Hepatocellular Carcinoma

Marc Uemura
Sunil Krishnan
Ahmed O. Kaseb
Nishin A. Bhadkamkar
Milind M. Javle
Rony Avritscher

Hepatobiliary malignancies comprise a diverse group of tumors, including hepatocellular carcinoma (HCC), variants such as fibrolamellar HCC (FLHCC) and cholangiocellular carcinoma, cholangiocarcinoma, carcinoma of the gallbladder, and rare cancers such as sarcoma, angiosarcoma, and hepatoblastoma. The relative frequency of these tumors is shown in [Table 22-1](#). The estimated new cases and deaths from liver and intrahepatic bile duct cancer in the United States in 2014 totaled 33,190 and 23,000, respectively (¹).

The majority of primary liver tumors are HCC or cholangiocarcinoma. These tumor types have different etiologies, epidemiology, clinical presentations, and treatment options. Thus, they are discussed separately.

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma is a malignancy of worldwide significance and has become increasingly important in the United States. It is the most common primary liver malignancy, the sixth most common cancer, and the third most common cause of cancer-related deaths worldwide (²). Eighty percent of new cases occur in developing countries, but the incidence is rising in economically developed regions, including Japan, Western Europe, and the United States (³⁻⁶). The worldwide distribution of HCC and its associated etiologies are summarized in [Table 22-2](#). Liver cirrhosis is the seventh leading cause of death in the world, the tenth most common cause of death in the United States, and acknowledged as a premalignant condition for developing HCC (⁷⁻⁹).

In the United States, hepatitis C virus (HCV), alcohol use, and nonalcoholic fatty liver disease (NAFLD) are the most common causes of cirrhosis (⁹). The incidence of HCC doubled during the period 1975 to 1995 and continued to rise through 1998 (^{10, 11}). This trend was previously expected to continue due to the estimated 4 million US individuals who are hepatitis C seropositive and the known latency of HCC development from the initial HCV infection, which may take two to three decades (¹¹). However, given the improved treatment regimens now available for patients with chronic hepatitis C, HCV-related HCC incidence may decrease in the next few years (¹²). It is also known that NAFLD-associated cirrhosis is on the rise in the United States (¹³⁻¹⁵). A majority of patients present with advanced disease that is not amenable to curative procedures. Overall, HCC has a very poor prognosis, with a 5-year survival rate of 5%.

EPIDEMIOLOGY

As shown in [Table 22-1](#), HCC represents approximately 85% of all primary liver cancers (¹⁶). The distribution of HCC varies significantly by geography; it is endemic in parts of the world where hepatitis B virus (HBV) is also endemic. In Western countries, HCV infection and alcoholic cirrhosis are the principal risk factors for HCC. Due to rising incidence of HCV infection in American subpopulations, the incidence of HCC is projected to increase fourfold by 2015 (¹¹). Moreover, HCC incidence increases with age, with the age of peak incidence varying somewhat with

Table 22-1 Relative Frequency of Hepatobiliary Tumors Diagnosed in the United States

Subtype of Hepatobiliary Cancer	Frequency (%)
Hepatocellular	84
Cholangiocarcinoma	13
Cholangiocellular and fibrolamellar	2
Angiosarcoma, sarcoma, hepatoblastoma	1

population. The median age group of HCC is between the fifth and sixth decades. The disease is also seen in children and young adults in areas where HBV is endemic, and most of these infections occur perinatally. In all populations worldwide, there is a strong male predominance in HCC incidence. In the United States, the male-to-female ratio is 2.7 to 1, and HCC incidence rates are higher among African Americans than Caucasians (6.1 vs 2.8 per 100,000 in men). Hispanics, Asians, Pacific Islanders, and Native Americans have a much higher HCC frequency. Independent of HBV status, a family history of HCC in first-degree relatives carries a relative risk (RR) of 2.4 and overall risk (OR) of 2.9 ⁽¹⁷⁾. Familial aggregation and germline mutations of the *APC* (adenomatous polyposis coli) gene have been reported in hepatoblastoma ⁽¹⁸⁾.

ETIOLOGY AND RISK FACTORS

Hepatocellular carcinoma develops commonly, but not exclusively, in a setting of liver cell injury, which leads to inflammation, hepatocyte regeneration, liver

matrix remodeling, fibrosis, and ultimately cirrhosis. The major etiologies of liver cirrhosis are diverse and include chronic HBV and HCV infection, alcohol consumption, certain medications or toxic exposures, and genetic metabolic diseases. The mechanisms by which these varied etiologies lead to HCC are not fully elucidated. The principal risk factors that have been associated with cirrhosis and HCC are listed in Table 22-3.

Chronic Viral Hepatitis

Chronic hepatitis B or C viral infection is the most important risk factor for developing HCC. Alone, HCV causes about 40% of HCCs in the United States. Chronic HBV or HCV carriers usually take 10 to 20 years to develop hepatic cirrhosis and 30 to 40 years to develop HCC. Hepatitis B virus is a DNA virus that commonly integrates into the host hepatocyte genome and may play a direct procarcinogenic role. Hepatitis C virus is an RNA virus with no insertional mutagenesis. Although HBV and HCV contain no known viral oncogene to immortalize hepatocytes, hepatitis Bx antigen may inactivate p53 protein and downregulate DNA repair ability ^(19, 20). Some of the principal differences between HBV- and HCV-associated HCC are listed in Table 22-4.

Alcohol and Cirrhosis

Excessive alcohol consumption can lead to hepatic cirrhosis and thus is a risk factor for HCC. The autopsies of patients with alcoholic cirrhosis have reported up to 10% undiagnosed HCC. In the United States, alcoholic cirrhosis is associated with about 15% of HCC and cholangiocarcinoma ^(21, 22). In HCV carriers,

Table 22-2 Incidence of Hepatocellular Carcinoma Worldwide

Region	Incidence ^a			
	Men	Women	Number of Cases	Principal Associations
Asia, sub-Saharan Africa	30-120	9-30	>500,000 cases per year	HBV, aflatoxin exposure
Japan	10-30	3-9		HCV
Southern Europe, Argentina, Switzerland	5-10	2-5		HCV
Western Europe	<5	<3		HCV
United States	<5	<3	19,000 predicted for 2004	HCV, alcohol

HBV, hepatitis B virus; HCV, hepatitis C virus.
^aCases per 100,000 population.

Table 22-3 Etiologic Factors Associated With an Increased Risk of Cirrhosis and Hepatocellular Carcinoma

Category	Specific Etiology	Comment
Infectious (77% of cases of HCC worldwide attributed to viral hepatitis)	Hepatitis B virus	Underlying etiology in a significant majority of HCC cases worldwide, primarily in Asia, sub-Saharan Africa
	Hepatitis C virus	Principal underlying etiology in Japan, the United States, Western Europe, Mediterranean basin countries; may account for 20%-25% HCC cases worldwide
Metabolic disorders deficiency	Hemochromatosis, α_1 -antitrypsin	
	Wilson disease	
	Porphyria cutanea tarda	
	Glycogen storage disease	
	Citrullinemia	
	Familial cholestatic cirrhosis	
Other	Alcohol	Significant cause of liver cirrhosis; cofactor with HCV
	Aflatoxin B	Cofactor with HBV that increases risk of developing HCC
		Relative risk varies from two- to fourfold in nonendemic regions
	Androgenic steroids	Some association reported, primarily case reports and small series
	Oral contraceptives	
	Autoimmune hepatitis	
	Nonalcoholic steatohepatitis (NASH)	Increasing evidence for association with HCC with or without cirrhosis; incidence of NAFLD is rising in the United States
	Tobacco	Weak association suggested that it is independent of HBV infection, alcohol

Table 22-4 Comparison Between Hepatitis B Viral Infection and Hepatitis C Infection and Hepatocellular Carcinoma

Factor	HBV	HCV
Mean age	52-56 (20-80)	62
Highest incidence	400 million carriers in Asia and Africa	170 million infected worldwide; accounts for 50% of HCC cases in Japan, the United States, and Western Europe
Cirrhosis	25%-50%	>75%
Morphology	Solitary lesions	Multifocal lesions, more severe inflammation
Rate of progression to HCC	10-30 years	>30 years
Percentage likely to develop HCC	4% per year	1%-7% per year

alcohol increases circulating HCV viral titer and HCC risk. Other types of cirrhosis and parenchymal liver diseases—such as primary biliary cirrhosis, hemochromatosis, Wilson disease, alpha-1 antitrypsin deficiency, and glycogen storage disease—significantly increase HCC risks when alcohol is a cofactor.

