes of breakthrough pain include end-of-dose failure of opioids and pain exacerbation by activity or spontaneous occurrence. Breakthrough pain is also characterized by a short duration, often less than 3 minutes in 43% of cases according to previous prospective surveys (⁵).

Classification of pain can help guide selection of appropriate interventions to improve pain control; however, they have not been universally accepted. Pain mechanism, incidental occurrences, psychological distress, addictive behavior, and cognitive dysfunction

Table 58-1 Symptoms in Advanced Cancer^a

• Pain (80%-85%)
• Fatigue (90%)
• Weight loss (80%)
• Lack of appetite (80%)
• Nausea, vomiting (80%-90%)
• Anxiety (25%)
• Shortness of breath (50%)
• Confusion/agitation (80%)

have been indicated as factors associated with higher ratings of pain intensity (⁶). The revised Edmonton Classification System for Cancer Pain (Fig. 58-1) characterizing these factors has been used at our institution to guide pain management.

Pain Assessment

Pain can be measured by using visual, analogue, verbal, or numerical scales and, in the research setting, complex pain questionnaires (⁷). The Edmonton Symptom Assessment Scale is a useful assessment tool that allows patients to rate pain between 0 and 10 over the past 24 hours, where 0 signifies no pain and 10 is the worst pain imaginable. Effective pain assessments can be converted into graphic displays of pain and incorporated with other symptoms, allowing quick dissemination of information regarding a patient’s symptom burden to all health-care providers (Fig. 58-2). Pain assessment needs to take into account other symptoms experienced by patients with cancer because they are often are interconnected.

In 1984, the World Health Organization (WHO) proposed an analgesic ladder for the pharmacologic management of cancer pain (⁸) and has shown that the simple principle of escalating from nonopioid to strong opioid analgesics is safe and effective (Fig. 58-3). Other guidelines have been published, such as the Analgesic Quantification Algorithm and National Comprehensive Cancer Network guidelines for treating cancer pain (⁹).

Principles of Management

- Assess pain syndromes and other symptoms accurately.
- Respect and accept the complaint of pain as real.
- Treat pain appropriately.
- Treat underlying disorders.
- Address psychosocial concerns.
- Multidisciplinary approach is essential.

1. Mechanism of pain	No Nc Ne	No pain syndrome Nociceptive pain Neuropathic pain with or without nociceptive pain
	Nx	Insufficient information to classify
2. Incident pain	Io li	No incident pain Incident pain Present
	Ix	Insufficient information to classify
3. Psychological distress	Po Pp Px	No psychological distress Psychological distress present Insufficient information to classify
4. Addictive behavior	Ao Aa Ax	No addictive behavior Addictive behavior present Insufficient information to classify
5. Cognitive function	Co Ci Cu Cx	No cognitive impairment Partial cognitive impairment ¹ Total cognitive impairment ² Insufficient information to classify

¹Sufficient impairment to affect patients ability to provide accurate present and/or past pain history.
²Patient unresponsive, delirious, or demented to the stage of being unable to provide and present and past pain history.

FIGURE 58-1 Edmonton System of Classification for Cancer Pain.

PHARMACOTHERAPY

Principles of Pharmacotherapy

- Match the drug to the pain syndrome.
- Low threshold to prescribe opioids for cancer pain.
- Use sustained-release formulations for constant, chronic pain and short acting for breakthrough discomfort.
- Use adjunct medications for certain pain syndromes.
- Use an oral route for analgesics if possible.
- Use an intravenous route for acute titration.

No Pain	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Pain
No Fatigue	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Fatigue
No Nausea	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Nausea
No Depression	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Depression
No Anxiety	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Anxiety
No Drowsiness	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Drowsiness
No Shortness of Breath	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Shortness of Breath
Best Appetite	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Appetite
Best Sleep	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Sleep
Best Feeling of Well-Being	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Feeling or Well-being
No Financial Distress	0	1	2	3	4	5	6	7	8	9	10	Worst Financial Distress
No Spiritual Pain	0	1	2	3	4	5	6	7	8	9	10	Worst Spiritual Pain
Completed By:	Patient			Family								

0 = No Symptom; Best 10 = Worst Imaginable on average in the past 24 hours

FIGURE 58-2 Edmonton Symptom Assessment Scale.

- Sequential opioid trials are often beneficial.
- Become familiarized with equianalgesic dosing.
- Become familiarized with the pharmacokinetics of opioids.
- Differentiate between tolerance, physical dependence, and addiction.
- Use caution with opioid and adjuvant drug titration in the setting of renal impairment.

Constipation Prevention and Treatment

A bowel regimen should always be prescribed with an opioid prescription because of the constipation opioids induce.

- Always include stimulant laxatives to prevent opioid-induced constipation.
- Preferred choices include sennosides and polyethylene glycol.
- Decreased motility, gastroparesis, is a common side effect of opioids and can be treated with metoclopramide.
- Activity and adequate hydration are important.
- Bulking agents without a prokinetic may worsen constipation.
- Refractory constipation may be managed with lactulose 30 mL by mouth every 6 h until a large bowel movement occurs.
- Intractable cases may require a suppository or enema.

FIGURE 58-3 World Health Organization three-step ladder for oral analgesic management of pain. Adapted with permission from the World Health Organization.

- Proximal impaction may require oral laxatives.
- In rare cases of hard stools present in the vault, manual disimpaction may be necessary.
- Constipation may be evaluated with imaging to assess the degree of severity of constipation (Fig. 58-4).

Opioid Rotation

Opioid rotation is the switching from one type of opioid to another in the setting of opioid neurotoxicity. The following are reasons to rotate opioids:

- Uncontrolled pain despite escalating opioid doses
- Development of tolerance or dose-limiting side effects of opioid neurotoxicity (hallucinations, confusion, myoclonus)
- Hyperalgesia as a result of the production of excitatory amino acids from the opioid itself
- Cost necessitating switching of opioid

Opioid rotation has been shown to not only improve pain control, resolve delirium, and alleviate myoclonus, but also may improve other symptoms, including depression and insomnia⁽¹⁰⁾.

In a recent study of an outpatient population of 114 patients with cancer at MD Anderson Cancer Center with mean Eastern Cooperative Oncology Group

(ECOG) performance status of 1, opioid rotation for side effects or uncontrolled pain achieved improved symptom control successfully in 65% of the patient population⁽¹⁰⁾.

Individual variability of opioid activation of multiple subtypes of opioid receptors accounts for the benefits of opioid rotation that should be considered when managing uncontrolled pain^(11, 12). In difficult cases, this may include rotation on two or three occasions to reduce opioid neurotoxicity and improve pain control.

The following are general guidelines for opioid rotation:

1. Calculate total daily dose.
2. Calculate dose of new opioid using opioid conversion table (Tables 58-2 and 58-3).
3. Reduce dose of new opioid by 30% to 50% to account for incomplete cross tolerance.

Codeine

Codeine is a prodrug used to treat mild-to-moderate pain, diarrhea, and intractable coughing spells. It is the second most common alkaloid in opium and is hypothesized to be 200 times less potent than morphine. Metabolism by the liver converts 90% of the drug to inactive metabolites and 10% as morphine. The cytochrome oxidase 2D6 (CYP2D6) gene is responsible for the conversion to morphine and, in some groups, may not be fully active, while others may express multiple copies of the gene and be considered ultrarapid metabolizers⁽¹³⁾. These ultrarapid metabolizers have greater risk of opioid neurotoxicity due to codeine rapidly metabolizing into morphine, especially in the pediatric population. On the other hand, patients who have decreased metabolism may experience ineffective analgesia with the drug.

In addition, some medications are CYP2D6 inhibitors and block conversion of codeine to morphine when coadministered. These include the antidepressants paroxetine, fluoxetine, bupropion, and diphenhydramine. Medications known to increase CYP2D6, such as dexamethasone, should also be used with caution with codeine (Fig. 58-5).

Hydrocodone

Hydrocodone has historically been considered a weak opioid on the WHO ladder. It is manufactured commonly in combination with acetaminophen or ibuprofen. It is a semisynthetic opioid derived from codeine and is metabolized by the liver and excreted in the urine. Hydrocodone is metabolized by cytochrome P450 2D6 to hydromorphone. Recent studies have shown that hydrocodone, when taken at doses of less than 40 mg per day, is equivalent to one and half the strength of

On a flat abdominal x-ray, draw two diagonal lines intersecting at the umbilicus as shown here. This transects the abdomen into four quadrants corresponding to the ascending, transverse, descending, and rectosigmoid colons. Then, assess the amount of stool in each of the four quadrants using the following scoring system: 0 = no stool; 1 = stool occupying <50% of the lumen of colon; 2 = stool occupying >50% of the lumen; 3 = stool completely occupying the lumen. The total score will therefore range from 0 to 12. A score of 7 indicates severe constipation and requires immediate intervention.

FIGURE 58-4 How to calculate a “constipation score” using a flat abdominal x-ray. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

Table 58-2 Opioid Analgesics

Drug	Usual Starting Dosages
Full opioid agonists	
Morphine ^a	15-30 mg by mouth every 3-4 h
Morphine extended release (MScontin)	30-60 mg by mouth every 8-12 h
Hydromorphone (Dilaudid)	2-4 mg by mouth every 4-6 h
Hydromorphone ER (Exalgo)	8-16 mg by mouth every 12-24 h
Fentanyl (Duragesic)	25-50 µg/h transdermally every 3 days
Codeine	15-30 mg by mouth every 3-4 h
Oxycodone (Percodan and others)	5-10 mg by mouth every 3-4 h
Methadone hydrochloride (Dolophine) ^b	5-10 mg by mouth every 3-4 h
Partial agonists and mixed agonists/antagonists^c	
Nalbuphine (Nubain)	10 mg IV every 3-4 h
Butorphanol (Stadol)	0.5-2 mg IV every 3-4 h 1-2 mg SL three times a day
Dezocine (Dalgan)	10 mg IV every 3-4 h
Pentazocine (Talwin)	50 mg by mouth every 4-6 h

^aMorphine can be given as an immediate-release or sustained-release preparation. It is recommended that a relatively rapid onset, short-acting opioid preparation (such as immediate-release morphine) be given to patients who take sustained-release morphine to provide rescue medication for breakthrough pain.

^bMethadone is 10 to 15 times more potent than morphine. Expertise is needed to use it.

^cThis class of drugs is *not* recommended for the management of chronic cancer pain because these drugs will reverse analgesia when coadministered with full opioid agonists and precipitate withdrawal in physically dependent individuals.

Table 58-3 Opioid Conversion Table^{a,b}

Intravenous MO	Oral MO	1:2.5
Intravenous HM	Oral HM	1:2
Oral HM	Oral MO	1:5
Intravenous HM	Intravenous MO	1:5
Oral oxymorphone	Oral MO	1:3
Oral oxycodone	Oral MO	1:1.5
Oral HCD	Oral MO	1:1 at ≥ 40 mg HCD/d
Oral HCD	Oral MO	1:1.5 at < 40 mg HCD/d
Fentanyl patch	Oral MO	Fentanyl patch \times 2 = Oral MO
Intravenous fentanyl	Intravenous MO	1:100

HCD, hydrocodone; HM, hydromorphone; MO, morphine.

^b(1) Take the total amount of opioid that effectively controls pain in 24 h.

(2) Multiply by conversion factor in table; give 30% less of the new opioid to avoid partial cross tolerance.

(3) Divide by the number of doses per day.

morphine; however, the ratio of morphine to hydrocodone at doses greater than or equal to 40 mg per day have been shown to be closer to 1:1 (¹⁴) (Fig. 58-6).

Morphine

Morphine is commonly used as a standard prototype drug for opioid pain management. It is a naturally occurring opioid purified from opium poppy seeds and is available in short- and long-acting preparations. In the liver, it is converted to morphine-3-glucuronide and morphine-6-glucuronide (M3G and M6G, respectively) by glucuronyl transferase. Morphine-3-glucuronide is responsible for excitatory neurotoxic side effects, including myoclonus, hallucinations, seizures, and confusion and accumulates with renal insufficiency. Morphine is available as oral, rectal, intramuscular, intravenous, and sublingual preparations (Fig. 58-7).

Hydromorphone

Hydromorphone is a semisynthetic opioid derived from morphine and is five to seven times more potent.

**FIGURE 58-5 Codeine metabolism.****FIGURE 58-6 Hydrocodone metabolism.**

It is available for administration via all routes, including neuroaxial. It may be an alternative to morphine when dose-limiting side effects require rotation to a more potent opioid. Long-acting formulations are available, known by the trade name Exalgo, but are expensive.

Oxycodone

Oxycodone is another semisynthetic opioid derived from thebaine, a minor natural component of opium similar to morphine and codeine. Oxycodone has been known to be 1.5 times more potent than morphine. Previously, its dosage was limited by its combination with acetaminophen or aspirin, but now it is commonly available as oxycodone by itself as a pill in the United States. It has a higher bioavailability than morphine and exists both as extended-release and short-acting formulations.

Oxymorphone

Oxymorphone is produced after the CYP2D6 metabolism of oxycodone. It is a semisynthetic opioid and, like oxycodone, is also derived from thebaine. It has a low bioavailability orally and is three times more potent than morphine. Its maximum serum concentration is reached in 30 minutes, and the effects of immediate-release tablets may last up to 6 to 8 hours. Extended-release oxymorphone effects last 12 hours, and it should be dosed as such due to its long half-life of 14 hours. Oxymorphone should be given on an empty stomach because coadministration with food can result in increased absorption and result in opioid toxicities.

**FIGURE 58-7 Metabolism of morphine in the liver.**

Meperidine

Meperidine (Demerol) is a weaker opioid with a potency 1/10 that of morphine. Dose escalation is limited by the risk of accumulation of the metabolite normeperidine, metabolized by the liver. Both meperidine and nor-meperidine cause central nervous system toxicity, including convulsions, especially in renal impairment and in the geriatric population. Due these risks, it is becoming less commonly used.

Fentanyl

Fentanyl is a synthetic opioid that is 80 to 100 times more potent than morphine and has a rapid onset and short duration of analgesia. It is used often in the setting of acute or incidental breakthrough pain. Transdermal sustained-release formulations, fentanyl patches, are a good choice for stable pain and are changed every 72 hours. Fentanyl patches are convenient in patients with oral routes that are limited or unavailable. Oral transmucosal fentanyl has been used for breakthrough pain; however, fentanyl has a very rapid onset of action, which makes it difficult to calculate total dose delivered, and erratic equianalgesic dosing often raises safety concerns.

Methadone

Methadone is a synthetic opioid. Recent research⁽¹⁵⁾ has characterized appropriate equianalgesic dosing^(16, 17), and advantages include low cost, less-active metabolites, good bioavailability, and *N*-methyl-D-aspartate antagonism, which may account for the absence of the development of tolerance associated with chronic use. Methadone potency can be 10 to 15 times that of morphine; thus, caution should be exercised when rotating to methadone. Close monitoring when initiated is necessary due to its tendency to accumulate as time advances before reaching a steady state. The half-life varies with the individuals; it can be between 15 and 190 hours. Clinicians prescribing methadone should be aware of potential drug interactions due to metabolism via the cytochrome P450 system, with these drugs including antifungals, antiretrovirals, and selective serotonin inhibitors⁽¹⁸⁾. Methadone also has been associated with QTc interval prolongation^(19, 20), so proper cardiac monitoring is indicated. Prospective studies at MD Anderson Cancer Center found it to be safe in advanced cancer⁽²¹⁾. It is being researched as a viable first-line treatment option for pain management⁽²²⁾ and is especially useful in refractory cancer pain⁽²³⁾.

Adjuvant Medications

Although opioids are often first-line analgesics, adjuvant medications are useful for pain control in some settings, such as neuropathic pain. Due to the delay in onset as well as side effects with some drug groups,

Table 58-4 Adjuvant Analgesics

Nonsteroidal anti-inflammatory drugs
Acetaminophen
Aspirin
Ibuprofen
Naproxen
Celecoxib
Ketorolac
Diclofenac
Tricyclic antidepressants
Amitriptyline
Nortriptyline
Doxepin
Antiepileptic drugs
Gabapentin
Topiramate
Levetiracetam
Tiagabine
Oxcarbazepine
Lamotrigine
Felbamate
Local anesthetics
Lidocaine
<i>N</i>-Methyl-D-aspartate receptor antagonists
Ketamine
Methadone
Dextromethorphan
Haldol
Topical analgesics
Capsaicin
Lidocaine patches

adjuvant drugs may be best reserved after optimal trials of opioids. Of the tricyclic antidepressants drug class, nortriptyline is felt to be the most efficacious and has less cardiovascular side effects. Tricyclic antidepressants are limited by anticholinergic and sedative side effects. Anticonvulsants are helpful in treating brachial and lumbosacral plexopathies. Side effects and safety limit their wide use. For the adjuvant treatment of neuropathic pain, gabapentin has been shown to be effective but does require dose adjustment in renal failure. Pregabalin has been used as an alternative to gabapentin but is costly and has not shown greater efficacy (Table 58-4).

Nonpharmacologic Treatment

Adjuvant nonpharmacological treatments include nerve blocks, neurosurgical procedures, and radiation therapy. Physical and psychological interventions to treat pain include counseling, psychotherapy, relaxation techniques, massage therapy, music therapy, and acupuncture. Addressing psychosocial and spiritual distress for both patients and family may be needed for

Table 58-5 Anesthetic Procedures^a

• Celiac plexus/splanchnic block for abdominal visceral pain (eg, pancreatic cancer pain)
• Subarachnoid neurolytic block for extremity and thoracic wall pain in terminally ill patients
• Epidural/intrathecal opioids +/- local anesthetic (eg, for neuropathic or plexopathy pain)
• Cordotomy for intractable lower-extremity pain
• Vertebroplasty (injection of cement into a vertebral body) for metastatic spinal pain involving one or two vertebrae

^aReproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.

patients with cancer experiencing complex, total pain at the end of life (Table 58-5).

CANCER-RELATED FATIGUE

Fatigue is among the most common and distressing symptoms encountered in approximately 60% to 90% of patients with cancer (24). The National Comprehensive Cancer Network defines cancer-related fatigue as a persistent subjective sense of physical, emotional, as well as cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and is both distressing and interferes with usual function (25). Fatigue may include a lack of interest and difficulty maintaining attention, concentration, or motivation in objects or activities (Table 58-6). Patients may present with depressed mood, have a flat affect, and appear lethargic or somnolent. Rest or sleep does not eliminate or alleviate symptoms of cancer-related fatigue.

Fatigue may be experienced at any point in the cancer trajectory and often worsens at the end of life. Cancer-related fatigue may render patients unable to tolerate physical or mental activity, resulting in an inability to complete activities of daily living, impairment in social and occupational function, and diminished overall quality of life. Fatigue may also heighten other symptoms associated with cancer.

The etiology of cancer-related fatigue is often multifactorial (Fig. 58-8), including not only the underlying cancer itself but also treatments such as chemotherapy or radiation therapy. Fatigue may be exacerbated by other underlying metabolic abnormalities, such as hypothyroidism or hypogonadism, and can be amplified by psychosocial distress (see Fig. 58-8).

Fatigue Assessment

Assessment of fatigue requires a multidimensional approach. Fatigue severity is included on the Edmonton

Table 58-6 International Classification of Diseases, Tenth Revision, Criteria for Cancer-Related Fatigue

Criteria	Yes	No
Fatigue, decreased energy, increased need to rest ^a		
Generalized weakness/limb heaviness		
Diminished concentration or attention		
Decreased motivation/interest to engage in usual activities		
Insomnia/hypersomnia		
Sleep unrefreshing or nonrestorative		
Struggle to overcome inactivity		
Emotional reactivity to feeling fatigue: sadness/frustration/irritability		
Difficulty completing daily tasks		
Problems with short-term memory		
Postexertional fatigue lasting several hours		

^aReproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.

Symptom Assessment Scale, where 0 equals no fatigue and 10 equals the worst fatigue imaginable (see Fig. 58-2). Other numeric and verbal rating scales have been validated for fatigue, including the Functional Assessment of Cancer Therapy–Fatigue, Piper Fatigue Scale, Schwartz Cancer Fatigue Scale, Fatigue Symptom Inventory, and Functional Assessment of Chronic Illness Therapy–Fatigue (FACIT-F).

Significant fatigue, diminished energy, or increased need to rest disproportionate to any recent change in activity level must be present in addition to five or more of the other symptoms present daily or nearly every day during the same 2-week period in the past month (26).

Cancer-related fatigue should not primarily be a consequence of comorbid psychiatric disorders, which must be excluded, including major depression, somatization disorder, somatoform disorder, or delirium.

Fatigue Management

The initial assessment of fatigue should focus on contributing factors that can be corrected, such as hypothyroidism, anemia, B₁₂ deficiency, and renal insufficiency. Treatment of cancer-related fatigue should be considered only after correction

FIGURE 58-8 Multifactorial etiologies of fatigue. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

of underlying etiologies^(27, 28). Treatment of pain, depression, anxiety, sleep disturbances, dehydration, and cancer anorexia-cachexia syndrome are critical to improve symptoms of fatigue. Medications that exacerbate fatigue should be reviewed and, if indicated, discontinued; underlying infections should be aggressively treated; and patients with symptomatic anemia should receive blood transfusions when appropriate⁽²⁸⁾.

Corticosteroids

Low-dose steroids may alleviate some symptoms of fatigue. Recent studies have confirmed their short-term benefit; however, more studies are required to determine the optimal dose⁽²⁹⁾.

Methylphenidate

Psychostimulants such as methylphenidate may be useful if the patient is experiencing concomitant problems, such as depression or drowsiness related to opioids⁽³⁰⁻³²⁾. However, a recent randomized trial examining methylphenidate reported no significant difference in median FACIT-F scores in regard to cancer-related fatigue when compared with a placebo⁽³³⁾.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) may improve fatigue; however, their benefit has not been proven and may be indirectly related to the treatment of underlying mood disorder. A Cochrane review that included two double-blind, placebo-controlled studies ($n = 645$) using paroxetine in a meta-analysis did not show any significant improvement in fatigue in patients with cancer⁽³⁴⁾.

Testosterone Replacement

Recently, there has been evidence that patients with cancer with hypogonadism on chronic opioid therapy may benefit from testosterone replacement⁽³⁵⁾. A pilot study of testosterone replacement at 4 weeks in hypogonadal males with advanced cancer did not have significant improvement of fatigue as measured with FACIT-F, although there was a trend for improvement with longer duration of treatment⁽³⁶⁾.

Homeopathic Dietary Supplements

Studies have evaluated dietary supplements for treatment of fatigue. Ginseng has been used medicinally in the Far East for several millennia and is a widely used supplement to treat fatigue in the United States. The composition of the active ingredients of ginseng root (ginsenosides and saponins) varies, and standardization can be problematic. A recent double-blind, randomized controlled trial of 132 patients with either a mixed solid tumor or cancer survivors has shown significant improvement in fatigue scores when patients were prescribed American ginseng, 2,000 mg daily, for at least 4 weeks⁽³⁷⁾. Other potentially promising homeopathic supplements include guarana extract and L-carnitine.

Integrative Nonpharmacological Interventions

Exercise therapy, such as brisk walking, may help with fatigue. In a recent meta-analysis of randomized trials examining supervised exercise therapy supported exercise improving cancer-related fatigue. These findings suggest that combined aerobic and resistance exercise regimens, with or without stretching, should be included as part of rehabilitation programs for

patients with cancer ⁽³⁸⁾. Yoga has also been studied for the treatment of cancer-related fatigue with some positive results, although level of bias and inconsistent methods in previous randomized studies may have influenced results ⁽³⁹⁾. Indirect natural light ⁽⁴⁰⁾ and massage therapy may also help to reduce fatigue.