Aflatoxin

Food contaminated with aflatoxin, a mycotoxin found in grains, can induce HCC in animals. There is also a strong association between aflatoxin exposure and HBV carrier status. Relative risks of HCC are 3-fold for aflatoxin, 9-fold for chronic HBV infection, and 59-fold for concurrent aflatoxin and chronic HBV infection. The underlying mechanism is polymorphism variants of glutathione-S-transferase M1 and epoxide hydrolase genes and G-to-T point mutation of the *p53* gene⁽²⁰⁾.

Other Environmental Factors

The use of oral contraceptive pills (OCPs) significantly increases the incidence of benign hepatic adenomas. There is some evidence that OCPs also increase HCC risk. Multiple studies of tobacco smoking and HCC risk have yielded mixed conclusions. Occupational exposure to arsenic or vinyl chloride significantly increases the risk of liver angiosarcoma. Exposure to the x-ray contrast medium thorium dioxide from 1930 to 1955 is associated with an extremely high risk of hemangiosarcoma, cholangiocarcinoma, and HCC.

CLINICAL PRESENTATION

Most cases of HCC are identified incidentally or through screening programs of high-risk individuals. It is common for patients to be asymptomatic until their disease is very far advanced; fewer than 30% of patients are candidates for surgery or other liver-directed therapy at presentation. Many patients present with symptoms of advanced liver dysfunction from both cirrhosis and HCC. The most common initial symptom is right upper quadrant abdominal pain. Anorexia or early satiety with weight loss is the second most common symptom. Also, HCC may present with various paraneoplastic symptoms through the secretion of numerous hormones. Late-stage symptoms include jaundice, tumor fever, bone pain due to metastatic lesions, and complications from portal venous hypertension, such as esophagogastric varices, hypoalbuminemia, ascites, thrombocytopenia, and coagulopathy.

On physical examination, hepatomegaly is present in over 90% of patients. A hepatic arterial bruit or a friction rub, ascites, splenomegaly, and jaundice are found in up

to 50% of patients. Muscle wasting, fever, and dilated abdominal veins are also common. The Budd-Chiari syndrome is caused by malignant invasion and occlusion of the hepatic veins. The HCC marker alpha-fetoprotein (AFP) is often elevated to above 400 ng/mL.

PATHOLOGY

Based on the growth pattern, HCC may be classified into four major gross anatomic types: spreading, multifocal, encapsulated, and combined patterns⁽²³⁾. Normal liver parenchyma is shown in Fig. 22-1. The spreading type of HCC grows in nodular, pseudolobular, or invasive patterns with poorly defined margins, occurs in the setting of hepatic cirrhosis, and accounts for nearly 50% of cases in the United States. The multifocal type has numerous tumors of similar size that make it difficult to determine whether the lesions are intrahepatic metastases or second primary tumors (Figs. 22-2A and 22-2B). The encapsulated type of tumor grows by expanding, compressing, and distorting the surrounding liver tissue. Satellite or metastatic lesions are seen in late-stage disease. This type is most common in Asia and Africa but seen in only 13% of cases in the United States. The combined patterns of the three are seen in up to 25% of cases. Figure 22-3 shows an HCC histopathology specimen.

Approximately 60% to 70% of Caucasian and 80% to 90% of Asian HCC cases show elevated AFP, which is the most useful marker for HCC. Originally, AFP is produced by the fetal liver and yolk sac but falls to below 10 ng/mL in adult serum. A transient elevation of AFP to 20 to 400 ng/mL may occur when there is hepatocyte regeneration, as in cirrhosis, active hepatitis, or partial hepatectomy. The HCC positive predictive value of an AFP level of 400 ng/mL is over 95%, and normal AFP levels may exist in patients with low tumor burden. The lectin-reactive isoenzyme of AFP (AFP-L3) has shown increased sensitivity. Other

FIGURE 22-1 Photomicrograph of normal parenchyma.

FIGURE 22-2 A. Gross pathologic specimens of multifocal hepatocellular carcinoma. B. Gross appearance of liver cell carcinoma. Courtesy of Dr RA Cooke, Brisbane, Australia. markers, such as gamma-glutamyl transferase isoenzymes, alkaline phosphatase, isoferitins, and monoclonal antibodies are not more useful than AFP⁽²⁴⁾. Currently, serum AFP level and ultrasonography are the “gold standard” for HCC screening in high-risk populations⁽²⁴⁾.

Variants of Hepatocellular Carcinoma

There are five HCC variants: HCC with biliary differentiation, clear cell HCC, cholangiocellular carcinoma (CCC), FLHCC, and focal nodular hyperplasia (FNH). Cholangiocellular carcinoma is a combination of cholangiocarcinoma and HCC. It occurs in the noncirrhotic liver and behaves like a cholangiocarcinoma; it has a predominance for men. The outcome of patients with CCC is uniformly fatal.

Fibrolamellar HCC is predominantly seen in the right hepatic lobe, accounts for 2% to 4% of HCC, and occurs equally in men and women. It typically occurs in

adolescents and young adults; the etiology is unknown. It is characterized by fibrosis arranged in lamellar fashion around HCC cells. Fibrolamellar HCC consists of well-circumscribed, large, solitary lesions without hepatic cirrhosis or elevated AFP⁽²⁵⁾. The imaging studies often show a heterogeneous mass with a central scar that is similar to FNH. In comparison to classic HCC, FLHCC demonstrates a higher resection rate and better survival, with a 3-year survival of almost 100%.

Focal nodular hyperplasia occurs predominantly in young women. Liver function studies and the serum AFP level are normal. A technetium sulfur colloid radioisotope scan of the liver shows increased radioisotope uptake in FNH compared with hepatic adenomas or carcinomas. The prognosis is excellent.

Clear cell HCC has a distinguishing appearance and better prognosis. Hepatocellular carcinoma with biliary differentiation has a much poorer prognosis because of its rapid growth, decreased vascularity, and resistance to embolic therapy.

Rare primary liver neoplasms include hepatoblastoma, sarcoma, angiosarcoma, rhabdomyosarcoma, and epithelioid hemangioendothelioma. Patients may present with fatigue, anorexia, weight loss, and abdominal pain. Hemorrhagic ascites is common, and AFP level is normal. Angiography and contrast-enhanced computed tomography (CT) of the liver are the best diagnostic tools. Open or percutaneous liver biopsy is needed for diagnosis. Surgical resection is still the principal means of therapy if tumors are diagnosed at relatively early stages. They are often resistant to chemotherapy and radiotherapy (RT), and the overall prognosis is poor.