In addition, treatment of fatigue should address underlying psychosocial factors such as depression, anxiety, as well as other symptoms, including pain, cachexia, or dyspnea, to be effective. Cognitive-behavioral therapy, in treating psychosocial distress or insomnia, may indirectly improve symptoms of fatigue. In the future, multimodality treatment of cancer-related fatigue should be personalized for each individual cancer patient, and more research is needed to develop successful interventions.

NAUSEA, ANOREXIA, AND CACHEXIA

The anorexia-cachexia syndrome (Figs. 58-9 and 58-10) is characterized by a loss of appetite coinciding with significant weight loss; loss in lean body mass, including muscle wasting; loss of fat; fatigue; immune dysfunction; and metabolic derangements. Cancer cachexia has been defined as a multifactorial syndrome of ongoing skeletal muscle mass atrophy with or without the loss of fat mass that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. Diagnosis of cachexia has been agreed on by a panel of experts as a weight loss greater than 5% or weight loss greater than 2% in individuals already with a body mass index (BMI) less than 20 ⁽⁴¹⁾. Studies have shown that even a loss of 5% or more of

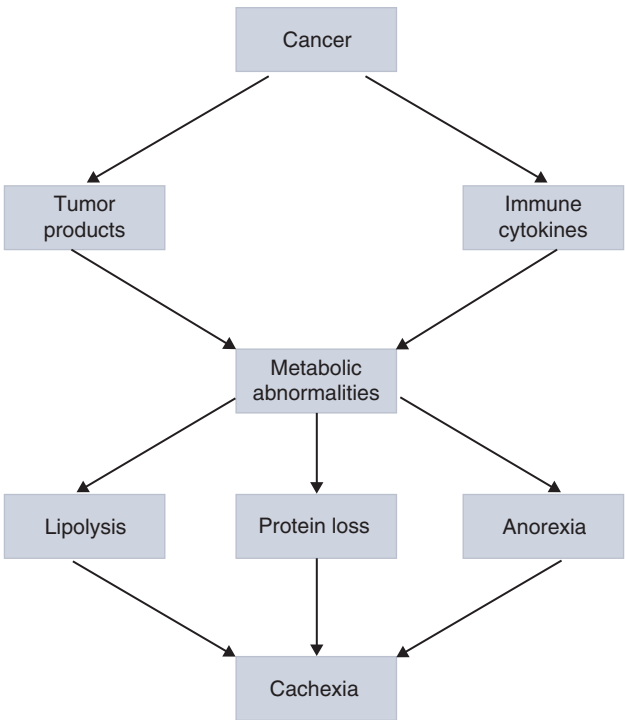

FIGURE 58-10 Mechanism of cachexia. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

premorbid weight prior to chemotherapy is associated with shorter survival ⁽⁴²⁾.

Cachexia is found in the majority of patients with advanced cancer and is a major contributing factor to death in about 50% of these patients ⁽⁴²⁾. Complex interactions between tumor and host lead to an aberrant immune response, neurohormonal dysfunction, and endocrine dysregulation. Both cachexia and

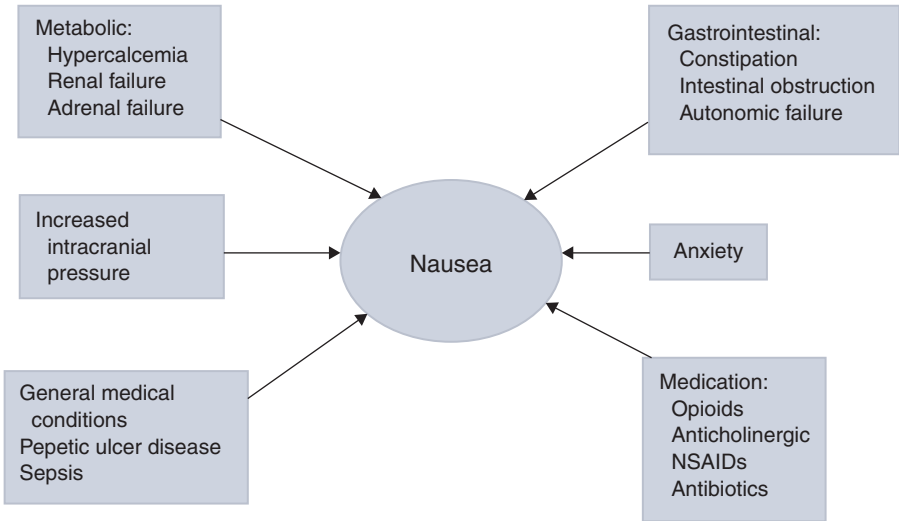

FIGURE 58-9 Causes of nausea. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

fatigue are associated with increased proinflammatory cytokines (interleukin [IL] 1, IL-6, tumor necrosis factor alpha), low testosterone levels, abnormal cortisol secretion, and resistance to insulin and ghrelin⁽⁴³⁾. These cellular derangements are associated with increased production of acute-phase proteins in the liver and loss of muscle protein due to proteolysis and lipolysis and results in elevated triglycerides and decreased high-density lipoproteins.

Unfortunately, neither nutritional supplementation nor artificial feeding reverses the cancer anorexia-cachexia syndrome⁽⁴³⁾. Multiple studies have examined the role of total parenteral and enteral nutrition in patients with cancer and have reported limited benefits. Artificial feeding of patients with cancer with cachexia was found to increase acute-phase protein production without influencing the rate of albumin synthesis⁽⁴⁴⁾. Other contributory factors resulting in weight loss (ie, depression, nausea, dysphagia, bowel obstruction, or constipation) should be treated aggressively.

Treating patients in the early stages of weight loss may be important to maintain or increase lean body mass because it is difficult to reverse cachexia in late stages⁽⁴³⁾. A comprehensive history, including recent changes in weight and diet patterns, is important. Simple and inexpensive tests are available to assess body composition, such as anthropometric measurements, skinfold thickness, arm muscle circumference and

area, and weight and BMI. Laboratory markers such as electrolytes, serum albumin, transferrin, and prealbumin may also be useful.

Management

For management, identify etiology and treat the underlying cause:

- Treat nausea/early satiety: metoclopramide 5 to 10 mg every 4 to 6 hours (renal adjustment required) (see Table 58-7 for nausea agents)
- Progestational agents
 - Megestrol acetate: 40 to 120 mg by mouth four times a day (risk of thromboembolism, hypogonadism, and adrenal suppression)
- Corticosteroids
 - Dexamethasone: 4 mg by mouth twice a day (lower mineralocorticoid effect than other steroids⁽⁴³⁾)
- For patients with cancer with depression: use antidepressants such as tricyclic antidepressants and SSRIs (ie, mirtazapine 15 mg by mouth at bedtime)

Nutritionist Consultation

Counseling and psychosocial support for cachectic patients and their family caregivers are critical at the end of life and will decrease patient-family conflict.

Table 58-7 Nausea Treatments^a

Drug ^b	Main Receptor	Main Indication	Starting PO Dose/Route	Equivalent Price ^c	Side Effects
Metoclopramide	D2	Opioid induced, gastric stasis	10 mg q4h PO, SC, IV	1	EPS (akathisia, dystonia, dyskinesia)
Prochlorperazine	D2	Opioid induced	10 mg q6h PO, IV	3	Sedation, hypotension
Cyclizine	H1	Vestibular causes, intestinal obstruction	25-50 mg q8h PO, SC, PR		Sedation, dry mouth, blurred vision
Promethazine	H1	Vestibular, motion sickness, obstruction	12.5 mg q4h PO, PR, IV	2	Sedation
Haloperidol	D2	Opioid, chemical, metabolic	1-2 mg bid PO, IV, SC	1	Rarely EPS
Ondansetron	5 HT ₃	Chemotherapy	4-8 mg q8h PO, IV	84	Headache, constipation
Diphenhydramine	H1, Ach	Intestinal obstruction, vestibular, ICP	25 mg q6h PO, IV, SC	0.2	Sedation, dry mouth, blurred vision
Hyoscine	Ach	Intestinal obstruction, colic, secretions	0.2-0.4 mg q4h SL, SC, TD	0.4	Dry mouth, blurred vision, urine retention, agitation

Ach, acetylcholine; D2, dopamine; EPS, extrapyramidal symptoms; H1, histamine; ICP, intracranial pressure; PR, per rectum; SL, sublingual; TD, transdermal.

^a From chapter 58 file

^b Corticosteroids are not included because they vary in dosage and have limited indications (see text).

^c Prices are compared to metoclopramide 10-mg tablets orally for 10 days based on the formulary prices at MD Anderson Cancer Center, November 2001.

Counseling should emphasize the pleasure of eating as well as promote the social participation of patients in family meals as opposed to increasing caloric intake. Counseling should highlight the normal loss of appetite as patients, who are often not hungry, approach the end of life, and family caregivers should not pressure patients to eat, which can result in nausea and psychological distress.

DYSPNEA

Dyspnea is a subjective symptom defined as an “uncomfortable awareness of breathing” ⁽⁴⁵⁾. It is often described as a sensation of air hunger, suffocation, choking, or heavy breathing. Dyspnea may be related to underlying tumor progression, altered by psychosocial factors, including anxiety, and exacerbated by preexisting pulmonary comorbidities. Shortness of breath can develop in response to pain or a mismatch between perceived ventilation rate and respiratory drive. Dyspnea is considered refractory when it persists at rest or with minimal activity and is distressful despite optimal medical therapy ⁽⁴⁶⁾.

Dyspnea in patients with advanced cancer is an indicator of poor prognosis ^(47, 48). The etiology of dyspnea is often multifactorial. It is postulated that in the brain, the cortical-limbic network is responsible for dyspnea perception. Recent research reported that the anterior cingulate cortex and the dorsolateral prefrontal cortex are involved in sensing dyspnea ⁽⁴⁹⁾. In addition, the insular cortex is modulated by sensations of dyspnea, and studies of patients with asthma have shown that it is downregulated in patients experiencing dyspnea as well as pain ⁽⁵⁰⁾.

Treatment of Dyspnea

The aim of treatment of dyspnea is to improve the patient’s perception of shortness of breath and involves not only treating the underlying cause but also palliating symptoms of air hunger. Treating the underlying etiologies can vary from thoracentesis for a pleural effusion, blood transfusions for anemic patients, corticosteroids for systemic inflammation or lymphangitic carcinomatosis, or antibiotics for pneumonia.

Symptomatic relief may include oxygen therapy, bilevel positive airway pressure, or high-flow oxygen therapy ⁽⁵¹⁾. In patients with chronic obstructive pulmonary disease (COPD), long-term oxygen therapy has shown mortality reduction but does not necessarily improve dyspnea. Palliative oxygenation is often prescribed irrespective of oxygen saturations. Oxygen delivery by nasal cannula does not always equate

to relief of dyspnea in nonhypoxemic patients with advanced illness when compared with room air.

Pharmacological interventions for dyspnea include opioids, benzodiazepines, and corticosteroids and are often utilized when medical therapy fails to improve the perception of dyspnea. Opioids, when titrated carefully, will often improve dyspnea without reducing oxygenation or causing respiratory depression ⁽⁴⁹⁾. Immediate-release, short-acting, and sustained-release morphine have been used in clinical trials of dyspnea management. The American Thoracic Society and the Canadian Thoracic Society advocate opioid dose titration to achieve the lowest effective dose based on patient ratings of shortness of breath ⁽⁴⁹⁾.

Corticosteroids are most useful in situations of lymphangitic spread or inflammation causing obstruction of airways ⁽⁵²⁾. Bronchodilators may also play a role when dyspnea is related to bronchospasm and reduce airway smooth muscle tone, thereby improving airflow and deflating an overinflated lung ⁽⁴⁹⁾. Tachycardia is a common side effect of bronchodilators.

Integrative approaches may also be effective, such as relaxation techniques or guided imagery, for patients with anticipatory or anxiety-driven dyspnea. Low-dose benzodiazepines in conjunction with opioids may have a role in the treatment of dyspnea complicated by severe anxiety, but they have the potential to cause delirium and decrease respiratory drive ⁽⁵³⁾. Acupuncture has also been researched for the treatment of dyspnea. In a study by Jones and colleagues ⁽⁵⁴⁾, one 45-minute session of transcutaneous electrical nerve stimulation at acupuncture sites resulted in improvement of dyspnea, increased FEV₁ (forced expiratory volume in first second of expiration) and blood levels of β -endorphin compared with placebo. Suzuki and colleagues reported exertional dyspnea was reduced in patients with COPD after receiving acupuncture once a week for 12 weeks compared to placebo ⁽⁵⁵⁾. Assist devices can be used to minimize muscular effort: postural drainage, a fan with airflow directed to the face ⁽⁵⁶⁾. Incentive spirometry can also help in certain settings.

DELIRIUM

Delirium, an acute state of encephalopathy, results from diffuse organic brain dysfunction. The prevalence of delirium is approximately 10% in hospitalized medical and surgical patients and is noted in 26% to 44% of patients with advanced cancer at the time of hospital admission. Roughly half of these cases may be reversible. In patients with advanced cancer, over 80% of patients will develop delirium at the end of life ⁽⁵⁷⁾. Delirium is often misdiagnosed and associated with increased morbidity and mortality ⁽⁵⁸⁾. It complicates

assessment of pain and other symptoms and results in distress for patients, family caregivers, and health-care providers.

Clinical Presentation of Delirium

Delirium is characterized by waxing-and-waning mentation. The main diagnostic criteria, according to the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) (*DSM-IV-TR*), include a disturbance of consciousness with reduced ability to focus, sustain, or shift attention; a change in cognition (disorientation/language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting dementia; and a disturbance that develops over a short period of time (hours to days) and fluctuates during the course of the day. Three clinical variants of delirium have been designated based on type of arousal disorder: hypoactive, hyperactive, and mixed.

Delirium Assessment

Delirium is often misdiagnosed as anxiety, insomnia, worsening pain, or mood disturbance, resulting in inappropriate treatment with anxiolytics or hypnotics, inappropriate increase in opioids, or use of antidepressants, which can worsen symptoms. Maintaining a high index of suspicion can help to avoid misdiagnosis of delirium, and routine use of screening tools such as the Memorial Delirium Assessment Scale or

Mini-Mental State Examination is recommended. Clinicians should pay attention to metabolic derangements that may precipitate delirium, such as liver or renal failure. Medications may be the cause as well and include opioids (responsible for almost 60% of cases in patients with cancer [59]), benzodiazepines, some antiemetics, and corticosteroids (Fig. 58-11).

Delirium Management

1. Provide patients a safe environment, including fall precautions; minimize noise and excessive light; place patients in a familiar setting with visible clock and calendar; and have family at bedside to help reorient patients.
2. Treat underlying causes, such as hypercalcemia or pneumonia.
3. Treat agitation (Table 58-8).
4. To treat severe agitation secondary to delirium, it may be necessary to give haloperidol more frequently initially. In patients refractory to haloperidol, a combination of haloperidol and a benzodiazepine may be necessary. However, in a study by Brietbart⁽⁶⁰⁾, lorazepam alone was ineffective in the treatment of delirium and actually contributed to its worsening and increased cognitive impairment in terminal patients with HIV. Newer atypical antipsychotics may be just as effective as typical antipsychotics but are more expensive. Olanzapine may be more sedating. Sometimes, acute dystonia and extrapyramidal side effects

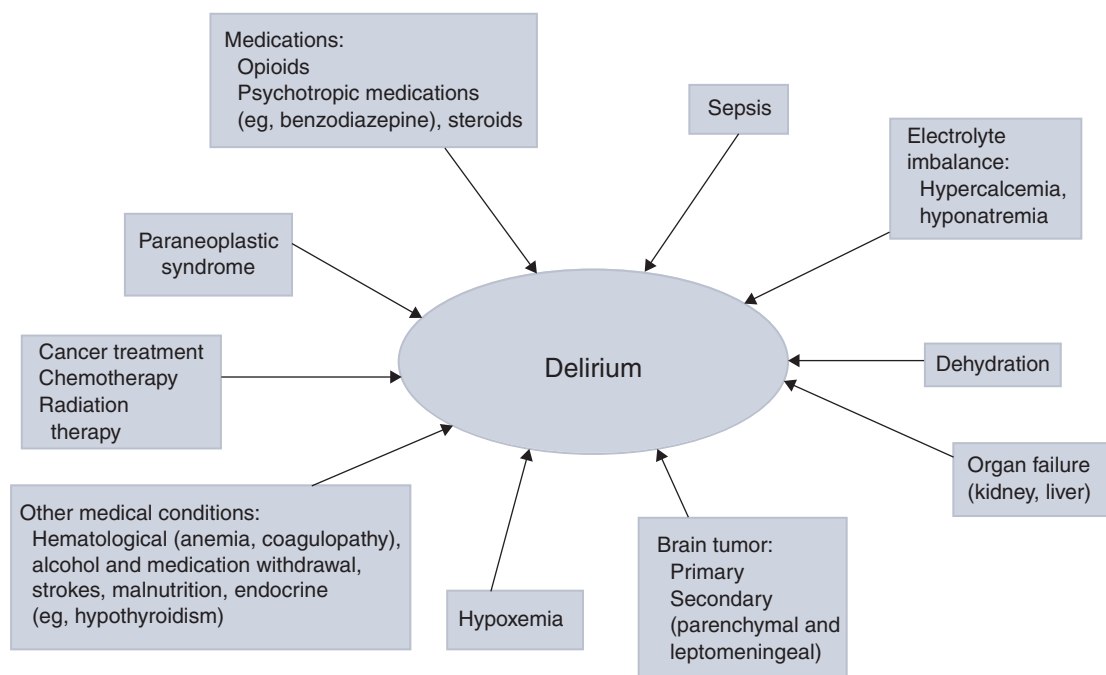

FIGURE 58-11 Delirium management. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

Table 58-8 Treatment of Agitation

Haloperidol ^a	IV/Oral/IM	Start 1-2 mg every 6 h and 1-2 mg every 2 h prn
Olanzapine	Oral/ODT/IM	2.5-5 mg daily, titrated to 5-10 mg daily
Risperidone	Oral/ODT/IM	0.25-0.5 mg every 12 h titrated to 1.5 mg every 12 h
Quetiapine	Oral/IM	12.5-25 mg by mouth every 12 h titrated to 100 mg every 12 h
Chlorpromazine	IV/Oral/IM	Start 10-25mg daily and 10-25 mg every 2 h prn
Ativan	IV/Oral/IM	0.5-1 mg every hour until calm; recommend against use as single agent

^a The oral bioavailability is approximately 60%-70% when converting from oral to parenteral.

- are seen with haloperidol, in which case benztropine can be administered. Once symptoms are under control, reducing haloperidol to the minimal effective dose is recommended ^(61, 62).
5. Counseling a patient’s family caregivers and health-care providers regarding the patient’s expression of previously well-controlled physical symptoms by grimacing or moaning may be inhibition of emotions due to delirium. In such cases, treatment should be directed at controlling delirium and not inappropriately increasing opioids (Fig. 58-12).

Palliative Sedation

Instances of refractory delirium, as well as other uncontrolled symptoms at the end of life, may require palliative sedation. Palliative sedation is defined as the monitored use of sedative medication to reduce patients’ awareness of intractable and refractory symptoms near the end of life when other interventions have failed to control them ⁽⁶³⁾. It is important to ensure all available symptomatic measures, including

CHAPTER 58

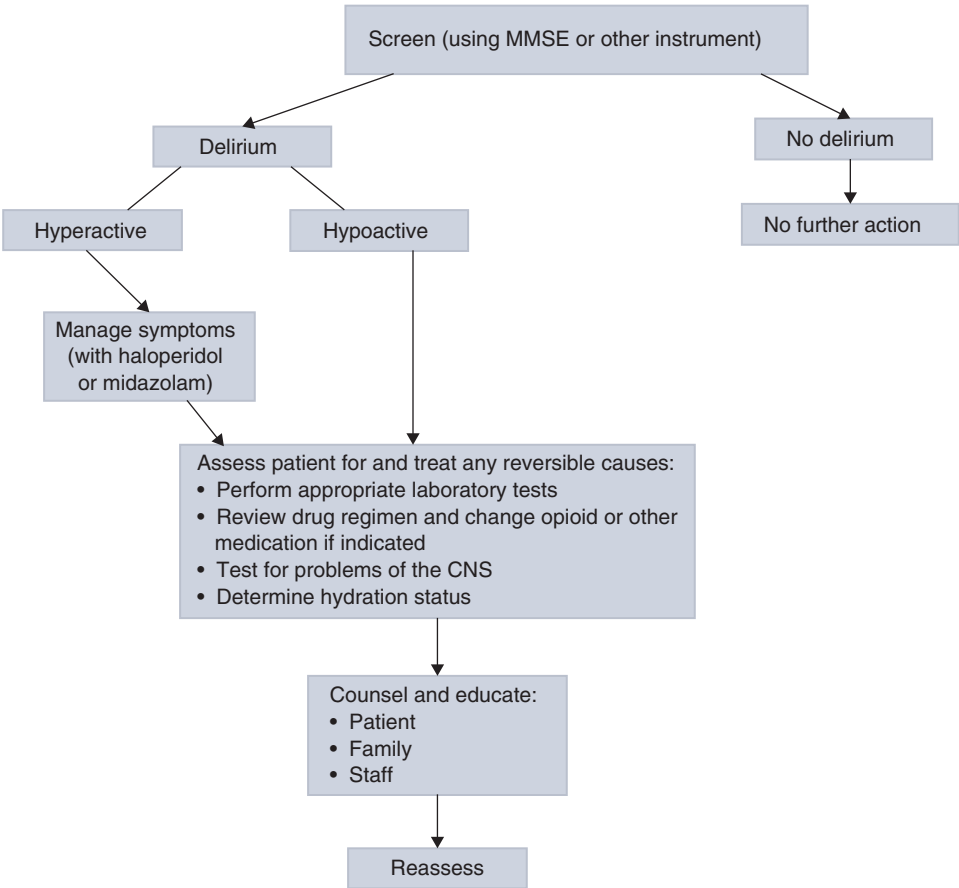

FIGURE 58-12 Algorithm for treating delirium. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

consulting palliative medicine specialists, have been tried before deeming symptoms refractory. The goal of palliative sedation is to control symptoms, not hasten death, which is differentiated from physician-assisted euthanasia. Therefore, it is imperative to discuss this with the patient and family caregivers to avoid misunderstanding. Midazolam, titrated to control symptoms, is often used for palliative sedation. Patients need regular assessments, including use of the Richmond Agitation Sedation Scale, to monitor for excessive sedation. If underlying symptoms have improved or been controlled, sedatives may be decreased and even discontinued.

DEPRESSION

Clinical depression is a common mood disorder encountered in patients with cancer and can affect from 25% to 35% of the patient population⁽⁶⁴⁾. Clinical depression increases in frequency in advanced disease⁽⁶⁵⁾, and diagnosis can be challenging in these patients. For instance, symptoms often strongly associated with clinical depression in healthy individuals (including fatigue, impaired decision-making ability, insomnia, and poor appetite) are frequently commonly encountered in patients with advanced disease. Per *DSM-IV* criteria⁽⁶⁶⁾, the cardinal features of clinical depression include anhedonia; feelings of guilt, hopelessness, or worthlessness; and suicidal ideation, and a thorough patient history directed at assessment for these symptoms is needed.

In addition, the diagnosis of clinical depression can be difficult to differentiate from adjustment disorder, anticipatory grief, or delirium. Validated measures of assessing depression in the primary care setting include the WHO-5 well-being index⁽⁶⁷⁾, PHQ-9 screening test⁽⁶⁸⁾, Hamilton Rating Scale for Depression (HAM-D)⁽⁶⁹⁾, and Montgomery-Asberg Depression Rating Scale⁽⁷⁰⁾ (MADRS). Other factors that increase the risk of depression include a history of substance abuse, family history of depression and suicide, concurrent life stressors, and poor social support.

Common antidepressants and their common initial doses are as follows⁽⁷⁸⁾:

- Nortriptyline 25 mg/d (at bedtime)
- Amitriptyline 25 mg/d (at bedtime)
- Fluoxetine 10 to 20 mg/d
- Paroxetine 10 mg/d
- Sertraline 20 mg/d
- Citalopram 20 mg/d
- Venlafaxine 37.5 mg/d
- Mirtazapine 15 mg/d (at bedtime)
- Methylphenidate 5 to 10 mg in the morning and 5 mg at noon

Escitalopram has a lower side-effects profile and works slightly faster than other first-generation SSRIs. Side effects include reduced appetite, nausea, and anxiety. Antidepressants should be given for a trial of 6 weeks for beneficial effects, and if there is no significant improvement, they may need adjustment of dose or a change to an alternate medication. In patients with cancer with unclear criteria for clinical depression or suicidal ideation, consultation with a psychiatrist is indicated.

COMMUNICATION

The majority of chronically ill patients in the United States want to be informed about their prognosis⁽⁷⁴⁾ and appreciate being told the truth⁽⁷²⁾. Health-care providers' ability to accurately prognosticate life expectancy of patients with cancer is still limited. In addition, a patient's acceptance of information regarding prognosis and end-of-life issues is heavily influenced by the manner in which this information is conveyed. It is common that health-care professionals feel uncomfortable with discussing prognosis and other end-of-life issues. Reasons include lack of training, stress, feeling rushed and not having enough time to address emotional needs of patients, fear of upsetting the patient or family, or reluctance to diminish hope with regard to the unavailability of further curative treatment. Avoidance of end-of-life discussions can lead to patient dissatisfaction and further psychological distress.

There are few trials testing the effectiveness of different strategies in delivering bad news⁽⁷⁴⁾. Most recommendations on discussing bad news agree on the following key features: preparing for the discussion, addressing the message content, dealing with the patient's responses, and ending the encounter⁽⁷⁴⁾ (Table 58-9).

Important guidelines regarding end-of-life discussions have emphasized the following: identify the reason for discussion and patients' expectations, elicit their knowledge of the situation, consider cultural awareness and preferences in regard to information, validate feelings and take an empathetic approach, explain information using language without medical jargon, use easy-to-understand terms, explain the limitations of prognostication and end-of-life information, and avoid exact timelines⁽⁷⁵⁾.

Family meetings are championed by health-care professionals as a tool to improve communication and can be helpful to inform, deliberate, clarify goals, and mediate difficult end-of-life discussions that family members might have in regard to the care of the patient. They can help to formulate acceptable care plans between patient, family caregivers, and

Table 58-9 SPIKES Protocol (Setup/Patient's Perception/Invitation/Knowledge/Emotions/Support)^a

Step 1: Setting Up the Interview	
Goals	Purpose
To prepare yourself for the interview To establish rapport with the patient and put the patient at ease To facilitate information exchange	Reflect on the task at hand. Arrange for uninterrupted time. Decide who should be present. Determine whether the patient is ready. Sit down when you speak to the patient. Have facial tissues handy. Maintain eye contact.
Step 2: Find Out the Patient's Perception of the Illness	
Goals	Purpose
To determine what the patient understands To assess denial in the patient/family To promote rapport through listening To understand the patient's expectations and concerns	Ask open-ended questions; ie, "Tell me what you've been told," or "I'd like to make sure you understand the reason for the tests." Correct misinformation and misunderstanding. Address denial. Address unrealistic expectation. Define your role.
Step 3: Get an Invitation to Give Information	
Goals	Purpose
To determine how much information the patient wants and when he or she is ready to hear it To acknowledge that patient information needs may change over time To resolve conflicts with families regarding information disclosure	Ask "Are you the type of person who wants information in detail?" Explore sources of family concern.
Step 4: Giving the Patient Knowledge and Information	
Goals	Purpose
To prepare the patient for the bad news To ensure patient understanding	"Forecast" the arrival of bad news; ie, "I'm afraid I have some bad news..." Give the information in small parcels. Check periodically for understanding. Avoid using medical jargon. Address all questions.
Step 5: Responding to Patient Emotions	
Goals	Purpose
To address emotional responses To facilitate emotional recovery To acknowledge our own emotions	Anticipate emotional reactions. Resist the temptation to try and make the bad news better than it really is. Support the patient by using emphatic response to expressions of emotion such as crying. Clarify emotions about which you are not sure. Validate the patient's feelings.
Supporting the Patient	
Be prepared, and have a strategy (escape is not a strategy). Have someone with you if it will be difficult. Shift to a supportive role. Give the patient time to emote. Have facial tissue ready.	Sit down and get close if you can. Respond to any emotions with one of the following: Empathic statements Validating statements Exploratory questions

^aReproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.

health-care providers ⁽⁷⁵⁾ and clarify goals of care so everyone is on the “same page” ⁽⁷⁶⁾ (see Table 58-9).

SPIRITUAL DISTRESS

Spirituality has generally been defined as a way an individual seeks and expresses meaning and purpose in life and how one experiences connectedness to the moment, self, others, nature, and the significant or sacred. While religiosity has been defined as the active participation in an organized religion ⁽⁷⁷⁾, recent studies conducted at MD Anderson have indicated that a majority of our patients identify themselves as being spiritual or religious. Almost all patients report that their spirituality or religious faith is a source of strength and assists with coping with a life-threatening illness. Caregivers have also shown similar patterns of identification with spirituality and religiosity. Caregivers expressed that their spirituality had helped them cope with their loved one's illness and had a positive impact on their loved one's physical and emotional well-being ⁽⁷⁷⁾. Patients with increased spiritual distress tend to have an association with a higher physical symptom burden. Acknowledging and addressing spiritual needs can be of value for improved quality of life in patients with advanced cancer.

MODELS OF PALLIATIVE CARE

Health care has traditionally been delivered in a dichotomous model with a focus on curative or life-prolonging treatment followed by an abrupt transition to palliative or hospice care in anticipation of death. In recent years, there has been a renewed emphasis on improving quality of life and integration of supportive care and palliative medicine earlier in the disease trajectory and concurrent with life-prolonging treatments. Integrating palliative care into the current best practice of cancer treatment allows for the prevention and relief of suffering while ensuring dignity during significant illness for both cancer survivors and patients at the end of life.

CONCLUSION

Patients with cancer will encounter distressing symptoms that can diminish a their quality of life and interfere with the ability to receive cancer therapy. Physical and emotional symptoms are encountered at any point during the illness trajectory from diagnosis, treatment, survivorship, or end of life. An oncologist may be overwhelmed with the challenges of cancer treatment when patients have uncontrolled symptoms. In collaboration with an interdisciplinary palliative care team,

health-care providers may simultaneously treat cancer aggressively while maintaining the integrity of human life and diminishing unnecessary suffering.

There is an urgent need to incorporate assessment and treatment of physical and emotional symptoms facing patients with cancer and integrating a palliative medicine team into the delivery of cancer care. For patients with complex symptoms, early adoption of interdisciplinary palliative care can aggressively treat symptoms to prevent the sequelae of physical and emotional pain. In addition, an open dialogue with patients and family caregivers regarding issues of treatment options, prognosis, and end-of-life care, including a transition from focus on curing cancer to care directed at controlling symptoms, is needed along the continuum of cancer treatment.

GENERAL PRINCIPLES

Cancer and its treatments are a major cause for impairments and disability. Because cancer treatments have become increasingly successful and have improved survival, there has been an increasing focus on quality of life and, in particular, rehabilitation. Cancer rehabilitation is practiced in outpatient clinics, oncology wards, inpatient rehabilitation units, skilled nursing facilities, nursing homes, long-term acute care centers, palliative care units, and hospices. Common diagnoses addressed include asthenia, deconditioning, hemiplegia, spinal cord injury, peripheral neuropathy, somatic and neuropathic pain, steroid myopathy, lymphedema, bowel/bladder management, limb amputation, and limb dysfunction.

The major goal of cancer rehabilitation is to improve quality of life by minimizing the disability caused by cancer and its treatments and decreasing the “burden of care” needed by patients with cancer and their caregivers. The more patients can do for themselves, the more personal dignity they are able to maintain and the less help they require from those around them.

In 1978, Justus Lehmann, supported by the National Cancer Institute (NCI), screened 805 randomly selected patients with cancer, identifying multiple problems in the population of patients with cancer who are amenable to rehabilitation interventions along with barriers limiting the delivery of rehabilitation care. More than 30 years later, many of Lehmann’s remediable cancer rehabilitation problems and barriers to rehabilitation care remain the same (Table 59-1).

These problems are familiar to rehabilitation professionals because many are also found in traditional

noncancer rehabilitation patients. Lehman also described major barriers to the delivery of cancer rehabilitation care, including the lack of identification of these problems by oncologists and the lack of referral to rehab professionals for a rehabilitation intervention. In addition, there are multiple patient-related factors that can affect the successful rehabilitation of the patient with cancer. Several reported by DeLisa include reduced life expectancy, extensive comorbidities, degree of pain, the dynamic nature of cancer lesions, the demands of anticancer therapies, and the desire to spend remaining time with loved ones (¹).

Phases of Cancer Rehabilitation

In 1980, Dietz categorized cancer rehabilitation into four stages: preventive, restorative, supportive, and palliative (²). Preventive rehabilitation occurs before or immediately after a treatment to prevent loss of function or disability. An example would include preamputation stump care teaching and ambulation with a walker in a patient with a lower extremity sarcoma. In 2001, Courneya described a concept called “buffering” whereby a patient with cancer undergoes exercises and therapies to increase the patient’s physical and functional reserves before cancer treatment (³).

Restorative rehabilitation occurs in patients who are believed to be disease free or will have an anticipated relatively stable disease course. Taking our previous example, a patient with lower extremity sarcoma with no known metastatic disease following amputation undergoes prosthetic rehabilitation. These first two stages are not significantly different from conventional

Table 59-1 Remediable Rehabilitation Problems and Barriers to Delivery of Rehabilitation Care

Remediable Rehabilitation Problems		Barriers to Delivery of Rehabilitation Care
Psychological/psychiatric impairments	Lymphedema management	Lack of identification of patient problems
Generalized weakness	Musculoskeletal difficulties	Lack of appropriate referral by physicians unfamiliar with the concept of rehabilitation
Impairments in activities of daily living	Swallowing dysfunction	Patient too ill to participate
Pain	Impaired communication	Patient denies need
Impaired gait/ambulation	Skin management	Cancer prognosis too limited
Disposition/housing issues	Vocational assessments	Rehabilitation unavailable
Neurologic impairments	Impaired nutrition	No financial resources
Vocational assessments	Lymphedema management	
Impaired nutrition		

Data from Lehmann JF, DeLisa JA, Warren CG, et al. Cancer rehabilitation: assessment of need, development, and evaluation of a model of care. *Arch Phys Med Rehabil.* 1978;59:410-419.

nononcologic rehabilitation. Fortunately, as survivorship has increased, restorative rehabilitation has become more prominent in addressing issues in this population, including disability, return to work, and lymphedema management.

If patients are unable to achieve or maintain a state of remission, supportive rehabilitation is performed to sustain function and provide symptom management. Expanding on our example, a patient with metastatic sarcoma may be provided therapies and durable medical equipment (DME) to promote functional independence while receiving chemoradiation.

Unfortunately, patients may succumb to their malignancy, or its accompanying morbidities, and efforts to maximize function may require a transition to focusing on quality of life. Palliative rehabilitation is provided to reduce discomfort and improve independence in patients with advanced disease. Our example patient with sarcoma and advancing metastatic disease may have failed multiple treatment regimens and now requires rehabilitation to return home with some degree of assistance. The emphasis of palliative rehabilitation is typically to get the patient home safely as soon as possible. The patient likely has limited time to live and the costs of a lengthy inpatient rehabilitation stay must be taken into consideration. Goals once the patient is home in a safe environment focus on family and transfer training. Higher-level goals should be addressed as an outpatient or through home health therapy.

The last two stages described by Dietz ⁽¹⁾ are relatively unique to cancer rehabilitation. The typical course for a patient in conventional rehabilitation (eg, after a stroke) is continued improvement after the inciting event. In the patient with cancer with persistent

disease, however, the war continues with brief victories followed by declines as the disease progresses ⁽³⁾ (Fig. 59-1).

Multiple studies have established a need for rehabilitation in the population of patients with cancer ^(4,5). Functional improvements of patients in cancer rehabilitation have been demonstrated in a number of settings, including inpatient ⁽⁶⁻⁹⁾ and palliative care ^(10, 11), on a consultation basis ⁽¹²⁾, in a hospice setting ^(13, 14), and for outpatient settings ⁽¹⁵⁾. The maintenance of physical activity and exercise has been implicated in increasing survival, with the greatest quantity of evidence in patients with breast and colon cancer. Multiple mechanisms may exist, and some have proposed these findings to be related to levels of insulin/c-peptide, along with the positive effects of buffering on physiological reserves, potentially allowing for more treatment ^(16, 17). Cancer physiatrists must also address medical sequelae and complications that are unique to this patient population. With limited training in general medical and surgical fields, these comorbidities may serve as a significant challenge and require frequent communication

FIGURE 59-1 Function/time graph of cancer patient.

FIGURE 59-2 Rehabilitation team.

between the primary oncology and rehabilitation teams. The transfer rate from inpatient rehabilitation to acute care teams is high compared to other rehabilitation diagnoses ⁽¹⁸⁾.

Rehabilitation goals are accomplished by the efforts of a comprehensive interdisciplinary team of health-care professionals, including the rehabilitation physician, rehabilitation nurse, physical therapist, occupational therapist, speech therapist, dietitian, pharmacist, chaplain, social worker, and case manager. Each member of the team has specific expertise in assisting the patient with a care plan of maximizing medical stability, function, financial resources, and caregiver involvement for a discharge that is as safe and meaningful as possible (Fig. 59-2).

Rehabilitation at MD Anderson

At the University of Texas MD Anderson Cancer Center (MDACC), our cancer rehabilitation practice includes seven physical medicine and rehabilitation physicians and a rehabilitation therapy staff of over 100 physical therapy and occupational therapy clinicians. Rehabilitation therapists see over 300 inpatients and 100 outpatients per day. Patients include those with most of the different tumor types seen in the institution, the most common being brain, spine, lung, breast, hematologic, genitourinary, gastrointestinal, and head and neck tumors. The most common inpatient rehabilitation diagnoses included asthenia, gait abnormality, dyspnea, hemiparesis, spinal cord injury, and neurogenic bowel and bladder. Common outpatient rehabilitation diagnoses include lymphedema, myofascial pain, rotator cuff dysfunction, peripheral neuropathy, and low back pain. Inpatient and outpatient electromyograms are performed for neuropathic and myopathic diagnoses and spasticity management.

Functional Metrics

When describing the functional status of a patient with cancer, the Karnofsky Performance Scale is often used.

It is the most widely used scale both clinically and in research in oncology patients ⁽¹⁹⁾. It is an easy and quick generalized measurement of a patient's function. Weaknesses of the scale include overgeneralization (unable to measure specific tasks) and poor correlation with cognition ⁽²⁰⁾.

In rehabilitation, the outcome scale most often used is the Functional Independence Measure (Fig. 59-3). This multidimensional scale addresses 18 items from a scale of 1 (total assistance) to 7 (complete independence). Items are subdivided into self-care, sphincter control, transfers, locomotion, communication, and social cognition. An aggregate score is also often useful out of a total of 126. Criticisms of the scale include that it is too general and omits items that are important for specific populations, such as those with spinal cord injuries ⁽²¹⁾.

PRACTICAL ASPECTS OF CANCER REHABILITATION

Physiatry is a holistic specialty that accounts for medical needs while focusing on a patient's functional issues. Safety is a primary concern of rehabilitation health-care professionals. The first question a physiatrist often asks is, What is the minimum level of safe function for this patient to be discharged? That "safe" functional level goal depends on the patient's current functional level, strength, cognition, amount of supervision or assistance available on discharge, accessibility of home conditions, and financial resources. Physiatrists must ask patients and their caregivers detailed social questions.

Common obstacles confronted are a lack of assistance or supervision at home. This often is due to the patient's significant other being required to work during the day, the significant other's inability either physically or mentally (eg, dementia) to care for the patient, or having no one available to care for them.

One of the most practical and simple rehabilitation techniques that an inpatient must learn is to transfer. A transfer is a change in station or position from sitting in bed to standing or from sitting in bed to sitting in a chair. A person must transfer to get into a wheelchair or into a car seat. Patients cannot effectively mobilize until this is accomplished. Depending on the patient's level of disability, a transfer may be performed to sit to stand, to stand and pivot, with a sliding board, or with a lift requiring total assistance. After basic transfers are mastered, ambulation may be the next goal to increase mobility. Weakness from paresis, deconditioning, neuropathy, or brain injury can also make self-care difficult. Practical skills such as feeding, grooming, bathing, and dressing are taught or relearned to improve independence.

ACUTE CANCER REHABILITATION

Rehabilitation begins when a patient is admitted into the hospital. Impairments are identified, and based on the practical considerations mentioned previously, realistic and suitable rehabilitation goals are set. If a patient is medically stable with unmet functional and safety goals, the patient's activity tolerance and performance trajectory are used to guide determination of the appropriate intensity and location for additional rehabilitation.

REHABILITATION OF INDIVIDUALS WITH BRAIN TUMORS

Primary brain tumors are less than 2% of all malignancies but are the second leading cause of death from neurologic disorders after stroke⁽²²⁾. One-half to two-thirds of intracranial tumors have been reported to be primary tumors⁽²³⁾. Primary brain tumors are classified by cell of origin; the primary system of classification is that of the World Health Organization (WHO), which divides tumors into nine categories. The most common categories include tumors that displace brain parenchyma of the intracranial supratentorial compartment. Of these tumors, the most common in adults are the astrocytomas, in particular grade IV astrocytoma, otherwise known as glioblastoma multiforme (GBM)⁽²⁴⁾. The median survival for a patient with GBM has been reported between 7 and 17 months⁽²⁵⁾.

In addition to primary brain tumors, brain metastases are estimated to occur in 20% to 40% of patients with cancer. The most common mechanism of metastasis to the brain is through hematogenous spread. Most of the metastases are located in the cerebral hemispheres, followed by the cerebellum and then the brainstem. The incidence of brain tumor metastases is rising, possibly due to the increasing length of survival of a patient with cancer⁽²⁶⁾, increasing ability to diagnose a tumor with improved radiographic imaging⁽²⁷⁾, and possibly recent chemotherapy agents, which may weaken the blood-brain barrier⁽²⁸⁾.

Normal brain parenchyma can be destroyed or compressed by the tumor, and the location of the tumor determines the resultant neurologic deficit. Surgical resection may exacerbate these deficits by creating inflammation or peritumoral infarct⁽²⁹⁾. Radiation treatment has long been an integral part of brain tumor treatments and often results in collateral damage. Early acute radiation leukoencephalopathy is likely due to increased cerebral edema. Late delayed radiation reactions include focal cerebral radiation necrosis, diffuse cerebral radiation injury (DCRI), and

combined-therapy diffuse white matter injury/leukoencephalopathy. Clinical DCRI has been reported in 2% to 5% of patients with metastases and 19% of 1-year survivors after whole-brain radiation^(30,31).

The most common neurologic deficits include impaired cognition (80%), weakness (78%), visual-perceptual deficits (53%), sensory loss (38%), and bowel/bladder dysfunction (37%). Other deficits include cranial nerve palsy, dysarthria, dysphagia, aphasia, ataxia, and diplopia, which are less common. Approximately 75% of patients with a brain tumor have three or more neurologic deficits concurrently, and 39% have five or more deficits⁽³²⁾. Because of the diverse nature of these neurologic deficits, comprehensive multidisciplinary inpatient rehabilitation is often necessary for these patients. In rehabilitation medicine, the physical impairments that could result in functional deficits are primarily addressed.

Patients who have impairments resulting in functional decline that could affect bed mobility, ambulation, transferring from sitting or lying to a standing position, or activities of daily living (ADLs) (eg, eating, grooming, dressing, bathing, and toileting) can benefit from comprehensive inpatient rehabilitation. Comprehensive cancer rehabilitation services are not widely available for these patients⁽³³⁾. Because of this, many patients with a brain tumor receive their rehabilitation at general rehabilitation facilities alongside patients with stroke and traumatic brain injury. Patients with a brain tumor have similar efficiencies of improvement when compared to traumatic brain injury, stroke, and between brain tumor types. Lengths of stay tend to be shorter among patients with a brain tumor, possibly secondary to a need to return the patients home sooner given their shorter life expectancies⁽³⁴⁻³⁸⁾. However, some notable differences between these populations should be noted (eg, physiatrists may need to be cognizant of the continued decline of patients with progressive tumors).

Neurologic Motor Impairment

Motor impairment can be due to hemiparesis, ataxia, and apraxia. Motor impairment may lead to an unsafe gait pattern creating a higher risk for falls and a need for inpatient rehabilitation transfer. In inpatient rehabilitation, the patient will be seen by physical and occupational therapists. Physical therapy would focus on gait and transfers. To address transfers, efforts could be focused on sliding board transfer or stand pivot transfers. With respect to mobility, physical therapists focus on wheelchair mobility and gait with or without an assistive device (eg, a single-point cane, quad cane, rolling walker, hemiwalker). Occupational therapy would focus on problems with ADLs. Commonly addressed basic ADLs include dressing, bathing,

toileting, grooming, eating, and the like. The occupational therapist and physical therapist are also aware of the cognitive component necessary for mobility and ADLs. Once a patient is functionally safe using an assistive device such as a rolling walker, he or she can be discharged home. Then, the patient can continue with outpatient rehabilitation, gradually improving his or her ambulation with an assistive device and further strengthening weakened muscles by way of a progressive resistance exercise program.

The pattern of recovery of muscle strength and function does not always follow the pattern of recovery observed in patients with stroke. However, the stroke recovery pattern is often used as a guideline for patients with brain tumors. The recovery of strength occurs in a proximal-to-distal direction, with flaccidity and decreased muscle tone progressing to spasticity and increased muscle tone. The spasticity in the affected limbs can evolve into flexor or extensor synergy patterns. Recovery of muscle movement may plateau at any stage or may progress to isolated coordinated volitional motor movement^(39, 40).

Several techniques and exercises are used for neuromuscular facilitation in patients with stroke. Often, a combination of procedures and techniques from the various programs are used in patients with cancer with neuromuscular weakness. Proprioceptive neuromuscular facilitation developed by Kabat, Knott, and Voss relies on several mechanisms, such as spiral diagonal movement patterns of the extremities and quick stretch. Brunnstrom movement therapy facilitates the use of the synergy patterns mentioned as a means of developing voluntary control. Rood proposed that cutaneous sensory stimulation in the form of superficial stroking, tapping, brushing, vibrating, or icing provides facilitatory or inhibitory inputs⁽⁴¹⁾.

In addition to the traditional range-of-motion and strengthening exercises as well as neuromuscular facilitation techniques, functional electrical stimulation can also be incorporated into the rehabilitation program for neuromuscular weakness. It uses a low-level electrical current that stimulates motor nerves or reflex sensory nerves to produce muscle contraction. The goal of functional electric stimulation is to produce purposeful, functional movements in paretic or paralytic muscles⁽⁴²⁾.

Sometimes, owing to weakness of the ankle dorsiflexors, it is necessary to use an ankle-foot orthosis (AFO) to improve hemiparetic gait. There are two major types of AFOs: the double metal upright AFO attached to an orthopedic shoe and the molded plastic AFO, which is more commonly used. With the plastic AFO, the footplate sits within the shoe and extends upward behind the calf. The advantages of a plastic AFO over a double metal upright AFO include better cosmesis, lighter weight, and the freedom to wear different shoes.