Benign Liver Tumors

Hemangiomas are the most common benign tumors of the liver. Their size ranges from a few millimeters to 25 cm. They appear as calcified solitary lesions in up

FIGURE 22-3 Photomicrograph with standard hematoxylin and eosin stain of hepatocellular carcinoma cells in hepatic parenchyma.

to 7% of the general population. Magnetic resonance imaging (MRI) is much better than CT in distinguishing HCC from hemangioma on heavily T2-weighted images. Surgical resection is used for symptomatic lesions or when malignancy cannot be excluded. Hepatic artery ligation is an alternative for large cavernous hemangiomas. Hepatic adenoma is another common benign solitary tumor seen in women who have used OCPs for more than 10 years. It is composed of sinusoids, central veins, and arteries without well-defined portal tracts or bile ducts. Hepatic angiography is the most valuable diagnostic tool. Small adenomas usually regress when OCPs are discontinued. Symptomatic lesions are treated with resection.

DIAGNOSTIC EVALUATION, STAGING, AND PROGNOSIS

In addition to performing a complete medical history and physical examination, the diagnostic workup for a patient suspected of having HCC should include serum for complete blood cell count, electrolytes, liver function tests (LFTs), albumin, prothrombin time, hepatitis B and C serologies, and tumor markers (AFP, CA19-9, CA125). The medical history should include a thorough review of potential HCC risk factors: transfusions, tattoos, intravenous drug abuse, high-risk sexual practices, familial syndromes, OCP or hormone replacement use, androgenic steroid use, and chemical exposures.

Several radiographic imaging modalities are useful in evaluating a patient with HCC. Ultrasound often serves as the initial screening modality, followed by triple-phase CT scan or MRI. Randomized studies have shown that hepatic ultrasonography has 78% sensitivity and 93% specificity to detect HCC in high-risk populations, especially for patients with normal

AFP levels (^{26,27}). Color-flow Doppler can assist preoperative assessment and planning.

Abdominal CT has relatively higher sensitivity and specificity than ultrasonography. With special arterial- and venous-phase scans, CT also makes it possible to evaluate the blood supply of the normal liver parenchyma (portal vein) and neoplastic lesions (hepatic artery). Magnetic resonance imaging is useful in distinguishing benign lesions from malignant tumors by the combination of T2-weighted phase contrast and spin echo sequences. Also, MRI can demonstrate fatty degeneration of tumor and vascular invasion (²⁸).

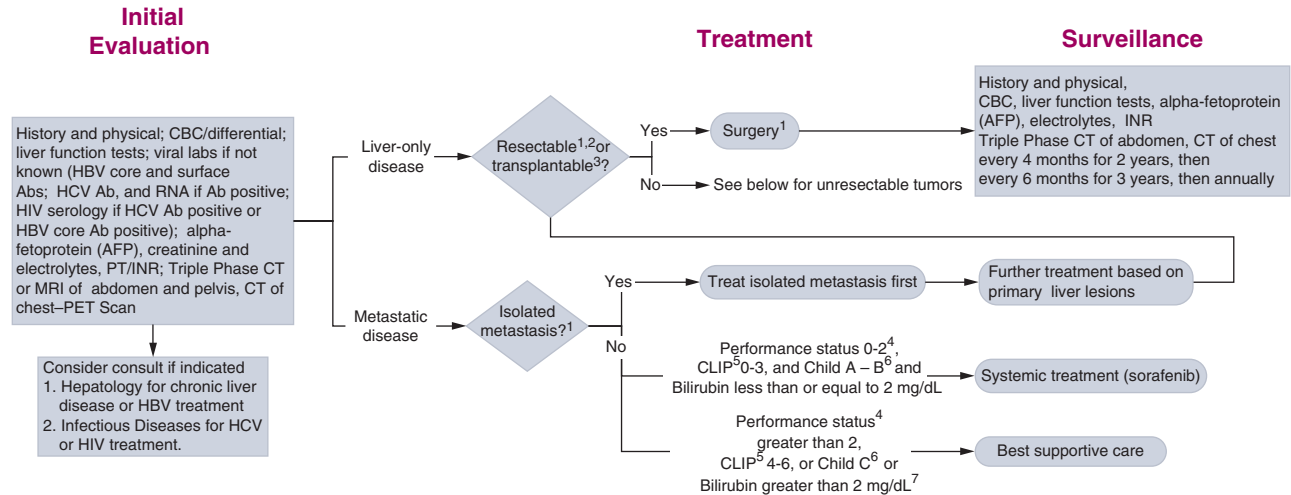

Hepatic radionuclide imaging has low spatial resolution and is only about 70% sensitive in demonstrating neoplasms. Using the glucose metabolic difference between neoplastic and normal cells, positron emission tomography (PET) differentiates benign lesions from malignant tumors, detects extrahepatic metastasis, and evaluates response to therapy.

In summary, ultrasonography is the most cost-effective HCC screening test in high-risk populations. Abdominal CT with liver protocol is the most helpful in accurately staging patients prior to surgery. No single diagnostic modality has greater than 50% to 60% sensitivity in detecting lesions less than 1 cm in size. The combination of AFP level, ultrasonography, and CT provides the best hope of early diagnosis.

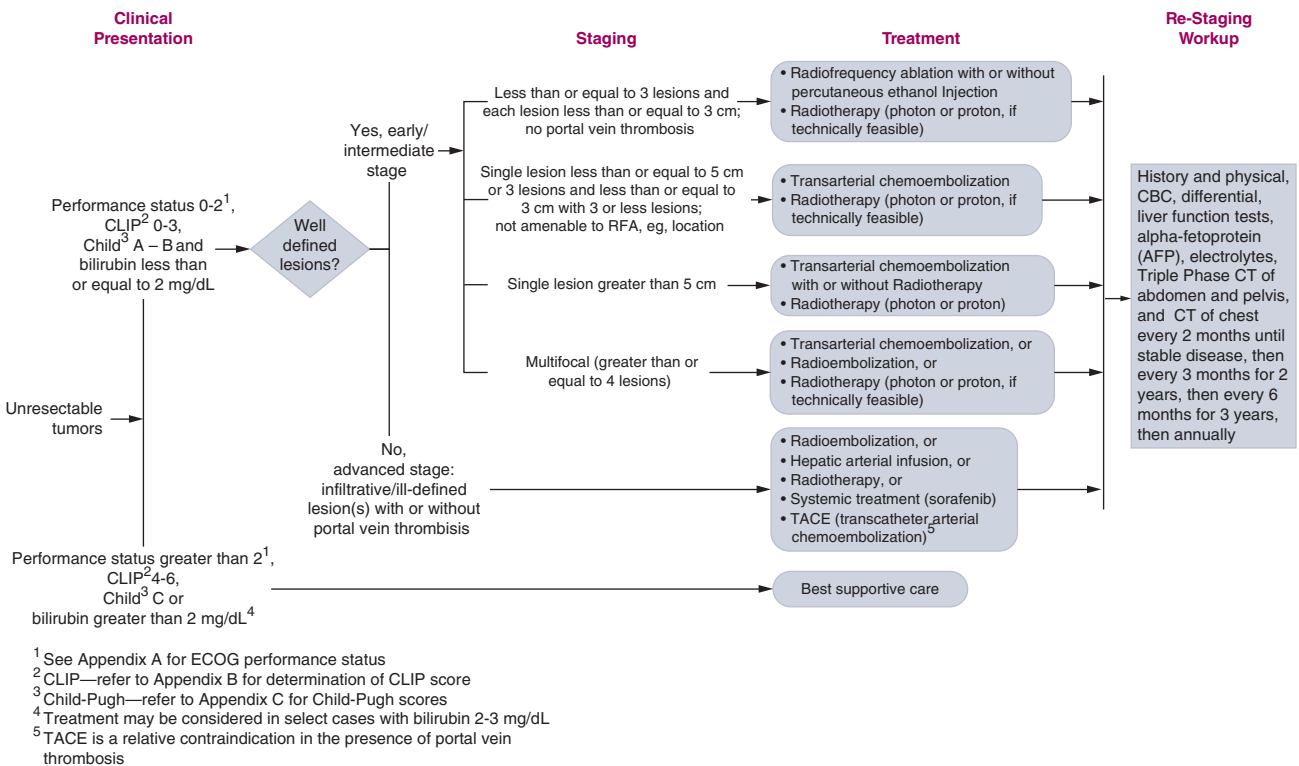

A variety of staging and prognostic systems has been developed to evaluate patients with HCC. Four staging systems (Okuda; CLIP, Cancer of the Liver Italian Program; CUPI, Chinese University Prognostic Index; and American Joint Committee on Cancer [AJCC] TNM) have evolved since the 1980s. Currently, we use a combined AJCC-TNM staging system at MD Anderson Cancer Center (MDACC) (Table 22-5) (²⁵). The Child-Pugh Classification System (Fig. 22-4 and its Appendix C) provides an