Shoulder subluxation, predominantly inferior, which is caused by the loss of normal motor control of the shoulder stabilizers, including the deltoid and supraspinatus muscle, is often seen in the hemiparetic patient⁽⁴³⁾. It can often be the cause of shoulder pain in hemiplegic patients^(44, 45). Other possible causes of shoulder pain in this patient population include complex regional pain syndrome, traction injury of the brachial plexus, rotator cuff tendinitis or tear, subacromial or subdeltoid bursitis, adhesive capsulitis, or heterotopic ossification. Diagnosis of glenohumeral subluxation is made through physical examination and radiographic evaluation. The acromiohumeral interval is compared on each side with the arms in an unsupported position during physical examination, and radiographic evaluation is used to quantify the amount of subluxation. Radiographic studies can provide an early evaluation for subluxation with slight gapping of the superior aspect of the glenohumeral joint⁽⁴⁶⁾.

Treatment of hemiparetic shoulder subluxation involves proper positioning of the arm, physical modalities, and exercise. The use of an arm sling can help maintain proper positioning and posture during ambulation. However, this is discouraged when the patient is seated, and its overuse may contribute to compromise of superficial blood flow as well as to joint contracture. Arm troughs and lapboards are used while patients are seated⁽⁴⁷⁾. Other interventions include biofeedback and functional electrical stimulation.

Hemisensory deficit and homonymous hemianopia may be seen with hemiparesis. Visual or somatic hemineglect is more frequently seen when the non-dominant cerebral hemisphere is affected. Hemispatial neglect has a negative effect on sitting balance, visual perception, wheelchair mobility safety awareness, and risk of falling⁽⁴²⁾. Patients with neglect have difficulty with hygiene and self-care activities on the affected side. Rehabilitation programs must address the issue of hemispatial neglect through focused measures led by speech therapists, occupational therapists, and physical therapists. Family training and education are important in this setting as well.

Ataxia

Cerebellar ataxia may be seen with mass effect within the posterior fossa. Of note, cerebellar ataxia can also be seen in paraneoplastic cerebellar degeneration and with high-dose administration of cytarabine (ara-C) or 5-fluorouracil (5-FU)^(48, 49). Involvement of the cerebellum can produce intention tremors, dysmetria, and dysidiadochokinesis as patients lose the ability to coordinate the agonist and antagonist muscle groups⁽⁵⁰⁾. The response to pharmaceutical management has been poor; consequently, physical and occupational therapy has been the mainstay of treatment for ataxia. This includes

the teaching of compensatory techniques for performing basic self-care and occupational activities and the possible use of weighted bracelets or similar devices to help decrease the oscillations. Physical therapy directed at gait training with the use of assistive devices can help improve mobility in ataxic individuals ⁽⁵¹⁾.

Aphasia

Depending on its location, a tumor may be associated with deficits in speech, which can vary in severity and type. Often, one can diagnose the type of aphasia from a comprehensive neurologic examination, including speech comprehension, fluency, and repetition. These include Broca's aphasia, Wernicke's aphasia, anomic aphasia, global aphasia, conduction aphasia, and the transcortical motor and sensory aphasias.

A speech pathologist will implement treatment approaches, including melodic intonation therapy, Amer-Ind Code treatment, functional communication treatment, stimulation approach, and Promoting Aphasics' Communication Effectiveness (PACE) therapy ⁽⁵²⁾.

Cognitive Deficits

Cognitive deficits often are more problematic than motor deficits. They can arise from direct injury to the brain tissue due to the tumor itself, from surgical resection, radiation, chemotherapy, depression/anxiety, as well as medications, particularly steroids and anticonvulsants ⁽²⁸⁾. Impairments most commonly seen involve limited memory and attention, decreased initiation, and psychomotor retardation ⁽⁵³⁾.

The rehabilitation physician will assess the patient's cognitive status as part of the physical examination. This assessment is needed to formulate a rehabilitation program involving speech pathologists. Specific deficits in language and cognition can further be delineated through specific testing performed by a speech pathologist. However, it is sometimes necessary to have formal neuropsychological testing done, especially if the patient wishes to return to work.

Dysphagia

A disruption in the swallowing process can also occur in patients with brain tumors or following craniotomies. It is important to determine, through clinical assessment, whether dysphagia is present because there is the potential for serious complications, such as malnutrition and aspiration pneumonia, if dysphagia remains undetected. Often, its presence can be established from a history and neurologic examination. If dysphagia is suspected, a speech pathologist is consulted; then, daily swallowing therapy and exercises are incorporated into the therapeutic milieu.

Treatments include dietary modifications and dysphagia exercise and facilitation techniques ⁽⁵⁴⁾. Depending on the results from a clinical swallowing evaluation or videofluoroscopic evaluation, food can be modified to different consistencies, including puree, semisolid, or solid. Liquids may also have to be thickened using various thickening ⁽⁵⁵⁾.

Exercises and facilitation techniques are employed to aid and strengthen various components of the swallowing process. These include exercises employed for treatment for the lips to facilitate the ability to prevent food or liquid from leaking out of the oral cavity. There are exercises to assist the pharyngeal swallow by improving tongue base retraction. Vocal cord adduction exercises are instituted to strengthen weak cords to prevent aspiration.

Compensatory strategies include proper head and trunk positioning, which for most patients is to be seated upright with head midline, trunk erect, and the neck slightly flexed forward. Other techniques include the chin-tuck method and head turning and tilting during swallowing.

After dysphagia has been identified and measures are implemented for its treatment, regular follow-up to assess for improvement is required. This again can be done through clinical examination or radiographically. If improvement is noted, the diet may be advanced appropriately.

Spasticity

Spasticity is defined as velocity-dependent resistance to passive movement across a joint. It is an abnormality involving increased muscle tone and is one of the positive findings of the upper motor neuron syndrome. Spasticity must be distinguished from soft tissue contractures. Soft tissue contractures result from scar tissue formation and may be the result of a number of causes, including uncontrolled spasticity.

Often, brain tumors can cause muscle spasticity. This can affect the gait pattern or ADLs and, in severe cases, can cause pain and joint contractures as well as being a detriment to hygiene of the involved areas. Sometimes, spasticity may be beneficial, as when a patient may use knee extensor spasticity to assist in transferring from a sitting to a standing position. Indications for the treatment of spasticity include the need to decrease pain, improve hygiene, improve gait and transfers, minimize contractures, and improve self-care.

Treatment measures for spasticity include physical and medical interventions. Proper positioning, passive range-of-motion exercises, serial casting, splints, and braces are some of the physical interventions used in treating spasticity. Oral medications may also be used, including tizanidine, dantrolene sodium, and baclofen.

Because these medications work systemically, the most common limiting side effects are excessive drowsiness and cognitive changes. Tizanidine or dantrolene is recommended by most clinicians for treating spasticity stemming from primary brain pathology⁽⁵⁵⁾. Often, because of the cognitive side effects of these oral medications, botulinum toxin injections, phenol injections, or intrathecal baclofen pumps may be useful. These medications act locally but are harder to administer and more invasive.

Bladder Dysfunction

As in patients with stroke, bladder incontinence may be present in patients with brain tumors. The causes of bladder incontinence can be multifactorial and include an untreated urinary tract infection, inability to ambulate to the bathroom, and altered cognitive status. If the pontine micturition center is preserved, patients with brain tumors can have upper motor neuron bladder dysfunction, which is characterized by bladder hyperreflexia with reflex or urge incontinence and complete emptying⁽⁵⁶⁾. Postvoid residual volumes are generally low in the absence of bladder outlet obstruction. Persistent areflexia and retention may occur with bilateral lesions⁽⁵⁷⁾.

Treatment first involves identifying the cause of the bladder dysfunction. Obtaining a urinalysis with cultures and sensitivities and then starting appropriate antibiotics is the treatment for urinary tract infections. Using a bedside commode or a urinal is of benefit for patients who have weakness or inability to safely ambulate to the bathroom. A timed voiding program that has the patient urinate at set times throughout the day, before the bladder can contract, can be of help for patients with hyperreflexic urgency. Anticholinergic medications such as oxybutynin (Ditropan) or tolterodine tartrate (Detrol) can be used for persistent incontinence in this setting of a hyperreflexic detrusor⁽⁵⁷⁾. If the patient's blood pressure can tolerate it, a trial of an alpha-adrenergic agent (eg, tamsulosin, terazosin) may be useful in reducing urinary resistance in older male patients who are experiencing symptoms of urinary retention.

LYMPHEDEMA

Physiatrists are often asked to assist with the care of patients with lymphedema. Malignancy (including breast, melanoma, gynecologic, lymphoma, and urologic cancers) is the number one cause of secondary lymphedema in the United States. The lymphedema can be caused by a combination of the cancer, surgical treatments, and radiation treatments. Breast cancer is the leading cause of upper extremity lymphedema in the United States and develops in 2% to 40% of patients after surgery, radiation, or both^(58,59).

The majority of lymphedema cases are diagnosed clinically. The differential diagnosis would include deep venous thrombosis (DVT), venous insufficiency, myxedema, lipedema, heart failure, kidney failure, and hypoproteinemia. In difficult-to-diagnose cases, lymphoscintigraphy is the gold standard.

The treatment of lymphedema typically starts with conservative treatments consisting of manual lymph drainage, compression sleeves, and sometimes pneumatic compression sleeves. Over one or two sessions by lymphedema-trained physical therapists, patients are taught a lymphedema regimen to do at home. Measurements are often taken, and the patients are followed up periodically to ensure that they are completing the regimen as prescribed and to measure changes in their lymphedema. Progression of lymphedema can be measured using a number of techniques, including volumetric/circumferential measurements, bioelectric impedance, tonometry, and perometry. In patients with severe or difficult-to-treat lymphedema, a number of surgical options are available, including microsurgery, liposuction, and debulking procedures.

REHABILITATION OF CANCER-RELATED SPINAL CORD INJURY

Spinal cord injury in the patient with cancer has several etiologies. These involve primary spinal cord tumor or metastatic lesions. Primary tumors such as meningiomas, neurofibromas, and gliomas are relatively rare, and the majority of tumors involving the spinal cord are metastatic. The metastatic lesions that cause nerve root or spinal cord compression can be paravertebral, extradural, intradural, or intramedullary; however, 95% of metastatic lesions are extradural. These lesions most often originate from primary tumors of the breast, lung, and prostate. Other tumors that metastasize to the spine include renal, melanoma, myeloma, and thyroid. Most extradural metastases arise from the vertebral body and result in compression of the anterior spinal cord. Approximately 70% of spinal metastases occur in the thoracic spine, which has a smaller ratio of canal-to-cord diameter than the other two spinal segments⁽⁶⁰⁾.

Pain worse at night and in the supine position is a common clinical presentation. Weakness and sensory loss, along with the development of bowel or bladder incontinence, may indicate spinal cord compromise. Rapid progression of paraparesis over only a few hours indicates arterial compromise by tumor invasion or pressure; slowly evolving symptoms suggest gradual cord impingement and may respond to steroids and radiotherapy⁽⁶¹⁾.

Corticosteroids can alleviate pain and improve neurologic function, and radiation therapy is the treatment of choice with most cases of cord compression. If the tumor involves two or three columns of the spine, spinal stability is of concern; consequently, treatment is aimed toward stabilization of the spinal column. This can be done with cervical orthoses. Sternal occipital mandibular immobilization is well tolerated and provides adequate flexion and extension as well as stability to the lower cervical segments. Philadelphia collars provide stability in flexion and extension for higher levels but do not restrict rotation and lateral bending in the lower cervical segments. The “clamshell” thoracic lumbar-spinal orthosis is used to provide thoracic and lumbar support but may not be an option in patients with friable or intolerant skin following chemotherapy or steroid use. Therefore, the Taylor-Knight brace, which limits spinal extension, and the Jewett brace, which limits spinal flexion, can be used to provide thoracic and lumbar support⁽⁶²⁾.

Surgery is also indicated sometimes with instability and neurologic compromise; indications include pathologic fracture and dislocation, failure of radiation therapy, and rapidly progressing myelopathic signs and symptoms. Surgical stabilization can frequently alleviate the need for external bracing, which is an added benefit.

Once spinal stabilization is achieved, comprehensive inpatient rehabilitation can address the impairments, functional limitations, and disabilities associated with spinal cord compression and injury due to cancer. Individuals with nontraumatic spinal cord injuries can achieve significant gains in functional independence measurements during inpatient rehabilitation⁽¹⁰⁾. It has also been suggested that due to the limited prognosis of patients with cancer with spinal cord compression, an expedited inpatient rehabilitation stay with the focus on family training and home safety should be emphasized.

Bladder Management

For all patients with cancer with neurologic involvement and those with profound deconditioning, it is prudent to check postvoid residuals for signs of bladder dysfunction. This can be performed noninvasively by an ultrasound-mediated bladder scanner or, more accurately, by straight catheterization and measurement postvoid. If the postvoid volumes are 100 to 150 mL or greater, an intermittent catheterization program is initiated.

Tumors involving the spinal cord cause suprasacral neurogenic bladder problems, which typically result in a hyperreflexic detrusor; this is characterized by low urinary volumes, high bladder pressures, and diminished bladder compliance. Incomplete lesions may

produce the supraspinal pattern, with urgency and adequate emptying, while patients with complete lesions have reflex incontinence and incomplete voiding due to detrusor-sphincter dyssynergia⁽⁵⁷⁾. Some patients have hypocontractile or areflexic bladders, with urinary retention and associated overflow incontinence if the lesion involves the sacral micturition center. Sometimes, there is a mixed picture of upper motor neuron dysfunction, hyperreflexic bladder and lower motor neuron dysfunction, and areflexic bladder.

Management of lower motor neuron bladder dysfunction involves the use of a condom catheter for men or an indwelling catheter for women if sphincter tone is diminished with normal or compromised detrusor tone. When the sphincter tone is competent but the bladder tone diminished, an intermittent catheterization program is instituted. This can frequently be seen in patients with sacral tumors such as chordomas and chondromas. The management of upper motor neuron bladder dysfunction involves the use of an anticholinergic medication such as oxybutynin to decrease detrusor tone and allow for greater capacity; then, an intermittent catheterization program can be instituted.

An intermittent catheterization program first involves daily measurements of postvoid residuals or the volume of urine left in the bladder after a void. If the postvoid volumes are 100 to 150 mL or greater, the patient is catheterized initially every 4 hours. The goal is to have the catheterized volumes not exceed 400 to 500 mL. If the volumes remain consistently below those numbers, the frequency of catheterization can be decreased to every 6 hours.

In addition, management of bladder dysfunction in this population involves assessing for urinary tract infections, which can be common. Appropriate antibiotics should be started based on urinalysis, cultures, and sensitivities.

It is important to note that, in the cancer population, life expectancy often plays a part in rehabilitation management. Intermittent catheterization is the preferred method of management for the scenarios mentioned; however, a Foley catheter is sometimes used instead for ease and comfort in those patients with limited prognosis.

Bowel Management

Typically, with lesions above the conus medullaris, an upper motor neuron bowel dysfunction is present, with the muscles of the external anal sphincter and pelvic floor becoming spastic. The connection between the spinal cord and the colon remain intact and bowel and stool can be propelled by reflex activity. With lesions below the conus medullaris, an areflexic lower motor neuron bowel dysfunction is present, with the myenteric plexus intrinsically moving stool slowly⁽⁶²⁾.

A complicating matter with patients with cancer is opioid-induced constipation. This and other premorbid factors and current bowel function must be ascertained before instituting a bowel program. Often, a plain x-ray of the abdomen is obtained to assess for obstipation before beginning a bowel program. If obstipation is present, suppositories or enemas can be given to clean out the bowels and especially to evacuate the rectal vault.

The goals of a bowel management program are to prevent fecal impaction and to facilitate bowel evacuation on a routine schedule compatible with one's daily activities. This is a logical, structured program based initially on evaluation of the current bowel pattern. A bowel management program begins with a proper diet, which should contain adequate amounts of fluid and fiber to create soft bulky stools, which can decrease bowel transit time. Fatty foods can increase transit time. Medication management involves the introduction of a stimulant such as senna. A bisacodyl suppository can be used as an adjunct.

In stepwise fashion, a bowel program begins with an x-ray to determine whether evacuation by enemas is necessary; then, an appropriate diet is begun, along with stool softeners or stimulants. To take advantage of the gastrocolic reflex, the patient is placed on the commode approximately 30 minutes after a meal, preceded by a bisacodyl suppository 10 minutes before the patient is placed on the commode. In addition, manual digital stimulation 20 minutes after suppository insertion can induce the rectocolic reflex ⁽⁵⁷⁾.

Spasticity

Similar to brain injury, many patients with spinal cord injury suffer from spasticity, which is an abnormality of muscle tone and is velocity-dependent resistance to passive movement across a joint. In addition, they experience muscle flexor spasms, which also respond to the same treatment strategies as those used for spasticity.

Treatment begins with proper positioning and can also involve splinting, casting, stretching, range-of-motion exercises, and the use of medications. In contrast to spasticity originating from brain pathology, spasticity associated with spinal cord injury is treated medically, primarily with baclofen. Tizanidine is also an appropriate choice. In addition, chemical neurolysis, botulinum toxin, and—for severe cases—an intrathecal baclofen pump may be used.

REHABILITATION OF GENERALIZED DECONDITIONING AND ASTHENIA

Generalized weakness and deconditioning are common problems in patients with cancer, and they simply imply a loss of their prior state of conditioning.

Asthenia is also a common diagnosis in patients engaging in inpatient cancer rehabilitation. It implies a combination of weakness and decreased exercise tolerance arising from a number of factors, including muscle wasting, disuse atrophy, malnutrition, anemia, and cardiac or pulmonary comorbidities. Functional impact from asthenia can include difficulty with transfers and ambulation, difficulty with ADLs, and decreased balance with risk for falls.

Rehabilitation treatment can begin with increased sitting time and gentle range-of-motion exercises. This is followed by a progressive increase in exercise dose, duration, and intensity, along with instruction in fatigue management and balance training. It is also important to address other medical conditions, such as anemia, malnutrition, sleep, pain, and mood disorders. Short-term inpatient rehabilitation can be effective in improving functional status after an acute decline, and outpatient therapy can help in maintaining or more slowly improving functional performance. However, if the primary malignancy progresses, functional performance will likely deteriorate.

To better grasp these concepts, an understanding of basic muscle physiology is important. There are three types of muscle fibers. Type I muscle fibers are the slow-twitch oxidative metabolism fibers, which have slow fatigability and are used for prolonged activity. Type IIB fibers are the fast-twitch fibers, which use glycolytic anaerobic metabolism and have rapid fatigability. Type IIA is an intermediate fiber.

Prolonged bed rest can result in muscle weakness. In a classic study by Mueller, the muscles of a person on strict bed rest can decrease approximately 1.0% to 1.5% of their initial strength per day, corresponding to approximately a 10% to 20% loss of strength per week ⁽⁶³⁾. Antigravity muscles like the gastrocnemius and back extensor muscles tend to lose strength disproportionately, with larger muscles losing strength more quickly than smaller muscles; handgrip strength is unaffected ^(64,65). Type I fibers are more affected than type II fibers ⁽⁶⁶⁾.

These effects on muscles can be counteracted by a daily stretching program, which delays muscle atrophy ⁽⁶⁷⁾. In addition, daily isometric muscle contractions of 10% to 20% of maximal tension for 10 seconds can help maintain muscle strength ⁽⁶⁴⁾. Electrical stimulation of muscles can also be used. In general, it may take two or more times as long as the period of immobilization to recover muscle strength ⁽⁶⁸⁾.

Joint contracture is an abnormal limitation of passive joint range of motion and can be caused by prolonged immobilization. Typical contractures from immobilization include hip flexion, knee flexion, elbow flexion, and internally rotated shoulder contractures as well as ankle plantar flexion contractures. Once they have developed, contractures are

treated with range-of-motion exercises. For more severe cases, deep heating followed by range-of-motion exercises and serial casting may be necessary. One goal of nursing and inpatient therapy should be to prevent joint contractures before they occur. Hip flexion contractures can be prevented with the avoidance of an overly soft mattress and lying occasionally in a prone position. Dorsiflexion exercises and footboards can help prevent ankle plantar flexion contractures.

Immobilization can also affect the bones. Wolff's law states that the ratio of formation to resorption is influenced by the stresses to which bones are subjected. The primary stress on most bones is weight bearing, which causes a buildup of bone; a lack of stress on bones leads to a predominance of bone resorption. Weight bearing is eliminated when lying in bed in a supine position and can lead to disuse osteoporosis. This is best treated with preventive measures such as active muscle contraction and active weight-bearing exercises. Exercises conducted in bed are not particularly effective⁽⁶⁹⁾. Activities involving getting out of bed to a chair are encouraged as soon as possible.

There are cardiovascular effects from prolonged bed rest. The first such form of cardiac deconditioning is resting tachycardia. After a period of bed rest, the heart rate can increase by about one-half beat per minute each day for the first 3 to 4 weeks of immobilization⁽⁷⁰⁾. In addition, there are decreased diastolic filling times, with resultant decreased myocardial perfusion, decreased stroke volume with submaximal and maximal exercises, decline in cardiac output at submaximal exercise, and deleterious hemodynamic and orthostatic changes.

The treatment of the cardiovascular effects is mainly aimed at prevention. Sitting in a chair prevents deterioration of $\dot{V}_{O_{2max}}$ (maximum oxygen consumption) and orthostatic intolerance. Isometric exercise minimizes decreases in $\dot{V}_{O_{2max}}$ ⁽⁷¹⁾. Cardiovascular deconditioning can be reversed by a progressive increase in activity and regaining an upright posture. Orthostatic intolerance can be helped by range-of-motion exercises, progressive ambulation, abdominal strengthening, and leg exercises to reverse venous stasis. In addition, supportive treatments for orthostatic intolerance include the use of a tilt table, supportive garments, leg stockings, abdominal binders, and medications such as ephedrine, midodrine, and fludrocortisone acetate (Florinef Acetate).

Thrombotic complications, such as the development of a DVT or a pulmonary embolism (PE), are a risk of immobility. Virchow's triad states that hypercoagulability, endothelial injury, and stasis of blood flow are factors that can contribute to clot formation. Rehabilitation often begins after a prolonged state of immobility, and it is imperative we take measures to

prevent DVT or PE development. Patients should be mobilized, encouraged to ambulate, provided with external intermittent leg compression devices, and administered low-dose anticoagulation when contraindications are not present⁽⁷⁰⁾.

DURABLE MEDICAL EQUIPMENT

Patients with cancer may have a number of rehabilitation-related DME needs, both as inpatients and outpatients. Many are covered by Medicare and third-party payers when patients demonstrate appropriate need. These can include, but are not limited to, artificial limbs; braces (arm, leg, back, and neck); canes; commode chairs; continuous passive motion machines; crutches; orthotics; patient lifts; prosthetic devices; reachers; tub benches; walkers; wheelchairs; and other power mobility devices. Table 59-2 lists several commonly prescribed pieces of equipment with a few of their most common indications. Many variations exist within the categories of orthotics and DME mentioned. Thus, consultation between a trained a physiatrist, therapist, and orthotist may be required to ensure adequate performance, safe mobility, and optimization of self-care.