Table 22-5 Combined AJCC-TNM Staging System for Hepatocellular Carcinoma

Stage Group	TNM	Scheme
Stage I	T1N0M0	Single tumor <2 cm without vascular invasion
Stage II	T2N0M0	Single tumor <2 cm with vascular invasion or multiple tumors <2 cm in one lobe or single tumor 2 cm without vascular invasion
Stage IIIA	T3N0M0	Multiple tumors in one lobe ± vascular invasion or any tumor >5 cm or single tumor >2 cm with vascular invasion
Stage IIIB	T1-T3N1M0	Positive regional lymph node
Stage IVA	T4N0-N1M0	Multiple tumor in 2+ lobes or tumors involving major portal or hepatic vein
Stage IVB	T1-T4N0-N1M1	Remote metastasis
Fibrosis score		0-4, none to moderate; 5-6, severe fibrosis/cirrhosis

- ¹ Consider biomarkers (See Appendix A for MDA approved hepatocellular biomarkers)
- ² Minor or Major Resection based on:
- Minor Resection: Child-Pugh A, normal liver function tests (bilirubin less than or equal to 1.0 mg%), absence of ascites, and platelet count greater than 100,000/mm³
 - Major Resection: Same as minor resection plus absence of portal hypertension, portal vein embolization (PVE) for a small future liver remnant
- ³ Milan criteria; criteria for eligibility for liver transplantation for patients with hepatocellular carcinoma and cirrhosis: the presence of a tumor 5 cm or less in diameter in patients with single hepatocellular carcinomas, or no more than three tumor nodules, each 3 cm or less in diameter, in patients with multiple tumors, and without macrovascular invasion per imaging studies
- ⁴ See Appendix B for ECOG performance status
- ⁵ CLIP—refer to Appendix C for determination of CLIP score
- ⁶ Child-Pugh—refer to Appendix D for Child-Pugh scores
- ⁷ Treatment may be considered in select cases with bilirubin 2-3 mg/dL

Prothrombin time prolonged	1-4 seconds	4-6 seconds	Greater than 6 seconds
Bilirubin	1-2 mg/dL	2-3 mg/dL	Greater than 3 mg/dL
For primary biliary cirrhosis	1-4 mg/dL	4-10 mg/dL	Greater than 10 mg/dL

Class A = 5 to 6 points
 Class B = 7 to 9 points
 Class C = 10 to 15 points

FIGURE 22-4 *Continued*

estimate of a patient's functional liver reserve and is used principally to assist in evaluating a patient's suitability for hepatic resection.

Based on a review of the database developed at MDACC, patients with HCC had an overall 3-year survival rate of 10% and a median survival time of 7.8 months. Favorable prognostic factors are female gender, absence of cirrhosis, and resection of the tumor; these factors correlated with longer survival, especially if the tumors were located in the left hepatic lobe. For patients with unresectable HCC, systemic chemotherapy or supportive care yielded a 44% 1-year survival rate, and no patient survived for 3 years. The size and number of nodules were

not determinants of survival. Poor prognostic factors included advanced stage, unresectability associated with cirrhosis, and vascular invasion.

TREATMENT

The current treatment options for HCC are summarized in Table 22-6. At present, liver transplantation is considered the only potentially "curative" treatment. The current 1- and 5-year survival rates for patients with HCC undergoing orthotopic liver transplantation are 77.0% and 61.1%, respectively. The 5-year survival rate has steadily improved, from 25.3% in

Table 22-6 Treatment Options for Management of Hepatocellular Carcinoma

Treatment Option	Comments
Liver transplantation	Historically low survival rates (20%-36%).
	Recent improvement (61.1%, 1996-2001), likely related to adoption of "Milan" criteria at US transplant centers.
	Currently HCC represents 20% or more of liver transplants performed annually in the United States.
Surgical resection	Historic 5-year survival rates 30%-40%.
	Recent series indicated 5-year progression-free survival as high as 48%. A majority of patients develop recurrence or second primary tumors.
	Resection in cirrhotic patients carries high morbidity and mortality.
Transarterial embolization/ chemoembolization (TACE)	Multiple trials showed objective tumor responses and "slowed" tumor progression but questionable survival benefit compared to supportive care. Greatest benefit seen in patients with preserved liver function, absence of vascular invasion, and smallest tumors.
	Modest survival benefit demonstrated for repeated TACE (82% 1-year survival) versus supportive care (63%) in patients with preserved liver function, PS 0, small tumor burden.
	Improvement in 1-year survival from 32% in control (supportive care) to 57% for TACE shown in randomized study of 279 primarily HBV+ patients with tumors <7 cm.
Percutaneous treatments (ethanol injection, thermal ablation, cryoablation, hypertonic saline injection)	PEI well tolerated, high RR in small (<3 cm) solitary tumors. No randomized trial comparing resection to percutaneous treatments. Recurrence rates similar to postresection.
Hormonal therapy	Antiestrogen therapy with tamoxifen studied in several trials; mixed results across studies, but generally considered ineffective.
	Octreotide (somatostatin analogue) showed 13-month MS versus 4-month MS in untreated patients in a small randomized study.
Chemotherapy	<i>Adjuvant:</i> No randomized trials showing benefit of neoadjuvant or adjuvant systemic therapy in HCC. Single trial showed decrease in new tumors in patients receiving oral synthetic retinoid for 12 months after resection/ablation. Results not reproduced.
	<i>Palliative:</i> Regimens including as single agents or combinations of doxorubicin, cisplatin, 5-fluorouracil, interferon, epirubicin, and paclitaxel have not shown any survival benefit; RR ranged from 0%-25%. A few isolated major responses allowed patients to undergo partial hepatectomy. No published results from any randomized trial of systemic chemotherapy.

PEI, Percutaneous Ethanol Injection.

1987 to 61.1% in the most recent period studied (1996-2001) ⁽²⁹⁾. The authors attributed this improvement to the incorporation of the “Milan” criteria as guidelines for patient selection at most US liver transplantation centers. These criteria, as published by Mazzaferro et al, suggest that long-term survival after liver transplantation is highest in patients with HCC with either a single lesion 5 cm or smaller or three lesions 3 cm or smaller each and no evidence of gross vascular invasion ⁽³⁰⁾. A large number of liver transplant candidates remain on the waiting list until they die of tumor progression or cirrhosis-related complications. Partial hepatectomy is the current standard treatment for localized T1 to T3, N0, M0 HCC. Resectability is determined by the extent of liver cirrhosis, the future liver remnant (FLR), and an adequate surgical margin. An FLR of 35% to 40% is considered the minimal cutoff for a safe liver remnant. Patients of Child-Pugh class B and C or with significant signs of portal hypertension are not surgical candidates.