Table 59-2 Commonly Prescribed Orthotics and DME

Prescribed Equipment	Common Indications
• Ankle-foot orthosis	• Ankle dorsiflexion weakness or "foot drop"
• Neutral wrist-hand orthosis	• Median neuropathy at the wrist or "carpal tunnel syndrome"
• Shoulder sling	• Hemiparesis with shoulder pain due to glenohumeral subluxation
• Thoracic-lumbar-sacral orthosis	• Mild spinal instability or vertebral compression fractures
• Rolling walker	• Impaired mobility, balance, or proprioception
• Hemiwalker	• Hemiparesis with impaired mobility or balance
• Manual wheelchair	• Unsafe gait, poor endurance
• Bedside commode	• Impaired transfers to/from toilet
• Sliding board	• Impaired transfers in/out of bed or chair
• Tub transfer chair	• Impaired transfers in/out of shower
• Shower chair	• Poor endurance, impaired ADLs
• Reacher	• Impaired mobility or ADLs

PRESSURE ULCERS

According to the National Pressure Ulcer Advisory Panel (NPUAP), a pressure ulcer is an area of unrelieved pressure over a defined area, usually over a bony prominence, resulting in ischemia, cell death, and tissue necrosis. Incidence of pressure ulcers in the acute care setting is 7% to 9%; long-term care incidence is estimated to be between 3% and 31%; estimates for home care incidence are 0% to 17%. Patients with cancer have a number of risk factors that can place them at risk of developing pressure ulcers (Table 59-3).

The NPUAP staging system for pressure ulcers includes the following:

- Stage I: intact skin with nonblanchable redness of a localized area, usually over a bony prominence.
- Stage II: partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough.
- Stage III: full-thickness tissue loss; subcutaneous fat may be visible but bone, tendon, or muscle is not exposed.
- Stage IV: full-thickness tissue loss with exposed bone, tendon, or muscle.

In suspected deep-tissue injury, there is localized discolored intact skin or a blood-filled blister due to damage of underlying soft tissue from pressure or shear. An ulcer that cannot be staged is described as full-thickness tissue loss with slough or eschar covering the wound bed. The mainstay of pressure ulcer treatment is the off-loading of pressure. This is frequently accomplished by a turning schedule if the patient cannot get out of bed. If the patient is a wheelchair user, frequent position changes (up to every 20 minutes) are recommended.

Other interventions include the use of appropriate support surfaces for the bed and wheelchair, nutritional consultation, physical and occupational therapy consultation for mobility issues, and addressing incontinence. Topical dressings may be used based on

Table 59-3 Risk Factors for Pressure Ulcer Development

• Impaired proprioception	• Decreased activity	• Impaired mobility
• Decreased nutrition	• Friction/shear forces	• Advanced age
• Male gender	• Low body mass index	• Urinary or fecal incontinence
• Fever/sepsis	• Hypotension	• Dehydration
• Anemia	• Immunosuppression	• Renal failure

Table 59-4 Wound Characteristics and Topical Dressings

Wound Characteristic	Type of Topical Dressing
• Scant or small amounts of drainage	• Foam dressing, hydrocolloid, gel/gauze dressing, composite dressing, transparent film
• Moderate drainage	• Foam dressing, calcium alginate, hydrofiber
• Deep wounds	• “Filler” dressing followed by a cover dressing
• High drainage	• Negative-pressure drainage management system, calcium alginate/foam dressing combination; increase the frequency of dressing changes

wound characteristics (Table 59-4). Surgical treatment can include sharp debridement of devitalized tissue if the patient’s immune status allows, and plastic surgery may be able to assist with flap coverage. If available, wound care nursing specialists can also assess the wound and help guide treatment recommendations.

Pressure ulcer healing will also depend on improvement in the patient’s overall health and medical condition. Healed ulcers can have decreased tissue tolerance and are at risk for reinjury without ongoing prevention measures. Patients should be monitored throughout cancer treatment for signs of skin compromise or wound degradation.

THROMBOCYTOPENIA

Thrombocytopenia, along with the suppression of other cell lines, is commonly seen in patients with cancer. These findings are especially frequent in patients receiving chemotherapy or extensive irradiation, with resulting myelosuppression, bone marrow infiltration, and splenomegaly. Hematologic malignancies introduce a variety of associated complications, which previously limited implementation of intensive rehabilitation programs with patients at greatest risk. A rehabilitation program or exercise in a severely thrombocytopenic patient remains somewhat controversial. The major concern in this situation is the development of a spontaneous intracranial hemorrhage.

Dimeo et al monitored patients during a 6-week intensive aerobic exercise program after high-dose chemotherapy and autologous stem cell transplantation. The investigators did not exclude for neutropenia, anemia, or thrombocytopenia, but in the end, they observed no adverse effects. Based on this initial study, the authors proposed utilizing lower-limit thresholds of 20,000/μL for platelet counts and 1,500/μL for leukocyte

counts prior to safely engaging in a rehabilitation program ⁽⁷²⁾. With platelet counts over 5,000/mm³, another study found fatal intracranial hemorrhage in only 1 of 92 patients receiving chemotherapy ⁽⁷³⁾.

No clear guidelines exist, but one recommendation is to allow nonresistive activities at platelet counts between 5,000 and 10,000/mm³ and light resistive exercises with counts above 10,000/mm³, with ambulation allowed with counts above 5,000/mm³ ⁽⁷⁴⁾. Clinicians must use their own judgment with individual patients. In addition, platelet transfusions with counts below 10,000 should be performed in patients undergoing comprehensive rehabilitation.

EXERCISE IN CANCER

Long considered a time to decrease physiologic burden, treatment algorithms for many patients with cancer often neglected to incorporate physical exercise as a primary component of care. More recently, however, many studies have emerged not only quelling the idea of exercise causing significant undue harm but also substantiating the short- and long-term benefits of a well-constructed exercise program. Along the time spectrum of cancer prevention, treatment, and survivorship, patients may benefit from an individualized exercise regimen at each stage.

As the prevalence of cancer continues to climb, researchers have developed an increased interest in prevention strategies. According to the International Agency for Research on Cancer, obesity and a sedentary lifestyle may contribute to a quarter of new cancer cases. Women are at greatest risk, with nearly three times the rate of overweight- and obesity-related cancer ⁽⁷⁵⁾.

In addition to reducing the burden of primary risk factors, physical activity may serve as a cancer prevention strategy by directly improving musculoskeletal strength, endurance, balance, and flexibility, while indirectly enhancing the performance of the body's cardiovascular, pulmonary, neurologic, and immune systems. A systematic review performed by Rajarajeswaran ⁽⁷⁶⁾ found convincing evidence for average risk reduction in colon (40%-50%) and breast (30%-40%) cancers. Additional evidence suggesting reduced risk for the development of prostate, endometrial, lung, and many other cancers has also been identified, but the relatively sparse quantity of evidence available for review continues to limit the strength of our recommendations.

In addition to the more obvious direct effects, there is an increasing body of research demonstrating improved cancer- and treatment-related symptoms with moderate increases in activity ⁽⁷⁷⁾. Rehabilitation regimens including a combination of aerobic and resistance training have demonstrated improvements in body weight, body composition, flexibility, strength, fatigue, depression, anxiety, rigor, anger, mood, self-esteem, perception of well-being,

pain, nausea, diarrhea, functional capacity, and life satisfaction ⁽⁷⁸⁾. Many patients with cancer experience significant amounts of weight loss, particularly involving lean tissues. This problem may be exacerbated by hormone or chemotherapy treatments used to combat their primary malignancy and may contribute to generalized weakness and fatigue. Cornie et al ⁽⁷⁹⁾ evaluated the potential to reduce factors leading to treatment-related deconditioning while promoting those that would maintain or improve fitness. In a randomized controlled trial among 63 men with prostate cancer receiving androgen-deprivation therapy, participants performed at least weekly 150 minutes of moderate-intensity training during a 3-month period. Compared to the control group, the exercise group demonstrated preserved appendicular lean mass and prevented gains in whole-body fat and trunk fat mass. Between-group analyses also demonstrated significant improvements in peak oxygen consumption, muscle strength, cholesterol levels, sexual function, and fatigue.

Speck et al ⁽⁸⁰⁾ performed a comprehensive meta-analysis of 82 studies involving 6,838 cancer survivors and assessing 60 different outcome measures. Of the studies reviewed with high internal validity, nearly all demonstrated positive effects of exercise on their respective primary outcome measures (Table 59-5). Additional studies also demonstrated positive effects on lean body

Table 59-5 Outcome Measures Improved With Exercise

Outcome Improvements During Treatment	Outcome Improvements Post treatment
• Physical activity	• Physical activity
• Aerobic fitness	• Aerobic fitness
• Upper body strength	• Upper body strength
• Lower body strength	• Lower body strength
• Body weight	• Body weight
• Body fat percentage	• Body fat percentage
• Functional quality of life	• BMI
• Mood	• Overall quality of life
• Anxiety	• Breast cancer-specific concerns
• Self-esteem	• Perception of physical condition
	• Mood disturbance
	• Confusion
	• Body image
	• Fatigue
	• General symptoms and side effects
	• Insulinlike growth factor 1 levels

mass, lower body flexibility, vigor/vitality, IFG-BP-III levels, pain, breast cancer subscale, and immune parameters such as neutrophil count, natural killer cell activity, C-reactive protein, and cytokines.

Significantly improved weighted mean effect sizes of outcomes were stratified by timing of rehabilitation administration ⁽⁷⁹⁾.

Safety of Exercise in Cancer

The reason for the limited numbers of intensive exercise regimens for patients with cancer is likely multifactorial but may often emanate from patient and provider fears. Cheville ⁽⁸¹⁾ interviewed a group of patients with late-stage non-small cell lung cancer and identified potential exercise barriers that included fear of harm and a lack of direction from their physician. Patients were found to be less receptive to guidance from ancillary health professionals, but early expert consultation with a physiatrist may prove helpful in formulating an individualized rehabilitation program with medical monitoring as it may alleviate some potential barriers.

Reported adverse events following a structured rehabilitation program are primarily limited to musculoskeletal injuries. Patients with breast cancer and survivors are among the most commonly studied, and population-specific concern exists for exacerbation of lymphedema ⁽⁸²⁾. However, evidence suggests breast cancer survivors undergoing a strength training protocol demonstrate a reduced risk of lymphedema exacerbations, while improving strength and bone mineral density ^(83, 84).

Hayes et al ⁽⁸⁵⁾ allocated patients following stem cell transplantation to a control group receiving a stretching program and an intervention group receiving an aerobic and resistance program performed three times a week over 3 months. Similar to findings of studies in solid tumor populations, results demonstrated increased recovery of fat-free mass and no significant body weight differences at the conclusion of the intervention period.

Prescribing Exercise in Cancer

With growing amounts of data supporting the benefits of exercise along the cancer diagnosis and treatment continuum, there has grown an emerging need for expert clinical exercise guidelines. The 2008 US Department of Health and Human Services (US DHHS) report of physical activity guidelines for Americans provides a generic foundation for patients with cancer to follow. The report recommends patient participation in physical activities as their abilities and conditions permit, with a goal weekly duration of 150 minutes of moderate intensity or 75 minutes of vigorous intensity (Fig. 59-4) ⁽⁸⁶⁾.

In 2009, the American College of Sports Medicine (ACSM) assembled an expert panel of 13 researchers and clinicians to evaluate the available evidence of safety and benefits of exercise in cancer. In the ACSM report, studies were stratified by cancer type, and the strength of evidence was assessed on the basis of several outcome measures. Many risks specific to particular cancer types have been outlined, but the

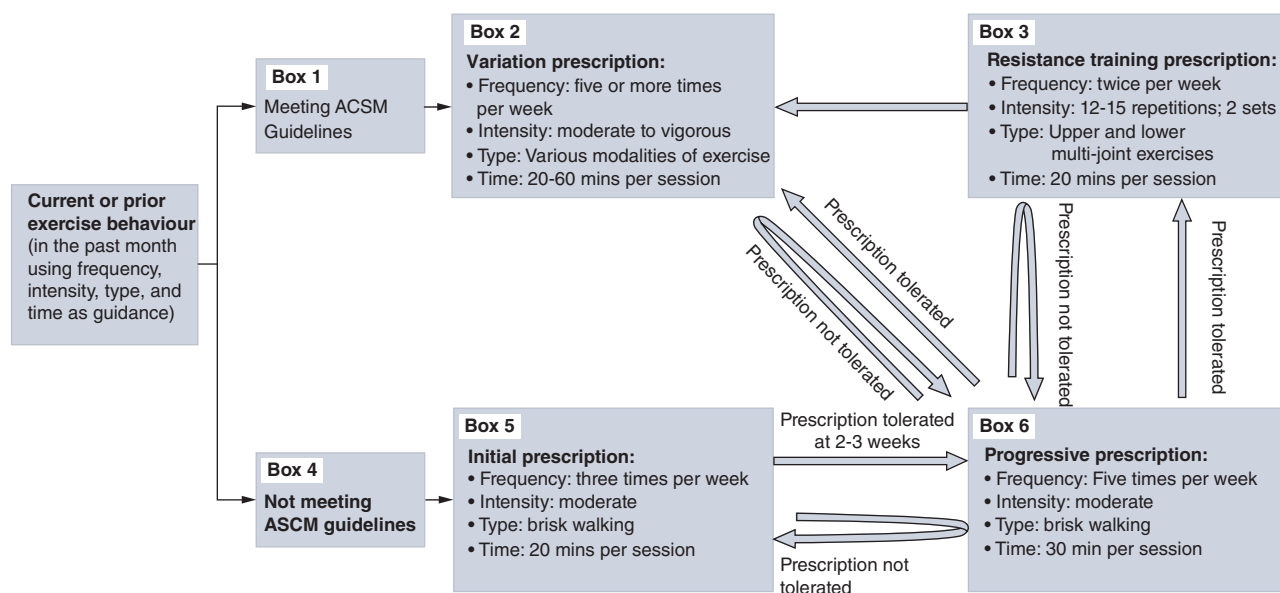

FIGURE 59-4 A model for prescribing an appropriate exercise regimen for a cancer patient. Reproduced with permission from Jones LW, Eves ND, Peppercorn J: Pre-exercise screening and prescription guidelines for cancer patients, *Lancet Oncol* 2010 Oct;11(10):914-916.

experts concluded that exercise testing and prescriptions are safe and efficacious for patients with cancer. The authors recommended utilization of 2008 US DHHS guidelines for aerobic training and supported the addition of resistance training exercises for a comprehensive rehabilitation program ⁽⁸⁸⁾.

Current research is demonstrating improved mortality in patients with cancer participating in an exercise program. However, due to the observational nature of many of these studies, significant variability exists in the prescribed intensity, frequency, duration, and combination of exercises. A clear dose response has yet to be established, and future research may require a more detailed evaluation of tumor marker expression and a patient's immunologic, hormonal, and metabolic factors, much in the same way targeted medical therapies are based on host factors ^(89, 90).

ELIMINATING BARRIERS

In the face of chronic disease or acute illness, the goal of rehabilitation is to restore a meaningful transition back to one's previous state of health and level of functional performance. The absence of function invokes the term *disability*. The WHO defines disability as "a complex phenomenon, reflecting the interaction between features of a person's body and features of the society in which he or she lives." To better elucidate such problems, health-care providers must first seek to identify a problem within a particular body structure or system, defined as the "impairment." Some impairments may directly or indirectly result in difficulty performing a specific task or action, coined an "activity limitation" or alternatively, a "disability." If an individual is unable to perform a specific activity in his or her normal environment or community, the individual is described as having a "participation restriction" ⁽⁹¹⁾.

Identifying each patient's unique set of impairments, activity limitations, and participation restrictions is an initial step in defining functional concerns. Unfortunately, such concerns are often missed by many primary and consulting providers. On reviewing 6 months of previous electronic medical record notes, Cheville et al found oncology patient-reported symptoms to be fairly well documented in the medical record, while activity limitations were very unlikely to be noted. Referrals for such problems were yet rarer, leaving a significant gap in functional problems requiring further assessment and those that were addressed ⁽⁹²⁾.

Physiatrists are optimally trained to help facilitate a patient's transition from illness, and its associated medical care, to home with functional restoration. With the appropriate tools and resources, we can modify, support, or remove impairments to focus on strengths and

abilities. In general, musculoskeletal injuries are among the most common causes of debility and contribute to a great deal of functional impairment. In a population of patients with cancer, these injuries may be overlooked due to more serious illnesses, but a well-trained physiatrist is well equipped to detect, diagnose, and treat them. If resolution of an impairment is feasible and presents relatively low risk, treatment should be pursued to alleviate activity limitations (Table 59-6). If treatment is inappropriate or not feasible, a physiatrist may employ alternative strategies, such as orthotics or DME, to reduce the burden of activity limitations and participation restrictions.

Employment-Related Disability Management

Impairment and disability evaluations are complicated by the fact that there are considerable variations between objectively measured impairments and subjectively reported disability. Psychological, social, and behavioral factors must be recognized as significant contributors to the relationship between impairment and disability.

Increasing survivorship among patients with cancer has led to an increased focus on disability. Many cancer survivors are unable to work secondary to the effects of chemotherapy, operations, the tumor itself, and symptoms associated with the tumor, including chronic pain and fatigue. The patient may have been cured of the cancer, but the patient must live with the sequelae of those treatments. It has been reported that 38% of cancer survivors are working age ⁽⁹³⁾. Survivors frequently wish to return to work for continued insurance benefits, income, and self-esteem. Quality-of-life assessments show that employed cancer survivors have a higher quality of life. It provides a sense of normalcy and control when cancer takes control away from other aspects of their lives ⁽⁹⁴⁾. Survivors may report an inability to work for a variety of reasons, including fatigue, physical limitations, emotional problems, changing personal priorities, cognitive deficits, awkward interaction with coworkers, and unsympathetic employers ⁽⁹⁵⁾.

Yankelovich surveyed 200 supervisors of cancer survivors in two studies. Of the supervisors, 66% were concerned about the cancer survivor's ability to work. Prior to the survivor returning to work after cancer treatment, 33% believed the survivor would not be able to handle the job, and 31% believed the survivor needed to be replaced. After the survivor returned to work, 34% of supervisors and 43% of coworkers were less concerned regarding the survivor's ability to work. About 50% of supervisors admitted that a cancer diagnosis would affect their decision to hire ⁽⁹⁶⁾. Ferrell surveyed 662 fellow employees of cancer survivors.

Table 59-6 Adjunctive Diagnostic and Treatment Interventions Which May Be Employed by a Trained Physiatrist^a

Procedure	Indication	Common Sites
• Botulinum toxin injection for chemodenervation	<ul style="list-style-type: none"> • Upper motor neuron or mixed motor neuron injury leading to spasticity or dystonia • Migraine headache • Spasmodic torticollis • Trismus • Postmastectomy syndrome • Postradiation muscle spasms 	<ul style="list-style-type: none"> • Shoulder internal rotators • Upper and lower extremity flexors • Lower extremity adductors • Facial and suboccipital musculature • Sternocleidomastoid, scalene, trapezius, levator scapularis musculature • Muscles of mastication • Shoulder adductors and internal rotators • Location dependent
• Phenol injection for chemical neurolysis	<ul style="list-style-type: none"> • Upper motor neuron or mixed motor neuron injury leading to spasticity or dystonia • Painful neuroma • Trigeminal neuralgia • Spasmodic torticollis 	<ul style="list-style-type: none"> • Terminal motor branch of femoral, obturator, tibial nerves • Morton's (intermetatarsal) neuroma • Postamputation neuroma • Terminal branch of trigeminal nerve • Sternocleidomastoid, scalene, trapezius, levator scapularis musculature
• Corticosteroid injection	<ul style="list-style-type: none"> • Arthritis • Rotator cuff tendinopathy • Bursitis • Adhesive capsulitis • Carpal tunnel syndrome 	<ul style="list-style-type: none"> • Shoulder and knee joints • Subacromial or glenohumeral space • Subacromial and trochanteric bursae • Shoulder • Wrist
• Hyaluronic acid injection	• Degenerative arthritis	• Knee joint
• Trigger point injection	• Muscle spasm with painful trigger points	• Trapezius, levator scapularis, rhomboid musculature
• Prolotherapy	<ul style="list-style-type: none"> • Tendinopathy • Fasciitis • Enthesopathy 	<ul style="list-style-type: none"> • Achilles or patellar tendons • Plantar fascia • Origin of extensor carpi radialis brevis (ECRB) musculature for "tennis elbow"
• Electrodiagnostic study	<ul style="list-style-type: none"> • Foot drop • Carpal tunnel syndrome • Ulnar neuropathy • Radiculopathy • Brachial plexopathy • Guillain-Barre syndrome • Peripheral mono- or polyneuropathy of unknown origin 	• Nerve conductions and needle electromyography of upper and/or lower extremities +/- Paraspinal musculature
• Diagnostic dynamic ultrasound	<ul style="list-style-type: none"> • Tendinopathy • Enthesopathy • Bursitis • Baker's cyst • Carpal tunnel syndrome 	<ul style="list-style-type: none"> • Rotator cuff, Achilles, gluteus medius, patellar tendons • ECRB • Subacromial, greater trochanteric, pes anserine bursae • Popliteal fossa • Median nerve proximal to and within carpal tunnel

^aNot intended to serve as an exhaustive list.

Of these fellow employees, 14% felt that cancer survivors probably would not be able to do their job, and 27% of workers felt that they would have to pick up the slack of their cancer survivor colleague (⁹⁷).

Of patients with cancer, 20% report some cancer-related disability. However, most working patients with cancer do return to work after treatment. At

1 year, 73% are employed, and 84% are at 4 years. Patients with central nervous system, head and neck, and stage IV hematologic cancer had the highest risk of disability. Also, patients who were involved in more physically demanding work, were less educated, were women, and were of older age were less likely to return to work after treatment. Also, 87% reported that

their employer was accommodating ⁽⁹⁸⁾. Of employed cancer survivors, 54% reported having to adjust their work schedule during their cancer treatment ⁽⁹⁹⁾. The Americans With Disabilities Act of 1990 brought legislative protection to cancer survivors with disabilities. It requires employers to make “reasonable accommodation” for employees with disabilities and prevents discrimination in pay, hiring, firing, fringe benefits, and working conditions. It also requires employers to make accommodations for family members that are not an “undue hardship.” Accommodations can include extended leave, flexible work schedules, permitting working from home, changing work environment, and allowing rest periods.

If there is uncertainty regarding whether a cancer survivor can return to work, several options are available. If the primary concern is energy and endurance, the cancer survivor’s hours are gradually increased each week, with the patient reporting any difficulties to the physician. When issues of coordination, strength, or endurance are uncertain, a functional capacity evaluation can be performed by a physical or occupational therapist. The evaluation can be useful for determining tolerance for lifting, bending, squatting, and the like. Often, the therapist is able to replicate the duties of the patient and recommend ergonomic or environmental modifications if necessary.

Without proper psychiatric training and experience, a variety of impairments may serve as barriers to initiating or maintaining exercise programs for patients with cancer. There is no doubt that social, economic, and psychological factors often also present significant problems for the successful implementation of a rehabilitation program. The involvement of a multidisciplinary team is essential to adequately address such problems. The assistance of a social worker, case manager, chaplain, registered dietician, registered nurse, and the appropriate therapists working with a psychiatrist as an experienced team can be a great asset for a patient or family with multidisciplinary needs.

REHABILITATION AT THE END OF LIFE

Mackey described caregiver concerns, which can include fear of hurting the patient physically by moving the patient, fear of hurting themselves when moving or transferring the patient, and a lack of clarity regarding how hard to push the patient. Family education in transfer training and positioning can decrease caregiver stress of providing care and also the patient’s concern about being a burden.

The practices of cancer rehabilitation and palliative care share several similarities. Both support quality of life and relieving discomfort. The framework for

intervention can be similar with a multidisciplinary team to adequately assess and treat the patient. Both have an emphasis not only on the disease process but also on physical symptoms, limitations of the patient, and how to improve or relieve them. Both emphasize the family in patient care and education. Rehabilitation interventions at the end of life can include mobility and ADL training, positioning and pressure relief techniques, chest physiotherapy, swallow therapy, edema management, and physical modalities to treat pain and bracing and splinting to relieve pain and assist with mobility.

FUTURE OF CANCER REHABILITATION

Survivorship

There are 13.7 million Americans who are cancer survivors. That number is expected to increase to 18 million by 2022 ⁽¹⁰⁰⁾. According to the National Coalition for Cancer Survivorship, a cancer survivor is any person diagnosed with cancer from the time of initial diagnosis until his or her death ⁽¹⁰¹⁾. This definition includes patients receiving active treatment for malignant disease. The numbers of long-term cancer survivors without evidence of disease is also growing. These growing numbers of long-term cancer survivors suffer from a multitude of disabilities that were acquired during cancer treatment. Rehabilitation can help patients with hemiparesis ⁽¹⁰²⁾, neuropathy/plexopathy ⁽¹⁰³⁾, myopathy ⁽¹⁰⁴⁾, chronic fatigue ⁽¹⁰⁵⁾, radiation fibrosis syndrome ⁽¹⁰⁶⁾, postmastectomy pain syndrome, cognitive deficits ⁽¹⁰⁷⁾, lymphedema ⁽¹⁰⁸⁾, spasticity ⁽¹⁰⁹⁾, cervical dystonia ⁽¹¹⁰⁾, trismus ⁽¹¹¹⁾, and chronic musculoskeletal pain ⁽¹¹²⁾. Once the focus has been changed from surviving the cancer to quality of life, rehabilitation often plays an integral role. The bulk of the growth in the field of cancer rehabilitation over the past two decades has been surrounding the growth in the numbers of long-term cancer survivors. This rehabilitation is predominantly provided in outpatient clinics.

Increasing Recognition

Cancer rehabilitation has suffered from underreferrals by oncologists and lack of availability at many cancer centers ⁽¹¹³⁾. Cancer rehabilitation education is still lacking in PM&R departments ⁽¹¹⁴⁾. However, the field has experienced tremendous growth and increasing acceptance over the past 5 to 10 years. Cancer rehabilitation has become increasingly viewed as important by psychiatry academic departments across the United States ⁽¹¹⁴⁾. Furthermore, cancer rehabilitation research publications have grown at a significantly faster rate than the whole field of rehabilitation ⁽¹¹⁵⁾.

Exercise and Cancer Survival

Most of the prior research in the field of cancer rehabilitation has shown improvements in quality of life, function, symptoms, and cardiopulmonary and muscular strength benefits. It has been noted that patients with a lower functional status have a higher risk of graft-versus-host disease and reduced survival⁽¹¹⁶⁻¹²⁰⁾. Some studies have shown possible beneficial effects of exercise programs on medical outcomes of patients with cancer, including survival⁽¹²¹⁾. The mechanisms for improved survival could be because performance status does have an impact on treatment decisions, treatment completion rates, treatment response, disease progression, and death from other causes⁽¹²²⁾. This has led some to call exercise a cancer “medicine” that should be discussed with all oncology patients.

In 1980, Dietz described four types of cancer rehabilitation. The first was called preventive rehabilitation⁽¹²³⁾. This concept has been more recently coined as “prehabilitation.” While the concept of prehabilitation is not unique to cancer, it has become of great interest to cancer researchers. Several studies have been published in the recent past, mostly regarding patients receiving oncologic surgery. The results suggest better medical and surgical outcomes with prehabilitation programs⁽¹²⁴⁻¹²⁸⁾. However, further study is needed.

The Anti-Inflammatory Effects of Exercise

The anti-inflammatory effects of physical activity may also contribute to improved survival. The role of inflammation in cancer symptoms has been well established in multiple studies. Exercise has been shown to reduce cancer symptoms, including fatigue, appetite, and cognitive dysfunction, presumably through an anti-inflammatory mechanism. A hyper-inflammatory state has been shown to be involved in the development of several maladies, including cardiovascular disease, Alzheimer’s dementia, and cancer. Inflammation also plays a role in tumor progression and proliferation^(129, 130). This has resulted in an increased interest in anti-inflammatory treatments. Research has identified the anti-inflammatory effects of exercise in different patient populations, including those with cancer^(131, 132).

Return to the Primary Acute Care Service

It has been shown that cancer rehabilitation inpatients are transferred back to the primary acute care service more frequently than patients without cancer⁽¹³³⁾. The medical fragility of these patients has led to interest in identifying predictors of medical complications while on inpatient rehabilitation. Published research

has identified a number of factors in general oncology patients^(134,135) and more specific groups, including those with lymphoma⁽¹³⁶⁾, leukemia⁽¹³⁷⁾, or hematopoietic stem cell transplantation⁽¹³⁸⁾. The presence of antimicrobial agents, elevated creatinine, and thrombocytopenia at the time of inpatient rehabilitation transfer have been identified as possible predictors of transfer back to the primary acute care service.

Long-Term Survivorship in Adult and Pediatric Cancer

Ravin Ratan
Joann Ater
Alyssa G. Rieber
Maria A. Rodriguez

INTRODUCTION

Over the last four decades, substantial improvements in treatment effectiveness for childhood and adult cancers have resulted in cure or increased survival for these populations. Over 80% of all patients diagnosed with cancer before the age of 20 years will be surviving at 5 years. As a consequence of both improved survival rates and increasing incidence of childhood cancer, the number of long-term survivors of childhood cancer in the United States is rapidly increasing. An estimated 320,000 or more childhood cancer survivors are living in the United States, and at least 75% of these survivors are now adults. Of these, 24% have survived more than 30 years^(1,2). These individuals are living long enough to demonstrate the lifelong consequences of the cancer and treatments^(3,4). The numbers of adult cancer survivors are growing as well, with an estimated 18 million adult survivors in the United States by 2022 (Fig. 60-1).

In 2006, the Institute of Medicine published *From Cancer Patient to Cancer Survivor: Lost in Transition* (Hewitt M, Greenfield S, Stovall E. *From Cancer Patient to Cancer Survivor: Lost in Transition*. Washington, DC: National Academies; 2006). This seminal report defined the “essential” components of survivorship care as (1) prevention of recurrent and new cancers; (2) surveillance for recurrence, secondary cancers, and medical effects of treatment; (3) intervention for the sequelae of cancer and its treatment; and (4) coordination of care between specialists and primary care providers. Other chapters address disease-specific surveillance; this chapter expands on the first three components of the report.

SCREENING FOR SECONDARY MALIGNANCIES

Patients who have been treated for a cancer are at higher risk for a second primary cancer or recurrence of their primary tumor, most particularly at the time of their transition from active cancer treatment to survivorship. In fact, second- and higher-order cancers accounted for as many as 16% of incident cancers in the SEER (Surveillance, Epidemiology, and End Results Program) database as of 2003⁽⁵⁾. The reasons for this are varied based on malignancy and include factors related to previous therapy (radiation, chemotherapy, hormonal therapies); previous or ongoing exposure to carcinogens; predisposing conditions (tobacco, alcohol, sun exposure, dietary influences, immunologic dysfunction); and familial genetic syndromes, including the *BRCA1* and *BRCA2* breast cancer syndromes, Bloom’s syndrome, Cowden’s syndrome, Li-Fraumeni, Lynch syndrome, and others⁽⁶⁾. The confluence of these factors, which are increased in their incidence in the population of cancer survivors, necessitates a careful approach to screening for second malignancies. In some cases, this entails increased surveillance for patients who have known risk factors related to their previous cancer or its treatment. For others, the cancer survivorship care provider must pay close attention to the best-practice screening guidelines that already exist for the greater population at large.

In survivors of childhood cancer, these issues are magnified. As childhood cancer survivors progress through adulthood, the risk of subsequent malignant neoplasms (SMNs) increases. Among 14,359

FIGURE 60-1 Estimated and projected number of cancer survivors in the United States. Reproduced with permission from de Moor JS, Mariotto AB, Parry C, et al: Cancer survivors in the United States: prevalence across the survivorship trajectory and implications for care, *Cancer Epidemiol Biomarkers Prev* 2013 Apr;22(4):561-570.

individuals who were 5-year survivors of childhood cancer at median of 30 years (range 5-56 years) the cumulative incidence was 20.5% at 30 years for subsequent neoplasm, representing a sixfold increased incidence compared to the age-adjusted general population (standardized incidence ratio, SIR) (7). The most frequent subsequent malignancies were nonmelanoma skin cancer and breast cancer. Patients treated in childhood for Hodgkin’s lymphoma and Ewing sarcoma had the highest risk (SIR 8.7 and 8.5, respectively). While the majority of SMNs are diagnosed within the first 10 years, they can occur up to 30 years after the original cancer diagnosis, with secondary leukemia having shorter latency than solid tumors (Table 60-1). Of solid tumors, the highest risks were observed for bone cancer (SIR 19), thyroid cancer (SIR 10.9), breast cancer (SIR 9.8), central nervous system (CNS) malignancies (SIR 10.4), and soft tissue sarcoma (SIR 8.1). In addition, survivors are at increased risk for other cancers, such as head and neck, kidney, bladder, lung, gastrointestinal and colon, and genitourinary cancers.

The increased risk of second malignancies is particularly well described in survivors of Hodgkin’s lymphoma (8-11). Radiation therapy, particularly when

Table 60-1 Screening for Subsequent Malignant Neoplasms in Childhood Cancer Survivors

Second Malignant Neoplasm	Risk Factors	Screening Recommendations
Skin cancer	10%-20% of patients; increased risk in irradiated skin	Annual skin exams by dermatologist; close monitoring of irradiated skin and palms and soles
Breast cancer	Risk in women younger than 30 years is elevated 5 to 54 times depending on radiation dose to thorax	Yearly mammograms or magnetic resonance imaging of breasts beginning 8 years after radiation or age 25 years, whichever occurs later, for women who had chest radiation
Thyroid cancer	Increased risk with radiation to head, neck, or chest	Annual history and physical examination; free thyroxine, thyroid-stimulating hormone tested yearly; thyroid ultrasound every 3-4 years after treatment completion or sooner if nodule is found
Leukemia (acute myeloid leukemia/ myelodysplastic syndrome)	Increased risk with exposure to alkylating agents, topoisomerase inhibitors	Annual history and physical examination, including complete blood cell count with differential and platelet count (highest risk first 5 years after exposure)
Brain tumors	Increased risk with cranial radiation; the younger the age at primary diagnosis, the greater the risk; received cranial radiation for brain tumor, acute lymphoblastic leukemia, some head and neck sarcomas	Latency period 9 to 10 years after radiation; monitor with annual history and physical examination, including yearly neurological exam (more often if indicated by examination or symptoms)
Other carcinomas	Can occur in patients who have or have not undergone radiation therapy	Latency period 5 to 30 years, median 15 years; yearly history and physical examination; if abdominal radiation: colon cancer screening with colonoscopy every 10 years beginning 15 years after completion of treatment or at age 35 years, whichever is later

delivered in adolescence, is known to be a predisposing factor for a host of second cancers in the radiation field, including cancers of the skin, breast, lung, and connective tissue⁽⁸⁾. Moreover, there is evidence to suggest that receiving chemotherapy in addition to radiation may increase the risk of subsequent development of solid tumors. Thus, it is not surprising that the risk of acute myeloid leukemia is also increased, likely due to both radiation exposure and the use of alkylating agents during treatment⁽¹¹⁾.

The recognition that patients who have received mantle radiation have a higher risk of malignancy has led to the tailoring of screening recommendations, particularly those regarding breast cancer, to address this increased susceptibility⁽¹²⁾. While formal guidelines for screening for cancer at sites other than the breasts in the involved fields do not exist, a key function of interval updates to history and physical exam during survivorship care is to focus on these important possible late complications of cancer treatment.

Like survivors of Hodgkin's lymphomas, there is significant literature regarding the importance of second cancers in patients with primary head and neck neoplasms^(13, 14). The human papilloma virus (HPV) is an important causative agent of oral and oropharyngeal cancers and also anal, vaginal, and cervical cancers. That said, there is little literature regarding synchronous or metachronous primary tumors of the anus or uterine cervix in patients with oral index tumors. Perhaps more

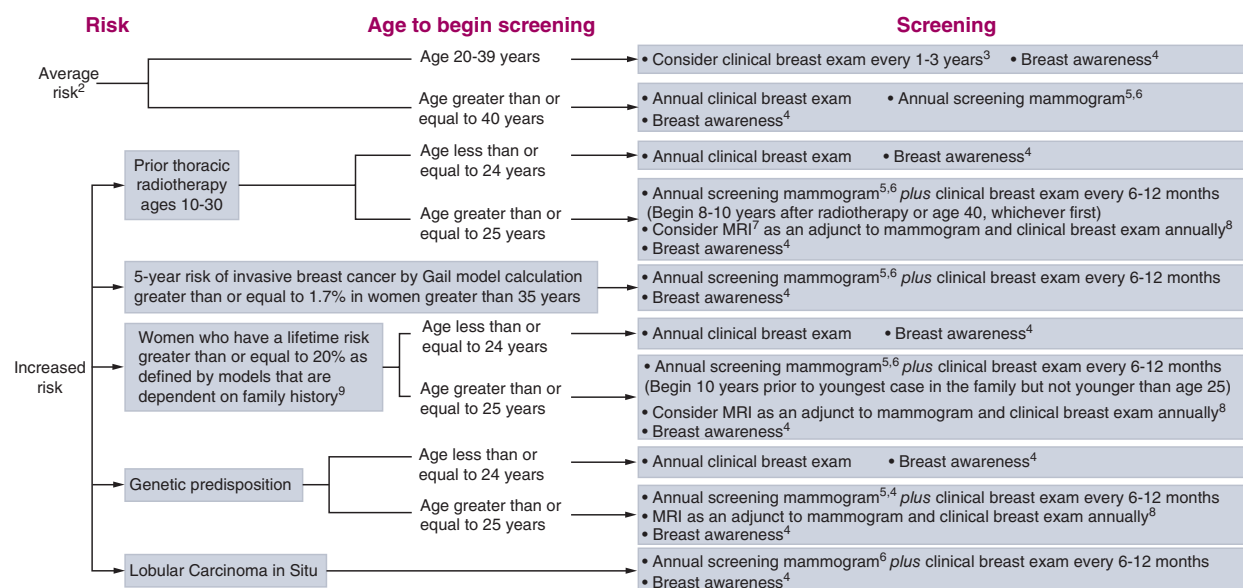

important, tobacco use is a major risk factor for this category of cancers, as well as for cancers of the lung, bladder, and other sites. Consequently, as many as a third of deaths in patients with head and neck cancers are attributable to second primary cancers, a larger number than those that die from distant metastases from the first tumor. In a recent analysis based on SEER data, the incidence and type of second cancers varied based on the site of primary tumor. Patients with index oral and oropharyngeal cancers had more second head and neck tumors, while patients with hypopharyngeal and laryngeal cancers had more lung cancers as their second primary, likely reflecting the diminished importance of HPV infection and increased contribution of tobacco exposure as a cause of cancer at these sites.

While the volume of literature regarding second tumors in survivors of other cancers varies, the survivorship care provider must understand that any survivor of cancer or cancer treatment may be at risk. Like primary tumors, occurrence of second cancers is due to a confluence of environmental exposures, behavioral influences, and genetic milieu.

Site-Specific Screening for Second Tumors

Breast Cancer Screening

The most important factor modifying breast cancer screening (Fig. 60-2) in cancer survivors is a history

¹Please see the Breast Cancer Treatment or Survivorship algorithms for the management of women with a personal history of breast cancer.

²Women who do not meet one of the increased risk categories.

³Effectiveness of clinical breast exams has not been assessed in women 20-39 years of age.

⁴Women should be familiar with their breasts and promptly report changes to their healthcare provider.

⁵Augmented breasts need additional views for complete assessment.

⁶3D screening mammography is not yet standard of care but may be considered as a supplement to 2D mammography.

⁷Risk of breast cancer begins to increase 8-10 years after thoracic exposure. The optimal age to begin MRI screening in this high risk population is not currently known.

⁸Current practice at M.D. Anderson is to alternate the mammogram and breast MRI every 6 months. While there are no data to suggest that this is the optimal approach, it is done with the expectation that interval cancers may be identified earlier. Other screening regimens, such as breast MRI done at the time of the annual mammogram, are also acceptable.

⁹Risk models that are largely dependent on family history include Tyrer-Cuzick and Claus.

FIGURE 60-2 MD Anderson breast cancer screening algorithm.

of radiation exposure to the chest. Of women who received radiation therapy involving the breast during childhood and adolescence, 13% to 20% will go on to develop a breast malignancy by the age of 40 to 45 years. This risk is most pronounced for women who received 20 Gy or more of radiation to breast tissue, but the increased risk is measurable even among women who received 1 to 9 Gy. International consensus guidelines recommend starting screening at age 25 or 8 years after treatment, whichever comes last, for women who received 20 Gy or more of radiation, with individualization of the screening approach for women who received lower doses of radiation. Our approach at MD Anderson involves starting at age 25 or 8 to 10 years after exposure to radiation, whichever comes first, and we alternate annual mammograms and annual magnetic resonance imaging (MRI) every 6 months, with clinical breast exam done annually. While we acknowledge that data to support the use of MRI as the optimal approach in these patients is still in evolution, this modality has the added benefit of sparing additional radiation exposure while providing excellent imaging detail. Thus, the use of MRI in breast cancer screening has greatly increased over the last decade, particularly in the pool of high-risk women⁽¹⁵⁾.

Similarly, for those patients who are diagnosed with predisposing familial syndromes during the workup for their breast cancers, we recommend annual MRI and mammograms, alternating every 6 months, with clinical breast exams every 6 to 12 months. The recommendations are similar for women with a lifetime breast cancer risk of 20% or more based on models that take into account family history. While screening recommendations for other survivors of breast cancer without identified predispositions do not materially differ from those for the general population, it is acknowledged that these women represent a higher-risk pool, and as such, adherence to screening regimens is of increased importance.

Colon Cancer

Colon cancer screening is also of increased importance among cancer survivors. There are several familial syndromes that predispose to both primary and second colon cancers, including the Lynch syndrome and familial adenomatous polyposis (FAP). In addition, environmental, dietary, and immunologic factors may contribute to an increased risk of second colonic primary in patients with a previous history of colorectal cancer or polyps. Thus, patients with a history of colon cancer require increased frequency of screening for second colorectal primary tumors indefinitely. In the MD Anderson colorectal screening guidelines, we suggest screening colonoscopy every 5 years in long-term survivors. For patients with adenomas at the time

of colonoscopy, more frequent screening is recommended (Fig. 60-3).

Colonoscopy

For patients with a diagnosis of Lynch syndrome, some of whom may have a history of gynecologic or other solid tumors, colorectal cancer screening is recommended starting at age 25 or 10 years prior to the earliest colorectal cancer in the immediate family, with colonoscopies every 1 to 2 years thereafter.

Cervical Cancer

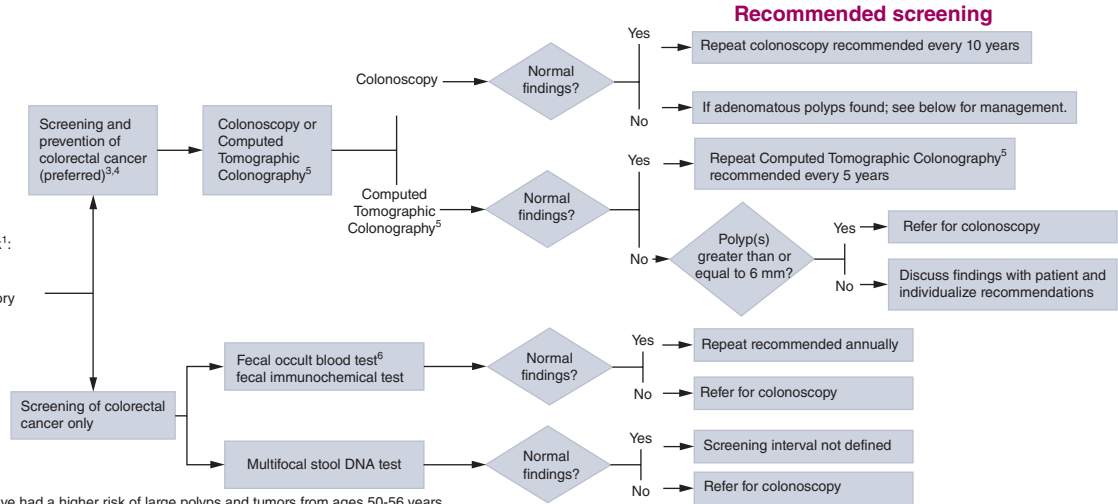

The decreased incidence of cervical cancer-related mortality in the United States is related primarily due to widespread screening for premalignant lesions by Papanicolaou testing. Screening for cervical cancer is logically important in survivors of HPV-associated malignancies, including cervical, anal, and oral cancers as these patients likely have a history of high-risk HPV exposures, in addition to possible immunocompromised or other risk factors. In addition, tobacco exposure is an important risk factor that may predispose survivors of other tobacco-related tumors to cervical cancer. Screening for this disease may be particularly important in survivors of adolescent and young adult cancers. In a recent study based on SEER data, it was noted that survivors of pediatric and young adult cancers seem to have a younger age of onset for cervical cancer than the overall population (33 vs 40 years). It is possible that this effect is explained by a surveillance bias. Survivors of pediatric cancer are likely to receive more frequent screening examinations, but this effect deserves further study⁽¹⁶⁾.

The cervical cancer screening guidelines of MD Anderson do not change for patients with a history of previous cancer. We recommend a liquid-based Papanicolaou test every 3 years for women from ages 21 to 29. Starting at age 30 until age 65, we recommend a liquid-based Papanicolaou test with high-risk HPV testing. If high-risk HPV testing is done and negative, repeat tests should be done every 5 years. If high-risk HPV testing is not done, the screening interval is every 3 years. For patients with abnormal Papanicolaou tests or positive high-risk HPV, appropriate workup according to diagnostic algorithms is recommended.

Ultimately, screening procedures for these and other malignancies will continue to evolve as additional information becomes available. The key point for the provider caring for the cancer survivor is that having a previous malignancy may predispose to additional cancers in the future and certainly is not protective against subsequent primaries. Therefore, attention to cancer screening is of critical importance in preventing or mitigating morbidity and mortality in survivors of a first cancer.

Presentation

- Patients with average risk¹:
- Age 50 years or older
 - No history of adenoma
 - No history of inflammatory bowel disease
 - Negative family history

¹African Americans have had a higher risk of large polyps and tumors from ages 50-56 years, thus it is important to start screening this population at age 50. Follow-up frequency would be based on colonoscopy findings.

²See the Colorectal Cancer Treatment or Survivorship algorithms for the management of individuals with a personal history of colorectal cancer.

³While there is good evidence to support Fecal Occult Blood Test, tests that both screen for and prevent colon cancer are the preferred screening modality. Annual Fecal Occult Blood Tests should not be performed if colonoscopy or CT colonography is used as the screening measure in an average-risk patient.

⁴Flexible sigmoidoscopy is an alternate option, but is not the preferred endoscopic modality as the entire colon is not visualized.