Minor or major resection is based on the following criteria: (1) minor resection: Child A, normal LFTs (bilirubin ≤ 1.0 mg/dL), absence of ascites, and platelet count above 100,000/mm; and (2) major resection: minor criteria as in criterion 1, absence of portal hypertension, and portal vein embolization for a small future remnant ⁽³¹⁾. The perioperative mortality has decreased from 20% in the 1980s to less than 5% at present ⁽³¹⁾. The median disease-free survival after partial hepatectomy is about 2 years. Tumor size less than 5.0 cm (0.6 RR) was associated with improved survival, while the presence of vascular invasion, AFP greater than 2,000 mg/mL, and advanced Child-Pugh classification was associated with worse outcome. Patients with cirrhosis generally are not considered good candidates for surgical resection due to the high morbidity and mortality associated with cirrhosis and its complications. For those who do undergo resection, recurrence rates are among the highest of any solid tumor and approach 75% to 100% at 5 years. Estimated 5-year survival rates are in the range of 26% to 50%, and disease-free survival is 13% to 29% ⁽³²⁾.

Locoregional Therapy for Hepatocellular Carcinoma

Hepatocellular carcinoma derives its blood supply almost exclusively from the hepatic artery. This important anatomic feature offers unique advantages for catheter-based therapies because arterial embolization interrupts blood flow to the tumor while preserving the portal vein and normal liver parenchyma. The combination of tissue ischemia with highly concentrated chemotherapy delivered into the hepatic artery enhances tumor necrosis. Transarterial

chemoembolization (TACE) was first described by Yamada and incorporates these concepts ⁽³³⁾. It has since become one of the most commonly utilized procedures in interventional radiology practice.

Landmark prospective randomized clinical trials published in 2002 validated the use of chemoembolization for unresectable advanced HCC. In the multicenter study by Llovet et al including 112 patients, when compared to bland embolization or best supportive therapy, patients who underwent TACE with a combination of doxorubicin and iodized oil followed by gelatin sponge demonstrated a clear survival advantage, leading to premature stoppage of the trial ⁽³⁴⁾. Survival in the chemoembolization group at 1 and 2 years was 82% and 63%, respectively. Survival in the bland embolization group was 75% and 50%, respectively; in the best supportive care group, survival was 63% and 27%, respectively, and reached statistical significance.

Lo et al conducted a single-center study comparing 80 patients with unresectable HCC randomized to TACE with cisplatin and iodized oil followed by gelatin sponge or best supportive care ⁽³⁵⁾. Survival in the chemoembolization group at 1 and 2 years was 57% and 31%, respectively. Survival for the patients randomized to the supportive care group was 32% and 11%, respectively, also reaching statistical significance. The difference in survival rates between the Llovet and Lo studies can be attributed to the inclusion of a larger proportion of patients with more advanced stages of underlying chronic liver disease in the latter study. Chemoembolization is contraindicated in patients with overt signs of portal hypertension and advanced underlying liver disease.

An important limitation of conventional chemoembolization using iodized oil lies in the uncontrolled washout of the cytotoxic drugs into the systemic circulation. Recently, a drug-eluting bead that allows controlled and sustained release of chemotherapeutic agents into the surrounding tumor was made available. This device enables delivery of a higher concentration of drugs with low systemic toxicity. Initial studies demonstrated that chemoembolization using drug-eluting beads is safe, with potentially increased effectiveness for patients with more advanced disease ⁽³⁶⁻³⁸⁾.

At MD Anderson, TACE is routinely utilized for patients with HCC with more than three lesions measuring up to 3 cm each or a single lesion greater than 5 cm. In patients with portal vein thrombosis, infiltrative disease, or more than four lesions, radio embolization with yttrium-90 microspheres is well tolerated and has been shown to improve outcomes. A recent study assessing the use of radio embolization in HCC showed response rates of 42% based on World Health Organization criteria ⁽³⁹⁾.

Radiofrequency ablation causes tissue necrosis by controlled deposition of thermal energy. This technique is highly effective in the treatment of small and early HCC, with outcomes similar to surgical resection⁽⁴⁰⁾. Radiofrequency ablation is limited by lesion proximity to adjacent structures such as colon, gallbladder, and diaphragm. In addition, vascular structures adjacent to the target lesion steal heat from the area and decrease effectiveness of the ablation. The combination of chemoembolization followed by radiofrequency ablation may improve cell death because occlusion of blood flow leads to larger ablation zones^(41, 42).

Systemic Chemotherapy and Hormonal Therapy

A majority (>80%) of patients diagnosed with HCC have advanced disease at presentation and—based on the number, size, and location of lesions, as well as the severity of the underlying cirrhosis—are not candidates for transplantation, surgical resection, or liver-directed therapies. At present, systemic chemotherapy is ineffective in HCC, as evidenced by low response rates and no demonstrated survival benefit (see Table 22-6). HCCs are inherently chemotherapy resistant⁽⁴³⁾ and known to express the multidrug-resistance gene *MDR-1*^(44, 45).

Few well-controlled, randomized chemotherapy trials have been published regarding HCC. That being said, we conducted a retrospective analysis of patients with unresectable HCC at MD Anderson who received either a conventional or a modified neoadjuvant PIAF chemotherapy regimen, consisting of cisplatin, interferon α -2b, doxorubicin, and 5-fluorouracil (5-FU). We found that select patients with HCC (patients who are noncirrhotic and without hepatitis B with good performance status [PS]) benefit from neoadjuvant-modified PIAF chemotherapy with improved response rates, resectability, and survival⁽⁴⁶⁾. Therefore, we consider this regimen in the neoadjuvant setting in select patients with unresectable tumors as bridge to surgery. Unfortunately, the ability to conduct controlled clinical trials of systemic regimens in patients with HCC has been hampered by many factors, including the multiple comorbidities of cirrhosis (Table 22-7), the advanced nature of HCC at presentation, rapid disease progression in many instances, and the distribution of patients primarily in developing nations, where multidisciplinary treatment of HCC may not be available.

Approximately 15% to 40% of HCCs are estrogen receptor positive. Hormonal therapy with tamoxifen or octreotide analogues has demonstrated some survival benefit⁽⁴⁷⁾; however, the results of other studies are conflicting.

Table 22-7 Medical Comorbidities Complicating Hepatocellular Carcinoma

Problem	Intervention
Esophageal, gastric varices	Beta blockade for portal HTN for primary prophylaxis of GI bleeding
	Endoscopic variceal banding for clinically significant GI bleeding
Thrombocytopenia	Splenic artery embolization
Hypoalbuminemia	Nutrition, caution with protein-bound medications
Ascites	K ⁺ -sparing diuretics, fluid restriction
Chronic active hepatitis	HCV: IFN/ribavirin have antiviral, antifibrotic effects. HBV: lamivudine, \pm IFN
Coagulopathy	PT most sensitive indicator of liver dysfunction

GI, gastrointestinal; HBV, hepatitis B virus; HCV, hepatitis C virus; HTN, hypertension; IFN, interferon; K, potassium; PT, protime.

Clinical Trials of Antiangiogenesis Agents

Several systemic targeted agents have recently been tested in clinical trials for patients with advanced HCC, including agents targeting the vascular endothelial growth factor (VEGF) pathway, either alone^(48–60) or in combination with other systemic therapies^(61–68). The cancer cell has been the only target of anticancer systemic therapy for more than 50 years. However, the cancer cell is genetically unstable, leading to accumulation of mutations. On the other hand, antiangiogenic therapy agents target endothelial cells that are genetically stable. Interestingly, the mechanism of action of thalidomide was thought to be partly based on its antiangiogenic effects. Nevertheless, several clinical trials of thalidomide showed rare responses, ranging from 0% to 6.3%^(58, 59).