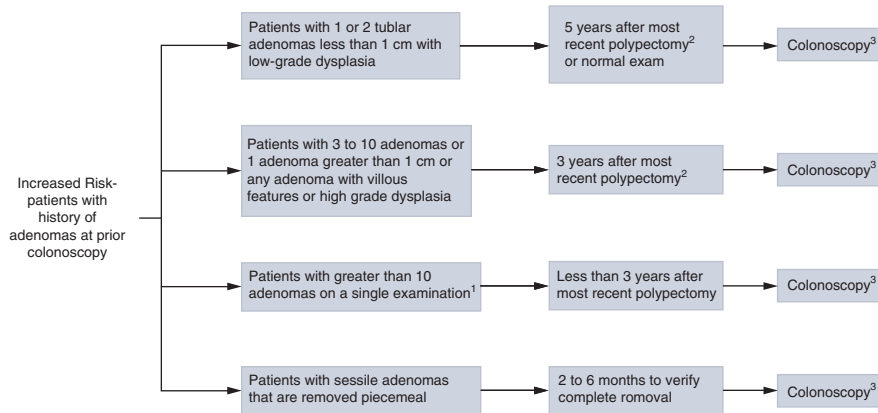

⁵Preauthorization with one's insurance carrier is always advised.

⁶High sensitivity Fecal Occult Blood Test (guaiac-based or immunochemical).

FIGURE 60-3 MD Anderson algorithm for colorectal screening for patients with adenomas on prior colonoscopy.

Screening in Survivors of Childhood Cancers

As in adults, the reasons for increased incidence are related to the survivors' exposure to radiation, chemotherapy, and possible increased genetic predisposition⁽¹⁷⁾. Therefore, screening for certain types of cancers is recommended to begin earlier in survivors of childhood cancer than in the general population, as shown in Table 60-1. As discussed previously in this chapter, screening for breast cancer in women who had chest radiation is especially important because magnitude of risk by age 50 is comparable to carriers of *BRCA* mutations⁽¹⁸⁾. In addition, children treated with abdominal radiation had increased risk of gastrointestinal cancers (SIR 11.2), warranting earlier screening colonoscopies⁽¹⁹⁾.

Screening in Patients With Genetic Predisposition to Cancer

Children and adults with a genetic predisposition to a second malignancy, such as those with neurofibromatosis, Li-Fraumeni syndrome, von Hippel-Lindau syndrome, Beckwith-Wiedemann syndrome, FAP, retinoblastoma germline mutations, or multiple endocrine neoplasia syndromes, should be followed in specialty clinics for these disorders or in a childhood cancer survivor clinic. At the MD Anderson Cancer Center (MDACC), a new program led by the Genetics Department is the LEAD (Li-Fraumeni Syndrome Education and Early Detection) program for patients and family members who have germline *p53* mutations. Individuals in the program undergo periodic biochemical and imaging surveillance, modeled after the published program that showed significantly improved survival of patient with Li-Fraumeni syndrome who had screening⁽²⁰⁾.

LATE EFFECTS OF TREATMENT

Cancer and its treatment can have myriad effects on the overall well-being of cancer survivors. Not surprisingly, patients with cancer rate themselves as having poorer health-related quality of life than noncancer survivors, with a significant component of this being physical impairment⁽²¹⁾. Broadly, a history of cancer and cancer treatment can have an impact on every system in the body, with common long-term issues that include painful or nonpainful neuropathy, sexual dysfunction, persistent fatigue, lymphedema, surgical disfigurement, and bowel and bladder dysfunction, among other symptoms.

As with the risk of second primaries, the risk of late effects of treatment is particularly important to the survivor of childhood cancers. Over the last 40 years, considerable literature has documented the

late effects of cancer treatments in this group. In a report from the Childhood Cancer Survivor Study (CCSS) of 14,359 survivors of childhood cancer with a median follow-up of 24.5 years after diagnosis (range 5 to 39.3 years), cumulative incidence of a severe, disabling, life-threatening, or fatal condition was 53.6% for survivors compared to 19.8% in siblings by age 50⁽²²⁾. The most common severe chronic conditions were congestive heart failure, second malignant neoplasm, cognitive dysfunction, coronary artery disease, cerebrovascular accident, renal failure, major joint replacement, hearing loss, legal blindness, and ovarian failure^(3, 23). New onset of these conditions continued to occur at higher incidence than for siblings in every decade for over 35 years from diagnosis. Among survivors who reached age 35 years without a previous grade 3 or 4 condition, 25.9% experienced a subsequent grade 3 to 5 condition (renal failure, stroke, heart attack, congestive heart failure, and pulmonary fibrosis) within 10 years compared with 6.0% of siblings ($P < .001$)⁽⁴⁾. The overall cumulative mortality rate of 20,483 survivors (over 5 years from diagnosis at enrollment) in the CCSS study was 18.1% at 30 years from diagnosis, with the most frequent causes of mortality second malignant neoplasm, cardiac death, and pulmonary death—largely due to treatment-related causes⁽²⁴⁾.

These late effects threaten both quality and length of life. With over 80% of children with cancer surviving more than 5 years, there is a need to screen for, and if possible prevent, late-occurring problems. With this in mind, the Children's Oncology Group in 2003 developed evidence-based guidelines that recommend follow-up screening and care of survivors of childhood cancer who are at risk for late effects. These guidelines are risk based depending on the specific exposures to surgery, radiation, and chemotherapy and are designed to begin when a child enters a survivorship clinic at either 5 years from diagnosis or 2 years off therapy when the child is cancer free and without recurrence. They are based on treatment rather than diagnosis and are available to the public (<http://www.survivorshipguidelines.org>). In our Childhood Cancer Survivor Clinic at MDACC, we follow these guidelines and use them to recommend the standard of care for follow-up in an individualized "Passport for Care."

CARDIOVASCULAR LATE EFFECTS

Cardiotoxicity is one of the most serious chronic complications of treatment of cancer for both adults and children, but children are particularly vulnerable. Thirty-year survivors of childhood cancer have been shown to have a 15 times higher rate of heart failure, a 10 times higher rate of other cardiovascular diseases, and a 9 times higher risk of stroke than age-matched

sibling controls. This risk can persist for 30 or more years after completion of treatment and represents an important source of excess morbidity in patients with cancer ⁽²⁵⁾. The most common causes of cardiotoxicity are anthracycline-based chemotherapy or radiation therapy to the neck and mediastinum.

Anthracyclines are a class of antineoplastic agents that are highly efficacious in the treatment of pediatric and adult hematologic cancers, including acute myeloid leukemia, acute lymphoblastic leukemia (ALL), Hodgkin's disease, and non-Hodgkin lymphoma, as well as solid tumors, sarcomas, and ovarian cancer. Among children in the United States who are survivors of childhood cancer, approximately 50% have received anthracyclines. Cumulative dose-related cardiac adverse effects may become apparent at the time that the first dose is administered, and clinical data suggest that deterioration of cardiac function is sustained throughout treatment and may become apparent many years after treatment is completed ⁽²⁶⁾.

Known risk factors for anthracycline-induced cardiac adverse effects include high cumulative doses of anthracycline, high anthracycline dose intensity, female sex, age younger than 5 years at diagnosis, radiation therapy, and combining anthracyclines with other cardiotoxic chemotherapy. Patients who were treated for lymphoma, Hodgkin's lymphoma, sarcomas, or myeloid leukemia generally have the highest risk of cardiotoxicity because of the high doses of anthracyclines they usually receive, often accompanied by radiation. Higher-than-expected occurrences of cardiac adverse effects are observed in patients who receive anthracyclines in combination with new targeted drugs, such as the human epidermal growth factor receptor 2 antibody trastuzumab. These risk factors are helpful in establishing monitoring guidelines, as has been done for children, although they do not predict the risk of cardiac adverse effects for all patients. A new scoring system based on CCSS data provides a score of individual risk for the survivors ⁽²⁷⁾.

Medications such as enalapril and carvedilol can support cardiac function when signs of deterioration in left ventricular function are noted on echocardiograms. While MD Anderson cardiologists prescribe these medications for survivors with decreased ejection fraction and have seen benefit for individuals, the long-term benefit in survivors of childhood cancer has not yet been proven and needs further investigation ⁽²⁸⁾. In adults, these medications have been shown to be effective in preventing chemotherapy-induced left ventricular systolic dysfunction in a randomized trial of adults undergoing aggressive chemotherapy and stem cell transplantation (SCT) ⁽²⁹⁾.

In 2003, the Children's Oncology Group released risk-based, exposure-related guidelines for children treated with anthracyclines. These guidelines include

recommendations for echocardiograms every 1 to 5 years depending on exposure (<http://survivorshipguidelines.org>). These recommendations differ substantially from those given for patients treated for cancer during adulthood and should be followed. They have been found to be cost effective ⁽³⁰⁾.

Stroke is another late vascular effect of radiation to the head and neck. Survivors of brain tumor and leukemia who received cranial radiation as well as survivors of Hodgkin's disease who had radiation to the neck have increased risk of cerebral vascular accident when compared to siblings ⁽³¹⁾. In addition, once a survivor has had a stroke, the risk of having another is significant; therefore, aggressive preventive treatment is recommended ⁽³²⁾.

PULMONARY LATE EFFECTS

Bleomycin or pulmonary radiation is associated with abnormal pulmonary function in 44% of survivors of childhood cancer referred for pulmonary function tests. They were found to have restrictive pulmonary function impairments and decreased diffusion capacity ⁽³³⁾. Pulmonary fibrosis may also occur after treatment with high doses of cyclophosphamide, busulfan, or nitrosourea-based drugs. Pulmonary function studies will reveal a diffuse interstitial fibrosis, restrictive pulmonary disease, and arterial hypoxemia. A chest x-ray will show a pattern of diffuse interstitial fibrosis with patchy basilar infiltrates. In the chronic stage, pulmonary fibrosis associated with treatment with cyclophosphamide or nitrosourea-based drugs also manifests as diffuse interstitial and intra-alveolar fibrosis. Whole-lung radiation even at low doses is associated with pulmonary fibrosis and increased risk of spontaneous pneumothorax many years later ^(33, 34). Patients who receive cranial-spinal radiation for CNS are also at risk for late pulmonary complications. Rates of emphysema, asthma, chronic cough, and need for oxygen were significantly higher for long-term CNS survivors than for their siblings ⁽³⁵⁾.

Our pediatric survivorship guidelines (those developed by the Children's Oncology Group in 2013) recommend a chest x-ray and pulmonary function tests at entry to the survivorship clinic in patients treated with bleomycin, busulfan, nitrosoureas, chest radiation, and allogeneic bone marrow transplantation/SCT with chronic graft-versus-host disease (cGVHD). Following these guidelines strictly, one clinic found that the screening yielded 84% with abnormal findings in survivors followed an average of 10 years from diagnosis ⁽³⁶⁾. Such guidelines are not available for adults entering survivorship, but awareness of the possible late pulmonary effects of chemotherapy, radiation, and surgery is important for the survivorship care provider.

ENDOCRINE LATE EFFECTS

Because growth and development to become a normal adult is one of our important goals of survivors of childhood cancer, hormonal screening and treatment are essential. Pediatric/adult endocrinologists often comanage patients in the Childhood Cancer Survivor Clinic. Pituitary hormone insufficiency can occur within months to many years from surgery involving the pituitary or radiation to the brain. Hormonal insufficiency can develop for survivors of brain tumor, even in tumors outside the pituitary/hypothalamic axis⁽³⁷⁾. Thyroid hormone deficiency is common after radiation either directly or indirectly to the thyroid. Because this problem is readily treated with oral replacement, thyroid screening in at-risk patients is an essential part of survivorship care. Thyroid cancer is also one of the most common second malignant neoplasms due to either radiation to the neck or chemotherapy.

Hormonal deficiencies, if untreated, can lead to short stature, early or delayed puberty, cortisol insufficiency with insufficient stress response, or thyroid deficiency. Patients with growth hormone deficiency require treatment with the hormone for adequate growth before they pass through puberty and the growth plates have fused. Some have also advocated for adult hormone replacement in patients with metabolic syndrome uncontrolled by other medications. Although there has been concern, growth hormone treatment has not been associated with increased risk of recurrence or of second neoplasms⁽³⁸⁾. Patients with brain tumors that involved the pituitary/hypothalamic axis are also at risk for diabetes insipidus. The most common diagnoses associated with this problem are hypothalamic astrocytoma, CNS germ cell tumors, and craniopharyngioma. In this setting, panhypopituitarism and the associated risks are lifelong and can lead to early death if not managed appropriately. Unfortunately, endocrine deficits and cognitive impairment can occur in the same patient, making these patients a challenge to manage if they do not have the support of a parent or caretaker.

COGNITIVE DEFICITS

The younger the patient when the radiation is administered, the greater the damage that can occur. This is especially important when the CNS or head are radiated⁽³⁴⁾. Children, especially those who receive radiation at age under 7 years, are at risk for cognitive deficits that include decrease in IQ, poor attention, poor memory, and deficits in executive functioning and mental speed. The degree of the deficit varies with individuals and the dose of radiation, size of the field, and critical structures within the radiation field. Young children treated with

Total Body Irradiation (TBI) also have risk of decreased cognitive function⁽³⁹⁾. Very young children who receive whole-brain radiation are less likely to achieve independence in adulthood. In addition, older children treated with lower doses of radiation, such as CNS prophylaxis for childhood ALL, still have risk of intellectual decline in later life⁽⁴⁰⁾. Cognitive impairment after whole-brain radiation in adults for metastatic disease or prophylaxis is also well known to have myriad long-term side effects, ranging from mild decline in memory, mood, or concentration all the way to dementia.

The patients at the highest risk are those who live for longer than a year, those who had concurrent chemotherapy, or those who received high fractional doses⁽⁴¹⁾. Many protocols for treatment of brain tumors such as both medulloblastoma and leukemia have attempted to decrease or eliminate radiation doses, with some success, without sacrificing decrease in cure rate. Now, methods such as proton radiation help decrease the radiation to normal tissues. It is yet to be proven that proton radiation will improve cognitive outcomes, although short-term results show some promise, but with radiation to left temporal lobe/hippocampus still leading to significant cognitive declines in young children⁽⁴²⁾. Developing interventions for cancer-related cognitive dysfunction in childhood cancer survivors is a priority⁽⁴⁰⁾.

PAIN

Approximately 33% of cancer survivors report some element of chronic pain after the completion of treatment⁽⁴³⁾. Chronic postoperative pain is an often-encountered sequela of lumpectomy or mastectomy for breast cancer treatment, with 50% to 60% of patients reporting some element of pain after surgery^(44, 45). The causes for this are complex and include nerve damage, phantom pains, intercostobrachial neuralgia, lymphedema, and psychological contributions. Predictors for postoperative pain in one large survey study of patients with breast cancer included young age, axillary lymph node dissection (ALND), adjuvant radiotherapy, and pain complaints at other sites in the body⁽⁴⁴⁾. Postthoracotomy pain relating to damage to intercostal nerves can complicate the course of up to 50% of patients. Other postoperative pain syndromes can include phantom limb pain and post-neck dissection pain for head and neck tumors⁽⁴³⁾.

Radiation can also predispose to a host of pain syndromes, including plexopathies, osteonecrosis, nerve entrapment, and chronic colitis and cystitis^(43, 46). Brachial plexopathies are most common in women who have received radiation for breast cancer and also occur in patients treated for lymphoma and lung cancer. Symptoms can start anywhere from 6 months to

20 years after radiation therapy and manifest as paresthesias, weakness, and pain. Lumbar plexopathies are less common but can be seen with treatment of gynecologic and colorectal tumors⁽⁴⁶⁾.

Hormonal therapies are an underconsidered cause of pain. As we transition to a period during which prolonged hormonal blockade is a favored therapy for patients with hormone receptor–positive breast cancer, these symptoms are more likely to be managed in the setting of cancer survivorship. Of women taking aromatase inhibitors, 47% and 44% report joint pain and stiffness, respectively. This typically manifests as symmetric small-joint arthralgia involving the hands and feet⁽⁴⁷⁾. Interestingly, there is also an increased incidence of carpal tunnel syndrome in patients on aromatase inhibitors^(48, 49). Most often, these symptoms are attributed to the acute decrease in estrogen levels, as perimenopausal women can report similar symptoms, although interestingly, the incidence of arthralgias is more common in patients who have received taxanes^(47, 50). It is important to address these symptoms as the occurrence of arthralgia leads to discontinuation of the aromatase inhibitor in up to 20% of cases⁽⁵¹⁾, despite the fact that these symptoms may be predictive of better efficacy⁽⁵²⁾.

Chemotherapy-induced peripheral neuropathy (CIPN) is perhaps the most characteristic cancer pain syndrome, due to both its high prevalence and the difficulty that can be experienced in successfully treating it. This most often presents as a burning or pins-and-needles sensation that occurs in a stocking-and-glove distribution. The most common implicated agents include platinum-containing agents, taxanes, vinka alkaloids, bortezomib, thalidomide and its derivatives, and ixabepilone. The duration of persistence of neuropathy after discontinuation of the drug varies by agent but can be indefinite⁽⁴⁶⁾. Unfortunately, effective treatment of CIPN has been elusive, although there are several recent promising preliminary studies. Randomized trials have been conducted for gabapentin, amitriptyline, nortriptyline, and lamotrigine, all of which are used to varying degrees for non-chemotherapy-related peripheral neuropathy. Unfortunately, these have not been definitively shown to be effective for CIPN⁽⁴⁶⁾.

That said, there are several agents currently under investigation that have shown some activity in early trials. In a phase II single-arm study of pregabalin in 23 patients with oxaliplatin-induced peripheral neuropathy, 48% of patients described some improvement in their neurologic symptoms⁽⁵³⁾. A multicenter randomized phase III trial of duloxetine versus placebo in patients with at least grade 2 CIPN showed a statistically significant reduction in pain and improvement in function⁽⁵⁴⁾. Similarly, venlafaxine has been shown to be of interest in treating oxaliplatin-induced peripheral

neuropathy in the acute setting, although its role in treating chronic CIPN is less clear⁽⁵⁵⁾. Another recently reported study suggested that a topical combination of ketamine, amitriptyline, and baclofen may also be of some utility in treating painful sensory as well as motor neuropathy⁽⁵⁶⁾.

Ultimately, pain in survivors of cancer is often a complex problem, with nociceptive, neuropathic, and inflammatory components. As such, its treatment often requires a multimodality approach, including μ -agonists, nonsteroidal anti-inflammatory agents, neuropathy-directed therapy, procedures, and physical rehabilitation to help with pain and maximize function and quality of life.

FATIGUE

Fatigue is a nearly universal issue in patients undergoing active treatment of cancer. Even after treatment ends, persistent fatigue can remain a disabling problem for survivors of cancer, with up to 29% of patients reporting some degree of fatigue⁽⁵⁷⁾. A variety of contributing factors may exist, including deconditioning and psychological issues. Immune dysregulation and evidence of persistent inflammation have also been implicated as contributing to persistent cancer-related fatigue^(58, 59). Our own survivorship algorithms as well as those of the National Comprehensive Cancer Network emphasize screening for fatigue, as this can be an underdiagnosed and undermanaged issue that remains distressing for patients.

Several interventions have been examined as options for the treatment of cancer-related fatigue. Behavioral counseling to promote energy conservation can be of utility in the immediate posttreatment period⁽⁶⁰⁾ but is of questionable utility in long-term survivors. In these patients, more evidence supports the use of increased physical activity as a way to improve endurance, emotional well-being, and health-related quality of life^(61, 62). Cognitive-behavioral therapy (CBT), on the other hand, is a validated approach to improving cancer-related fatigue, with evidence to suggest that positive effects on level of fatigue can be observed up to 2 years after completion of therapy.

Studies of pharmacologic treatment of cancer-related fatigue must be interpreted carefully, as more than half of patients may experience improvement in their symptoms with placebo⁽⁶³⁾. Several stimulants have been examined as possible treatments of cancer-related fatigue in survivors. A recent meta-analysis of five randomized trials of methylphenidate for cancer-related fatigue found limited evidence to support its use⁽⁶⁴⁾. Modafinil has also been of interest, with several small, uncontrolled trials supporting its use. Unfortunately, two randomized controlled trials have now

failed to show any benefit over placebo for this agent in patients with cancer-related fatigue^(65, 66). However, psychostimulants may still have a role in treating contributing conditions such as narcotic-related fatigue and depression⁽⁶⁷⁾.

SEXUAL DYSFUNCTION

Infertility is a non-life-threatening late effect of treatment that for young adult survivors, and in their 20s and early 30s is one of their greatest concerns. Fortunately, most survivors have normal sexual function, but exposures to alkylating chemotherapy or brain or gonadal radiation can lead to sterility. In a CCSS study of female survivors of childhood cancer who were currently 18 to 39 years old and who had been sexually active, 16% had total infertility. Increasing doses of uterine radiation and alkylating chemotherapy were strongly associated with female infertility⁽⁶⁸⁾. In a similar study of men, 46% reported infertility, but of these, 37% reported at least one pregnancy with a female partner that resulted in a live birth. The best way to preserve fertility is to bank sperm or ovum/embryos before chemotherapy. Unfortunately, this is not generally available to children and is difficult in adolescent females.

Many chemotherapeutic drugs have the potential to cause gonadal failure or impairment. Alkylating agents, particularly cyclophosphamide and ifosfamide, can damage the testes, resulting in sterility or lack of testosterone production. The risk is greater in pubescent boys than in younger boys. The ovaries can also be damaged in pubescent girls. This may result in infertility, lack of estrogen production, or premature menopause. Damage to the gonads may manifest as delayed puberty, amenorrhea (in girls), and absence of secondary sexual characteristics, growth retardation, or infertility. Levels of follicle-stimulating hormone, luteinizing hormone, and insulin-like growth factor should be determined, semen analysis performed (in boys and girls), and testosterone or estrogen levels checked. A referral to a fertility expert is always indicated if pregnancy is desired. Conceptions achieved by “infertile” long-term survivors, both male and female, have been reported in survivors of cancer. If these survivors have children, an increased risk of birth defects has not been found.

Other forms of sexual dysfunction can vary based on the patient's tumor type and the therapies used to treat it. Among the increasing numbers of women on selective estrogen receptor modulators or aromatase inhibitors, loss of libido, vaginal atrophy, and dyspareunia are common complaints⁽⁶⁹⁾. Women who have undergone pelvic surgery may suffer from painful intercourse due to vaginal shortening; nerve damage from pelvic surgery, resulting in anorgasmia; or the psychological consequences of disfigurement^(70, 71).

Similarly, treatment of prostate cancer can result in sexual dysfunction among men. The majority of patients receiving surgery or radiotherapy report some degree of erectile dysfunction 2 years after completing treatment, and this increases with time, likely due to increasing age and possible additional cancer-directed therapy⁽⁷²⁾. In one study, men younger than 50 at the time of radical prostatectomy were more than twice as likely as men older than 70 to recover sexual function⁽⁷³⁾.

Survivors of breast, genitourinary, and gynecologic cancer are prone to sexual dysfunction, but this is an issue common to almost all cancers. Nerve damage due to pelvic surgery for colon cancer can cause erectile dysfunction and anorgasmia, and body image issues related to ileostomy or colostomies can also be distressing⁽⁶⁹⁾. Even for patients undergoing SCT, where the anatomical issues are less obvious, survivors report lower sexual satisfaction than patients without cancer histories. Perhaps not surprisingly, this finding was associated with the presence of cGVHD.

Treatments of sexual dysfunction also vary based on the etiology. For men with erectile dysfunction, the most commonly used treatments are the PDE5 inhibitors. Other treatments, such as vacuum pumps and penile implants, are also available and effective, although less commonly used⁽⁷⁴⁾.

Pharmacologic therapies for female sexual dysfunction have been less successful. Studies examining the use of testosterone supplementation and PDE5 inhibitors have been disappointing^(75, 76). One recent development is the availability of a Selective Estrogen Receptor Modulation (SERM), ospemifene, which has been shown in a phase III randomized controlled trial to be effective in the treatment of vaginal dryness. There is little evidence regarding the safety of this intervention in cancers that are breast and other hormone receptor positive, but this may be a useful therapy for women with a history of other malignancies. Another important approach is counseling regarding vaginal care, including the use of lubricants and dilators to increase blood flow and treat or prevent atrophy⁽⁷⁷⁾. Psychoeducational training, including elements of CBT, may also be of utility in treating female sexual arousal disorder in survivors of cancer⁽⁷⁸⁾.