Newer agents that target this antiangiogenic mechanism include sunitinib and sorafenib. Sunitinib is an oral multikinase inhibitor that exerts its antiangiogenic effects by targeting VEGF receptor (VEGFR) and platelet-derived growth factor receptor (PDGFR) tyrosine kinases. Sorafenib, another oral multikinase inhibitor, exerts its antitumor effect by targeting Raf/MEK/ERK signaling at the level of Raf kinase and possesses an antiangiogenic effect by targeting VEGFR-2/-3. Recently, two phase III trials of sorafenib have been reported^(48, 60). The pivotal randomized,

placebo-controlled phase III trial of sorafenib in patients with advanced HCC (SHARP trial [Sorafenib Hepatocellular Carcinoma Assessment Randomized Protocol Study group trial]) reported modest activity with a 2.8-month improvement in median overall survival (OS) ($P = .0006$). In addition, it demonstrated an increased time to progression and disease control rate while showing a response rate of 2.3% as defined by RECIST criteria (⁴⁸). This led to Food and Drug Administration (FDA) approval of sorafenib for advanced HCC in 2007, and it remains the only FDA-approved drug for this indication.

Other agents that target antiangiogenesis include bevacizumab and erlotinib. Bevacizumab is a recombinant, humanized monoclonal antibody that exerts its antitumor activity by targeting VEGF and may augment chemotherapy administration by making tumor vasculature less permeable, which decreases the elevated tumor interstitial pressure. Erlotinib is an oral tyrosine kinase inhibitor that blocks phosphorylation at the intracellular domain level of the *EGFR*. Most recently, we reported a phase II single-arm, open-label trial of bevacizumab and erlotinib that showed improved response rate, median OS, and progression-free survival (⁵³).

Collectively, application of antiangiogenesis agents to patients with advanced HCC has eventually led to improved survival despite surprisingly low response rates. Notably, there is a poor correlation between survival benefit and conventional methods of response assessment, namely, RECIST. This poses questions regarding how best to evaluate response to antiangiogenic agents and quantify efficacy of antiangiogenic agents. Despite tumors increasing in size sometimes, the observation of tumor necrosis in many studies is intriguing. Therefore, in 2000, a panel of experts recommended that the response criteria be amended to take into account tumor necrosis induced by targeted agent therapy (⁶⁹). Although its utility in assessing efficacy of anticancer agents in HCC needs to be established, tumor necrosis is a potentially significant clinical end point that warrants further investigation in future studies.

Targeted Therapies in Hepatocellular Carcinoma: Beyond Sorafenib

Given the paucity of available FDA-approved medications for advanced HCC, a number of other targeted agents have been tested in clinical trials in the adjuvant and advanced/metastatic setting. In the adjuvant setting, sorafenib did not show improved OS versus placebo in patients with previously resected or ablated HCC (⁷⁰). Similar results were seen for orantiniib, a multireceptor tyrosine kinase inhibitor of VEGFR2, PDGFR, and

fibroblast growth factor receptor (FGFR), in patients who received previous transcatheter arterial embolization (⁷¹).

In the advanced, unresectable or metastatic setting, first-line therapy with linifanib (VEGFR and PDGFR tyrosine kinase inhibitor), sunitinib (VEGFR and PDGFR), and brivanib (VEGFR and FGFR) have all been tested in phase III trials against sorafenib with no improvement in OS (⁷²⁻⁷⁴). In the second-line setting, brivanib, everolimus (mTOR pathway inhibitor), and ramircumab (fully human immunoglobulin G1 monoclonal antibody against VEGFR2) have all been tested versus placebo in patients who have either progressed on or were intolerant to sorafenib. None of these trials showed any significant improvement in OS (⁷⁵⁻⁷⁷). Two other agents, tivantinib (MET inhibitor) and cabozantinib (MET, RET, and VEGFR tyrosine kinase inhibitor) are currently being studied in clinical trials for patients in the second-line setting described. Enrollment in these trials is ongoing, and results are incomplete (^{78,79}). At present, no therapy has better proven efficacy than sorafenib in the advanced, unresectable, or metastatic setting. Table 22-8 is a summary of targeted therapies in HCC.

Radiation

Advances in our understanding of partial liver tolerance of RT, ability to visualize target tumors during respiration, and radiation planning and delivery techniques have permitted us to escalate the dose of radiation to focal HCCs without dose-limiting toxicity. This improved ability to deliver tumoricidal doses of RT safely has led to a resurgence of interest in treatment of HCC using RT. Promising clinical data from multiple studies suggested that HCCs are indeed radiosensitive. Sustained local control rates ranging from 71% to 100% have been reported following 30 to 90 Gy delivered over 1 to 8 weeks (^{80,81}).

Investigators from Michigan have used conformal RT (1.5 Gy twice daily over 6-8 weeks) with concurrent hepatic arterial fluorodeoxyuridine to treat HCCs safely to doses as high as 90 Gy and achieved a median survival duration of 15.2 months (⁸²). Analysis of these data suggested that doses greater than 75 Gy resulted in more durable in-field local control than lower doses.

A prospective French phase II trial administered 66 Gy in 33 fractions to HCCs ineligible for curative therapies and noted 92% tumor responses and 78% 1-year local control rates (⁸³). Using higher doses and fewer fractions (hypofractionated RT), Canadian researchers have noted excellent local control rates ranging from 70% to 90% when the radiation beam can be directed from multiple planes (stereotactic RT) converging on the tumor; the majority of the liver can

Table 22-8 Targeted Therapies in HCC

Trial	Drug	Primary End Point	Median (Months) (Drug vs Placebo)	Median (Months) (Drug vs Sorafenib)
Adjuvant trials				
STORM	NEXAVAR® (sorafenib)	RFS	33.4 vs 33.8	–
ORIENTAL	TSU-68 (orantinib)	OS	Unknown, terminated	–
First-line trials				
NCT01009593	ABT-869 (linifanib)	OS	–	9.1 vs 9.8
NCT00699374	Sutent® (sunitinib)	OS	–	7.9 vs 10.2
BRISK-FL	Brivanib	OS	–	9.5 vs 9.9
Second-line trials				
BRISK-PS	Brivanib	OS	9.4 vs 8.2	–
EVOLVE-1	Affinitor® (everolimus)	OS	7.6 vs 7.3	–
REACH	Cyramza® (ramucirumab)	OS	9.2 vs 7.6	–
METIV-HCC	Tivantinib	OS	Ongoing	–
CELESTIAL	XL184 (cabozantinib)	OS	Ongoing	–

OS, overall survival; RFS, relapse-free survival.

be spared from irradiation, and treatment is image guided^(81, 84, 85).

In contrast to photon irradiation, for which the dose delivered to the tumor is limited by the entrance and exit doses that can potentially harm normal tissues, accelerated proton beams deposit a dose within the tumor without exiting through normal tissues beyond the tumor⁽⁸⁶⁾. Japanese investigators have reported mature results of the treatment of 162 patients with 192 unresectable HCCs with 72 Gy in 16 fractions of proton beam therapy⁽⁸⁷⁾. The 5-year local control rate of 87% and OS rate of 23.5% in the absence of significant toxicity are clinically noteworthy. Furthermore, an impressive 5-year survival rate of 53.5% was achieved in a subset of 50 patients with solitary tumors and Child-Pugh Class A cirrhosis.

Our own experience reflects these observations that higher doses are associated with better overall, in-field progression-free and biochemical progression-free survival⁽⁸⁸⁾. Across all partial liver radiation paradigms, the most common site of first recurrence is intrahepatic but outside the high-dose irradiated volume, and toxicities are more common in Child-Pugh class B patients.

Given the excellent local control rate as noted with RT alone, RT has been combined with TACE to overcome treatment resistance. Korean researchers initially noted more than 60% response rates and a significant drop in tumor marker levels using this combination treatment strategy^(89, 90). It was reported that TACE

followed by RT improved OS over TACE alone in a retrospective analysis of this experience. Similar results have been reported by other groups as well^(91–93).

For the treatment of unfavorable tumors, multiple groups have reported favorable outcomes in patients with portal venous tumor thrombus (PVTT) treated with RT^(94–103). Response rates ranged from 37.5% to 100%, and median survival durations ranged from 3.8 to 10.7 months.

Taken together, these advances have permitted the escalation of radiation dose to unresectable HCCs without causing undue toxicity. Strategies that combine RT with other therapies merit continued evaluation to maximize the relative benefits of each approach.

MDACC APPROACH TO HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma and other primary liver tumors require multidisciplinary input, and patients benefit from clinical care that integrates the expertise of surgical oncology, liver transplantation, diagnostic and interventional radiology, gastroenterology and hepatology, radiation oncology, and medical oncology. New cases of HCC are reviewed at a weekly multidisciplinary liver tumor conference to develop a consensus approach to each patient's case. Careful attention is paid to precise tumor staging, histopathologic diagnosis, and each patient's PS.

Patients with HCC who meet current United Network for Organ Sharing (UNOS) criteria are offered liver transplantation or resection if they are highly likely to benefit. Liver-directed therapies, principally RFA and TACE, are commonly employed in patients who are not candidates for surgical intervention. In addition, select patients who present with unresectable tumors are considered for neoadjuvant chemotherapy as a bridge to surgery. Patients with good PS with advanced HCC are encouraged to participate in a clinical trial of systemic therapy. Figure 22-4 depicts the general approach followed by the multidisciplinary hepatobiliary team in managing patients with HCC evaluated at MDACC.

Small Bowel Cancer and Appendiceal Tumors

Michael J. Overman

Kanwal Raghav

Christopher H. Lieu

Commentary: Keith F. Fournier

PART A: SMALL BOWEL CANCER

Small bowel cancer is a rare malignancy representing approximately 3% of gastrointestinal neoplasms ⁽¹⁾. In 2014, it was estimated that 9,160 new cases of small bowel cancer and 1,210 small bowel cancer-related deaths would occur ⁽¹⁾. The two most common histologies seen in cancers of the small intestine are carcinoids and adenocarcinomas ⁽²⁾. Because of the nonspecific clinical presentation of small bowel adenocarcinoma and the difficulty in imaging the small bowel, most patients with small bowel adenocarcinoma present with lymph node involvement or distant metastases. Even in patients with localized disease who undergo resection with curative intent, the prognosis is poor, and no studies have yet demonstrated a clear benefit from adjuvant therapy. However, there have been some recent advances in the use of chemotherapy as palliative treatment. In this chapter, the epidemiology, diagnosis, and treatment of small bowel cancers, in particular small bowel adenocarcinoma, are reviewed.

Epidemiology

Based on an analysis of the Surveillance, Epidemiology, and End Results (SEER) database, the age-adjusted incidence rate for small bowel cancers has slowly increased from 0.9 per 100,000 persons in the years 1973 to 1982 to 1.8 per 100,000 persons in the years 2000 to 2004 ^(3,4). The majority of this increase has been attributed to an increase in the incidence of carcinoid tumors. A recent analyses of 67,643 patients with small

bowel malignancies between 1973 and 2004 using the National Cancer Data Base and SEER showed carcinoids to be dominant with 37.4% cases compared to 36.9% cases of adenocarcinomas ⁽⁵⁾. The incidence of histologic subtypes varies in the different sections of the small intestine, with adenocarcinomas representing 80% of duodenal cancers and carcinoids representing 60% of ileal cancers.

The incidence of small bowel adenocarcinoma peaks in the seventh and eighth decades of life, with a mean age at diagnosis of 65 years. A slightly increased incidence is seen in men and blacks ⁽⁶⁾.

One of the more interesting aspects of small bowel adenocarcinoma is its rarity in comparison to large intestine adenocarcinoma. Even though the small intestine represents approximately 70% to 80% of the length and over 90% of the surface area of the alimentary tract, the incidence of small bowel adenocarcinoma is 30-fold less than the incidence of colon adenocarcinoma. Numerous theories have been proposed to explain the small intestine's relative protection from the development of carcinoma. Proposed protective factors have centered on two concepts. First, the rapid turnover time of small intestinal cells results in epithelial cell shedding prior to the necessary acquisition of multiple genetic defects. Second, the small bowel's exposure to the carcinogenic components of our diet are limited due to rapid small bowel transit time, the lack of bacterial degradation activity that occurs in the small bowel, and the relatively dilute, alkaline environment of the small bowel. In a population-based comparison of adenocarcinomas of the large (n = 261,521)

and small ($n = 4,518$) intestine identified from the SEER registry, small bowel adenocarcinomas demonstrated a distinctly worse stage-adjusted cancer-specific survival compared to colorectal adenocarcinomas (⁷).

Anatomy

The small intestine is divided into three sections. The duodenum represents the first 25 cm of the small intestine and is subdivided into four anatomic segments. The proximal portion of the first (ascending) segment of the duodenum is intraperitoneal, and then the distal portion, as well as the rest of the duodenum, becomes retroperitoneal. The second (descending) segment of the duodenum contains the ampulla of Vater, through which the pancreatic and biliary secretions exit. The third (horizontal) segment of the duodenum is the longest, and as it crosses the left border of the aorta, the fourth (ascending) segment of the duodenum begins. The duodenal-jejunal junction is characterized by the attachment of the suspensory ligament of Treitz. The next segment of the small bowel, the jejunum, is approximately 2.5 m long, and the final segment, the ileum, is approximately 3.5 m long.

Etiology

Little is known about the etiology of small bowel adenocarcinoma. As seen in colorectal adenocarcinomas, adenocarcinomas of the small intestine undergo a similar phenotypic adenoma-carcinoma transformation (⁸⁻¹⁰). An increase in the size of small bowel adenomas and the presence of a villous histology are risk factors for the development of invasive adenocarcinoma.

Common underlying genetic or environmental factors of both large and small intestine adenocarcinomas have been suggested by studies that have demonstrated an increased risk of small bowel adenocarcinoma in patients with colon adenocarcinoma and vice versa (¹¹). In small bowel adenocarcinoma, microsatellite instability occurs at a similar rate to that seen in colorectal cancer (CRC). In a study of 89 patients with small bowel adenocarcinoma identified from a Swedish population-based cancer registry, the rate of microsatellite instability was 18% (¹²). This result along with the known clinical association between hereditary nonpolyposis colorectal cancer (HNPCC) syndrome and small bowel adenocarcinoma indicate that in a subset of patients with small bowel adenocarcinoma, a germline mutation in one of the mismatch repair proteins contributes to carcinogenesis.

The possible role of pancreaticobiliary secretions in the development of adenocarcinoma of the duodenum has been suggested by the anatomic clustering of duodenal carcinomas in the periampullary area. For example, in patients with familial adenomatous polyposis

(FAP), 80% of small intestinal adenocarcinomas will occur in the second portion of the duodenum. One study evaluating 213 cases of duodenal carcinomas identified from the Los Angeles County tumor registry determined that 57% of the cases originated in the second part of the duodenum (¹³).

Environment and Dietary Risk Factors

A number of case-control studies have analyzed associations between environmental and dietary factors and the development of small bowel adenocarcinoma. Two studies have demonstrated that there is an association between the ingestion of smoked or salt-cured foods and the development of small bowel adenocarcinoma (^{14, 15}). An association between tobacco use and cancer risk has been inconsistently demonstrated. Case-control studies have demonstrated an association between an increased risk of small bowel adenocarcinoma and high alcohol intake, high sugar intake, high red meat intake, low fiber intake, celiac disease, peptic ulcer disease, and prior cholecystectomy (¹⁴⁻¹⁸). Studies of the relationship with obesity have been conflicting, although a recent case-cohort study of 500,000 subjects with 134 incident cases of small bowel cancer showed a statistically nonsignificant trend toward increased risk in subjects with high body mass index (BMI) (hazard ratio [HR] 1.5 [95% CI, 0.76-2.96] for BMI >27.5 kg/m² compared with 22.6-25.0 kg/m²) (¹⁹).