LYMPHEDEMA

Lymphedema is generally a postsurgical complication that can take place at any site where a downstream lymphadenectomy is performed. Survivors of breast cancer are likely the most visible group of patients with lymphedema, with up to 49% of women who undergo ALND reporting some element of lymphedema at 20 years after treatment⁽⁷⁹⁾. The practice of

doing a sentinel lymph node biopsy prior to proceeding to ALND if necessary can decrease the incidence and severity of this complication, but a significant fraction of women still require ALND for locally advanced disease and are at risk for this long-term complication. Moreover, while patients with breast cancer may represent the most visible group of patients with lymphedema, this complication is also seen in patients who have undergone lymph node dissection for head and neck cancers, melanoma, gynecological malignancies, and others.

Treatment of most afflicted patients is conservative, including modalities like elevation of affected extremity, compressive therapy, or lymphedema-specific manual lymphatic drainage massage. These are effective in patients with mild-to-moderate lymphedema, but are also highly dependent on patient compliance. Benzopyrones, drugs that are believed to decrease vascular permeability, have little convincing evidence for their use ⁽⁸⁰⁾. Surgical techniques are also available for patients who have failed less-invasive interventions. Microsurgical lymphovenous bypass is the most commonly reported procedure, with one large study demonstrating subjective symptom improvement in 87% of patients and 83% of patients demonstrating improvement in volume measurements ⁽⁸¹⁾.

At MD Anderson, we more commonly use a subtype of this procedure, lymphaticovenular bypass. In this procedure, distal lymphatics, which are typically less affected by lymphedema changes and consequently more available for bypass, are anastomosed to subdermal venules, which are under lower pressure and thus may result in less backflow into the lymphatic system and better long-term effect. A small prospective study at our institution demonstrated subjective benefit in 95% of patients undergoing the procedure, although long-term follow-up is needed to illustrate the durability of these results over time ⁽⁸²⁾.

PSYCHOSOCIAL CONSEQUENCES OF CANCER TREATMENT

Financial difficulty can contribute considerably to the well-being of cancer survivors and is an important source of distress. Adult patients with cancer are more likely to be retired or unemployed than their siblings without cancer, although the likelihood increases as patients get further away from their diagnosis ^(83, 84). Patients with breast cancer, male genital cancers, and skin cancers more likely to return to work than patients with lung or gastrointestinal cancers ⁽⁸³⁾. Not surprisingly, the risk of not returning to work is higher for patients with higher-stage tumors and patients who required extensive surgery ⁽⁸⁵⁾. Even among those who do return to work, productivity can suffer due to

physical and cognitive limitations. While it is important for the survivorship care provider to be aware of these issues, there is little guidance regarding effective interventions. Even though employer education and policy initiatives are likely to be of utility, most evidence to date focuses on intensive multidisciplinary evaluation and guidance for patients. A recent Cochrane review found moderate evidence to support interventions with physical, psychological, and vocational components ⁽⁸³⁾.

Another cause of psychological concern among patients with cancer is altered body image related to surgery, weight changes, or other sequelae of treatment. This in turn is a predictor for depression in survivors ⁽⁸⁶⁾. Patients with male genitourinary cancers have variable outcomes. One study found that orchiectomy in older survivors of testicular cancer was not associated with worsened body image regardless of whether a prosthesis was placed, as long as sexual function was preserved. Among younger patients, however, concern over scars made many patients report feeling less attractive. Encouragingly, 88.2% of spouses in the same study did not report any decrease in attraction to their partners. For patients with prostate cancer, hormonal therapy is associated with worsening body image, and over 50% of patients report a decrease in perception of body image over 2 years. Moreover, the decrease seems to be associated in a decrease in quality-of-life metrics ⁽⁸⁷⁾.

The financial and physical concerns relating to cancer survivorship can lead to distress, defined as depression and anxiety that may lead to somatic symptoms. Interestingly, while older cancer patients seem to be at higher risk for suicide, there is a suggestion that adolescent and young adult patients are at higher risk for long-term distress ^(88, 89). At particular risk seems to be patients that are younger at diagnosis, female, those with late effects, those with lower education, and those with less perceived parental support ⁽⁸⁹⁾.

Childhood survivors of cancer represent an important subgroup within survivors of cancer in general. Although many survivors of childhood cancer show tremendous resilience and strength in overcoming the trauma of cancer at a young age, a significant proportion report more symptoms of global distress and poorer physical function than controls. Other reported late effects include anxiety, depression, and posttraumatic stress. These factors can significantly hinder attainment of lifetime educational, social, and vocational goals. As a result, survivors are less likely to be married, have a higher risk of experiencing unemployment and legal difficulties, and are likely to attain lower educational achievements than other adults. Survivors who have had cranial radiation or surgery are at the highest risk of experiencing psychosocial problems and are likely to face problems related to

motor, sensory, and behavioral disturbances, often culminating in social isolation and failure to attain independence^(40, 90). In addition, survivors who experienced psychological problems as adolescents have an increased risk of developing poor health behaviors in adulthood. In our clinic, we frequently refer patients to our vocational counselors, psychologists, and psychiatrists for psychosocial support and advice about school and careers^(91, 92).

The most feared complication of distress in patients with cancer is suicide. The risk of suicide is highest in patients recently diagnosed and is more common among patients with poor prognoses. Completed suicide is more common within 3 to 6 months of diagnosis; however, excess risk seems to persist past 5 years. In a Finnish study of 60 patients with cancer who committed suicide, 25 were patients who were in a remission. Most of these suicides were of patients with mental illness or other comorbidities. Other risk factors for suicide that have been identified include male sex and a history of previous suicide attempts. A study of adult survivors of childhood cancer found suicidal ideation among survivors of childhood cancer was reported in 12.6% of respondents, with occurrence in the general population estimated at 2.65% to 3.3%. Interestingly, in addition to depression, a history of cranial radiation was described as a risk factor in this study, possibly due to cognitive or cosmetic sequelae⁽⁹³⁾.

HEALTHY LIFESTYLES IN CANCER PATIENTS

Management of risk factors for heart disease takes on special importance in survivors of cancer. Survivors should be encouraged to have a healthy lifestyle with exercise and a healthy diet to prevent other known risk factors for cardiovascular disease, such as obesity and hyperlipidemia. The combination of elements of metabolic syndrome and exposure to anthracyclines or chest radiation increase the risk of a serious cardiac event⁽⁹⁴⁾. Therefore, control of weight, hypertension, cholesterol, and diabetes is especially important in all survivors of cancer, particularly those treated as children or adolescents. In one study, among survivors of childhood cancer, adherence to a heart-healthy lifestyle was associated with lower risk of metabolic syndrome. Even after adjusting for known treatment and demographic risk factors, failure to follow a heart-healthy lifestyle was associated with a more than two-fold increased risk of developing metabolic syndrome. Additional work is needed to evaluate the impact of lifestyle interventions on risk for metabolic syndrome among survivors of childhood cancer, especially in individuals predisposed to adverse cardiovascular outcomes because of their treatment of childhood cancer⁽⁹⁵⁾.

Female survivors, adolescents and young adults, and survivors of cancers of the CNS and lymphoma are the highest-risk populations for poor dietary behaviors, sedentary behaviors, and poor health-related quality of life⁽⁹⁶⁾.

Physical activity has been linked to improved all-cause mortality in survivors of cancer with a variety of tumor types^(97, 98). While a decreased cardiovascular risk profile is likely the explanation for much of this effect, there is also noted to be a decrease in the risk of cancer recurrence and disease-specific mortality in patients with many tumor types, including breast and prostate cancers⁽⁹⁹⁾. Exercise also leads to improvements in overall quality of life, including decreased anxiety, depression, and fatigue and improved body image⁽⁹⁹⁾.

Diet is another component of a healthy lifestyle that has been examined in patients with cancer. The largest studies to date are the Women's Interventional Nutrition Study (WINS) and the Women's Healthy Eating and Living (WHEL) Study, both of which were done in women with early breast cancer⁽⁹⁹⁾. The WINS study compared women placed on a low-fat diet with a control group of women. The dietary intervention group experienced weight loss and an increased disease-free survival, with a median survival of 5.6 years⁽¹⁰⁰⁾. The WHEL study similarly prescribed a low-fat diet that increased fruit and vegetable intake and dietary fiber. At 7.3 years, there was no difference in recurrence rates between the dietary intervention and control groups. Consequently, the intervention in the WINS trial has been attributed to the observed weight loss rather than the lower fat content of the diet in the experimental group⁽⁹⁹⁾.

A continued emphasis on smoking cessation, which should begin prior to a cancer diagnosis, remains important in the survivorship setting. Patients who continue to smoke after being diagnosed with early-stage lung cancer have increased all-cause mortality as well as increased recurrence rates compared to patients who do not smoke after being diagnosed. This has also been demonstrated in patients with esophageal cancer. Smoking while drinking moderate amounts of alcohol (at least 7 alcoholic beverages a week) seemed to amplify the increased risk of cancer recurrence.

Index

Note: Page numbers followed by f indicate figures; those followed by t indicate tables.

A

Abemaciclib, for breast cancer, 579
 Abiraterone, for prostate cancer, 785
 ABVD regimen
 for AIDS-related primary central nervous system lymphomas, 949
 for Hodgkin lymphomas
 classical, 214–215, 216, 217, 219, 220
 pediatric, 979
 ABV regimen
 for classical Hodgkin lymphoma, 215
 for Kaposi sarcoma, 939
 ACE regimen, for malignant gestational trophoblastic disease, 724
 Acquired immunodeficiency syndrome, cancers related to, 935–954, 954t–955t. *See also* AIDS-related non-Hodgkin lymphoma; Hodgkin lymphoma; Kaposi sarcoma
 AC regimen, for breast cancer, 557
 Acute lymphoblastic leukemia, 3–15
 B-cell
 mature, 3, 7. *See also* Burkitt lymphoma
 precursor, 4, 5t
 clinical presentation of, 3
 diagnosis of, 4–6
 cytogenetic-molecular profiling in, 5–6, 5t, 6f, 7t
 immunophenotyping in, 4–5, 4f, 5t
 epidemiology and etiology of, 3
 frontline therapy for, 6–12, 8t
 for adolescent and young adult acute lymphoblastic leukemia, 9, 10t, 11
 allogeneic stem cell transplantation for, 11–12
 for CD20-positive pre-B-cell acute lymphoblastic leukemia, 7–8
 in elderly patients, 11
 for mature B-cell and Burkitt acute lymphoblastic leukemia, 7
 MDACC approach to, 14t
 for minimal residual disease, 12
 for Philadelphia-positive acute lymphoblastic leukemia, 8–9
 for T-cell acute lymphoblastic leukemia, 9
 laboratory abnormalities in, 3
 MDACC approach to, 14–15, 14t, 15t
 novel strategies with immunotherapy for, 13–14
 chimeric antigen receptor T cells as, 14
 pediatric, salvage strategies for, 977–979
 salvage therapy for, 12–13
 MDACC approach to, 14t

T-cell
 diagnosis of, 4–5, 5t
 treatment of, 9
 Acute myeloid leukemia, adult, 19–37
 clinical presentation of, 20
 diagnosis and classification of, 20, 21t, 22t
 epidemiology, etiology, and risk factors for, 19–20
 minimal residual disease, 34, 35t, 36, 36t
 promyelocytic, 32–34, 33t–35t
 risk stratification of, 20, 22t, 23
 supportive care for, 31–32
 treatment of, 23–24, 23t
 for core-binding factor acute myeloid leukemia, 29–30
 induction therapy in, 24–25
 investigational agents for, 32
 for patients 60 and older, 27–29
 for relapsed/refractory acute myeloid leukemia, 30–31, 30f
 stem-cell transplantation for, 31, 31t
 in younger patients, 25, 27
 Acute myeloid leukemia, secondary, in long-term survivors, 1212t
 Acute promyelocytic leukemia, 32–34, 33t–35t
 Acute respiratory distress syndrome, chemotherapy-induced, 1127
 ACVBP regimen, for diffuse large B-cell lymphoma, early-stage, 166–167
 Acyclovir, 1043t
 for herpes simplex virus infections, 1043
 toxicities of, 1044t
 for varicella zoster infections, 1044–1045
 Adenocarcinoma
 of anal canal, 533
 endometrioid, 647
 of lung, 346–347, 349f, 350t
 with *ALK* translocations or *ROS1* fusions, 363–364, 365t
 for EGFR mutant, 360, 362–363, 365t
 nonmucinous/colonic-type, 493
 of uterine cervix, 692–693, 693f
 adenocarcinoma in situ, 692
 early invasive or microinvasive, 692
 in situ, management of, 698, 699
 Adenomatous polyps, colorectal cancer and, 502
 Adenosarcoma, uterine, 684
 histology of, 684
 prognosis and clinical course of, 684
 treatment of, 684

Adenovirus infections, 1050–1051
 following alloSCT, 278t
 viral-specific T cells for treatment of, 317
 Adrenal insufficiency
 primary, as complication of cancer therapy, 1066
 secondary, as complication of cancer therapy, 1066
 Adrenocortical carcinoma, 924–930
 diagnosis of, 924–927
 imaging for, 924–925, 926f
 laboratory studies for, 924, 925f
 genetics of, 927, 927t
 pathology of, 925–927, 926f, 927t
 prognosis of, 927–928
 staging of, 926, 927t
 syndromes associated with, 924, 925t, 927, 927t
 treatment of, 928–930
 chemotherapy for, 928–930, 928f, 929f
 radiation and radiofrequency ablation for, 930
 surgical, 928
 Adult T-cell lymphoma/leukemia, 182, 183, 185, 187f
 Afatinib, for lung cancer, 1010
 Aflatoxin, hepatocellular carcinoma and, 466
 AIDS-related cancers, 935–954, 954t–955t. *See also* AIDS-related non-Hodgkin lymphoma; Hodgkin lymphoma; Human immunodeficiency virus (HIV); Kaposi sarcoma
 AIDS-related non-Hodgkin lymphoma, 940–948
 central nervous system, primary, 944–948
 clinical presentation and diagnosis of, 945–946, 949f
 epidemiology and pathogenesis of, 944–945
 treatment of, 947–948
 systemic, 940–944
 clinical features of, 942–943, 943t
 epidemiology of, 940–941, 942t
 highly active retroviral therapy and, 941–942
 pathogenesis of, 941
 pathology of, 942
 therapy for, 943–944, 944t, 945t, 946f, 947f, 948t
 Air contrast barium enema, for colorectal cancer screening, 503
 Airway obstruction, as oncologic emergency, 1093

- Alcohol consumption, hepatocellular carcinoma and, 464, 466
- Alectinib, for non-small cell lung cancer, 1014
- Alemtuzumab
for cutaneous T-cell lymphoma, 196
for hypereosinophilic syndrome, 122
thyroid disorders due to, 1064, 1065
for Waldenström macroglobulinemia, 246
- Alisertib, for peripheral T-cell lymphoma, 192t, 193
- ALK inhibitors, for adenocarcinomas with ALK translocations or ROS1 fusions, 363–364, 365t
- Allogenic stem cell transplantation (alloSCT), 267–285, 307–317
for acute lymphoblastic leukemia, 11–12
autologous stem-cell transplantation versus, 258–259
background of, 267
for chronic myeloid leukemia, 75–76, 76t
for classical Hodgkin lymphoma, 222
complications of
acute graft-versus-host disease as, 277, 279, 279t
chronic graft-versus-host disease as, 280–281
infectious, 277, 278t–279t
late, 281
pulmonary, 277
veno-occlusive disease/sinusoidal obstruction syndrome as, 274, 276–277
disease-specific considerations for, 282t–283t, 284–285, 285f
donor for, 269f
myeloablative conditioning as, 269–270, 270t, 271t
reduced-intensity conditioning as, 271
for follicular lymphoma, 142
graft-versus-host disease reduction and, 313–314
adoptive transfer of regulatory T cells for, 314
cellular therapy for, 313–314, 315–316
infection prevention and treatment and, 314–317, 315f
viral-specific T cells for, 316–317
graft-versus-tumor effect and, 307–313
adoptive transfer of natural killer cells to enhance, 312–313, 312f
bi-specific T-cell-engaging antibodies for, 310
cellular therapy to enhance, 309
chimeric antigen receptor-modified T cells for, 310–312, 310f, 311t
donor lymphocyte infusion problems and challenges and, 309
optimizing natural killer cell efficacy and, 313
pathophysiology of, 307–309
prophylactic donor lymphocyte infusion for, 310
tumor escape from immunologic destruction and, 309
- immunomodulatory drugs and, 313
for peripheral T-cell lymphoma
frontline, 190
for relapsed or refractory disease, 191
posttransplant supportive care for, 274–277, 274f, 276f
for graft failure, 274
infectious disease prophylaxis as, 274, 275f
myelosuppression as, 274
for pulmonary complications, 277
for veno-occlusive disease/sinusoidal obstruction syndrome, 274, 276–277
preparative regimen for, 269–271
for primary myelofibrosis, 120
rationale for, 267–268, 268f
recipient of, 268
relapse following, 281, 282t–283t
stem cell sources for, 271–272
graft-versus-host disease prophylaxis and, 272–273, 273f
- Alteplase, for venous thromboembolism, 1091t
- Altered mental status, as oncologic emergency, 1080, 1081f, 1082t
- Alveolar damage, diffuse, chemotherapy-induced, 1127
- Alveolar soft parts sarcoma, 886
- Amantadine, 1043t
- Amitriptyline, for depression, 1183
- Amphotericin B
for serious fungal infections, 1034, 1035t, 1036t, 1038, 1040, 1041
toxicities of, 1035t
- Amrubicin, for small cell lung cancer, 333
- Amyloidosis, cardiac, arterial ischemia and, 1108
- Anagrelide, for essential thrombocythemia, 114–115
- Anal cancer, 525–534
adenocarcinoma, 533

 laboratory studies for, 232, 232f
 epidemiology and risk factors for, 229–230
 maintenance therapy for, 240–241
 MGUS and, 229, 242–243, 243t
 newly diagnosed, treatment of, 235–238
 frontline therapy for transplant-eligible patients for, 235–237
 frontline therapy for transplant-ineligible patients for, 237–238, 238t
 pathophysiology and genetics/molecular classification of, 230–231, 230t
 relapsed/refractory, treatment of, 241–242
 response criteria for, 233–235
 IMWG guidelines for, 233, 235t
 minimal residual disease and, 234–235
 risk stratification for, 233, 234
 smoldering, 243–244
 solitary plasmacytoma of bone and, 244
 staging of, 233, 234
 stem cell transplantation for, 238–240
 allogenic, 239–240
 autologous, 238–239
 Muramyl tripeptide phosphatidylethanolamine, liposomal, for osteosarcoma, pediatric, 979–980
 MUTYH-associated polyposis, colorectal cancer and, 503
 M-VAC regimen, for bladder cancer, 766
 Mycophenolate mofetil, for graft-versus-host disease prophylaxis, 297–298
 Mycosis fungoides, 193
 classification of, 193, 193f
 presentation and diagnosis of, 193
 treatment of
 for early mycosis fungoides, 194
 for intermediate-stage, refractory or transformed mycosis fungoides, 194–195, 195t
 Myeloablative conditioning regimens, for cord blood transplantation, 293–294, 294f
 Myelodysplastic syndromes, 81–98
 clinical and laboratory features of, 83
 cytogenetic and molecular analysis in, 85–88, 86t, 87f
 diagnosis of, 88–89, 88f, 89f
 epidemiology and etiology of, 82–83
 flow cytometry in, 88
 fluorescent in situ hybridization in, 88
 morphological features of, 83, 83t, 84f, 85, 85f
 prognosis of, 89–91, 90t–92t, 93
 secondary, in long-term survivors, 1212t
 treatment of, 93–97, 93f
 cytotoxic chemotherapy for, 96
 hematopoietic growth factors for, 94–95
 hematopoietic stem cell transplantation for, 97
 hypomethylating agents for, 95–96
 immunosuppressive therapy for, 96–97
 lenalidomide for, 95
 in patients with hypermethylator failure myelodysplastic syndrome, 98
 in patients with lower-risk disease and poor prognosis, 97–98
 supportive care for, 94
 Myeloproliferative disorders
 arterial ischemia and, 1108
 Philadelphia chromosome-negative, 103–127 . *See also* Chronic eosinophilic leukemia; Chronic neutrophilic leukemia; Essential thrombocythemia; Hypereosinophilic syndrome; Mast cell disease; Polycythemia vera; Primary myelofibrosis
 WHO classification system for, 103, 104t
 Myelosuppression, following alloSCT, 274
 Myocardial dysfunction, 1100–1106, 1102t
 Myocardial ischemia, as oncologic emergency, 1084–1086
- N**
 Nab-paclitaxel
 for breast cancer, 582
 for pancreatic cancer, 455–456
 Nalbuphine, for cancer pain, 1173t
 Nasopharyngeal carcinomas, 382–383
 Natural killer cells
 adoptive transfer of, to enhance anti-tumor effect of alloSCT, 312–313, 312f
 optimizing efficacy of, with alloSCT, 313
 to prevent disease relapse following haploSCT, 305
 Natural killer/T-cell lymphomas
 extranodal, 186–187, 187f
 treatment of, 191
 Nausea, management of, 1179, 1179t
 Nelarabine, for acute lymphoblastic leukemia
 pediatric, 978
 as salvage therapy, 13
 Nephrectomy, cytoreductive, for renal cell carcinoma, 737
 Neratinib, for inflammatory breast cancer, 615
 Neuroendocrine features, colorectal adenocarcinoma with, 520
 Neuroendocrine tumors, 537–546
 carcinoid, 540–541
 appendiceal, 541
 gastric, 540, 540t
 rectal, 541
 small intestinal, 540–541
 carcinoid crisis and, 543
 carcinoid heart disease and, 542–543
 carcinoid syndrome and, 542, 542t
 carcinomas, 337–338, 338t
 clinical presentation of, 539
 clinical staging of, 540
 diagnostic workup for, 539–540
 epidemiology of, 537, 538t
 hepatic metastases of, resection of, 544–545
 molecular biology of, 538
 pancreatic, clinical features of, 541–542
 pathogenesis of, 538
 pathologic classification of, 538–539, 538f, 539t
 prognosis of, 537–538
 treatment of, 543–546
 for advanced tumors, 543–546
 chemotherapy for, 546
 hepatic arterial embolization/chemo-embolization for, 545
 peptide receptor radionuclide therapy for, 546
 radiofrequency ablation for, 545
 of resectable tumors, 543
 selective internal radiation therapy for, 545–546
 somatostatin analogues for, 544
 surgical resection of hepatic metastases for, 544–545
 targeted therapy for, 546
 of unknown primary, 971
 Neurofibromatosis type 1, brain tumors and, 831–832
 Neurologic motor impairment, with brain tumors, rehabilitation of patients with, 1193–1194
 Neurologic oncologic emergencies, 1073–1080, 1082t
 altered mental status as, 1080, 1081f
 increased intracranial pressure as, 1075–1088, 1076f, 1077f
 leptomeningeal disease as, 1078–1079
 seizures as, 1079–1080, 1079f
 spinal cord compression as, 1073–1075
 Neutropenic fever, following alloSCT, 278t
 Nigro regimen, for anal cancer, 528–529
 Nilotinib
 for chronic myeloid leukemia, 69
 for gastrointestinal stromal tumor, 887
 for melanoma, 1011
 Nipples, in inflammatory breast cancer, 604f, 605