Genetic Cancer Syndromes

The genetic cancer syndromes HNPCC, FAP, and Peutz-Jeghers syndrome (PJS) are all associated with small bowel adenocarcinoma. The estimated lifetime risk for small bowel adenocarcinoma is 1% to 4% in patients with HNPCC, 5% in those with FAP, and 13% in those with PJS (²⁰⁻²³). Patients with HNPCC develop small bowel adenocarcinoma at a younger age, with a median age at diagnosis of 49 years. Patients with PJS, an autosomal dominant polyposis disorder characterized by multiple hamartomatous polyps throughout the intestinal tract, have a markedly increased risk for small bowel adenocarcinoma, with one meta-analysis demonstrating a 520-fold increased relative risk (²⁴). Duodenal adenomas are seen in approximately 80% of patients with FAP, and regular endoscopic screening for the development of adenocarcinoma is required for these patients. The optimal frequency of endoscopic screening depends on a number of factors, such as the number of polyps, polyp size, polyp histology, and amount of dysplasia present (²⁰). With the early use of colectomy in patients with FAP, duodenal adenocarcinomas and desmoid tumors are now a more common cause of death in this population than cancer arising from the colorectum.

Inflammatory Bowel Disease

Inflammatory bowel disease, particularly Crohn disease, is associated with the development of small bowel adenocarcinoma. The increase in risk varies depending on both the extent and duration of small bowel involvement. In one study, the cumulative risk of small bowel adenocarcinoma in patients with Crohn disease was 0.2% at 10 years and 2.2% at 25 years⁽²⁵⁾. Because Crohn disease frequently involves the ileum, 70% of the small bowel cancers in patients with Crohn disease will occur in the ileum. Patients with Crohn disease who develop small bowel adenocarcinoma appear to have a worse prognosis, with one study of 37 patients with small bowel adenocarcinoma demonstrating significantly shorter overall survival (OS) in the patients with Crohn disease⁽²⁶⁾.

Molecular Profile

Early limited data has begun to accumulate regarding molecular characterization of small bowel adenocarcinomas. Accumulation of genetic defects such as loss of e-cadherin and *smad4* and mutations in *KRAS*, *P53*, and *SMAD4* have been implicated in the adenoma-dysplasia-carcinoma sequence of small bowel adenocarcinomas⁽²⁾. In a pivotal study comparing chromosomal copy number aberrations in 85 gastric, colorectal, and small bowel adenocarcinomas, hierarchical clustering revealed a substantial overlap of sba copy number profiles with matched colorectal adenocarcinomas but less overlap with profiles of gastric adenocarcinomas, indicating a genetic profile similar to CRC⁽²⁷⁾. Large screening of somatic mutations in 83 patients revealed *KRAS*, *TP53*, *APC*, *SMAD4*, *PIK3CA*, *erbb2*, *braf*, and *fbxw7* mutations in >5% of small bowel adenocarcinomas⁽²⁴⁾. Understanding the biology of small bowel adenocarcinomas may lead to the possibility of developing targeted therapy in this rare cancer.

Presentation and Diagnosis

Clinical Presentation

The symptoms associated with small bowel adenocarcinoma are nonspecific and frequently do not occur until advanced disease is present. The most commonly reported symptoms are abdominal pain (45%-76% of patients), nausea and vomiting (31%-52%), weight loss (22%-29%), and gastrointestinal bleeding (8%-34%). Delays in diagnosis are common, with one retrospective study reporting a mean delay of 7.8 months from the time of initial physician evaluation until a final diagnosis was made⁽²⁸⁾. According to the National Cancer Database, 39% of patients present with stage I/II disease, 26% present with stage III disease, and 32% present with stage IV disease⁽²⁹⁾.

Diagnosis

Given the nonspecific presenting symptoms, a high index of suspicion is a crucial first step in diagnosis. Because imaging of the small intestine is difficult, multiple tests may be needed. However, with the availability of wireless capsule endoscopy, the need for older small bowel imaging techniques has declined.

A barium small bowel follow-through study has been the radiographic gold standard for small bowel evaluation. In patients with advanced-stage disease, this technique has a sensitivity of approximately 60% for diagnosing small bowel tumors. Enteroclysis, in which contrast material is infused directly into the small intestine through a nasogastric tube, provides a slightly higher sensitivity than small bowel follow-through. Endoscopic evaluation of the small intestine, or enteroscopy, requires expertise and is frequently unable to evaluate the entire small intestine.

The incorporation of wireless capsule endoscopy, which was approved by the US Food and Drug Administration in 2001, has allowed a much simpler and improved method for evaluating the lumen of the small intestine. This technique has primarily been applied to the evaluation of obscure gastrointestinal bleeding, for which it has shown superiority over other imaging and endoscopy techniques⁽³⁰⁾. In one study evaluating capsule endoscopy in 60 patients with suspected small bowel pathology but without gastrointestinal bleeding, the overall diagnostic yield of capsule endoscopy was 62%⁽³¹⁾. In that study, all patients had undergone upper and lower gastrointestinal endoscopy, and many had undergone enteroclysis, small bowel follow-through, push enteroscopy, and abdominal computed tomography (CT). In a large single-center retrospective review of 562 patients who underwent capsule endoscopy, small bowel tumors were found in 8.9% of cases⁽³²⁾. The major limitations of capsule endoscopy are that no tissue sampling can be conducted and that the patients cannot have bowel obstruction, which could result in the capsule's becoming trapped in the bowel.

Three-dimensional imaging with either CT or magnetic resonance imaging (MRI) is useful in identifying locoregional lymph node involvement and the presence of distant metastatic disease. For tumors of the duodenum, endoscopic ultrasonography can be useful in assessing both the tumor and nodal status. Although not directly studied for duodenal adenocarcinomas, endoscopic ultrasonography has been demonstrated to improve staging accuracy for both ampullary and pancreatic cancers.

Staging and Prognosis

The TNM (tumor, node, metastasis) staging system for small bowel adenocarcinoma is shown in Table 23-1⁽³³⁾.

Table 23-1 TNM Staging for Adenocarcinoma of the Small Intestine

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1a	Tumor invades lamina propria		
T1b	Tumor invades submucosa		
T2	Tumor invades muscularis propria		
T3	Tumor invades through the muscularis propria into the subserosa or into the nonperitonealized perimuscular tissue (mesentery or retroperitoneum) with extension 2 cm or less ^a		
T4	Tumor perforates the visceral peritoneum or directly invades other organs or structures (includes other loops of small intestine, mesentery, or retroperitoneum >2 cm and abdominal wall by way of serosa; for duodenum only, invasion of pancreas or bile duct)		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in 1-3 regional lymph nodes		
N2	Metastasis in 4 or more regional lymph nodes		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T4	N0	M0
Stage IIIA	Any T	N1	M0
Stage IIIB	Any T	N2	M0
Stage IV	Any T	Any N	M1

^aThe nonperitonealized perimuscular tissue is for the jejunum and ileum, part of the mesentery; and for duodenum in areas where serosa is lacking, part of the interface with the pancreas.

In a study of 4,995 patients who were diagnosed with small bowel adenocarcinoma between 1985 and 1995 (identified in the National Cancer Database), the 5-year disease-specific survival (DSS) rate was 65% for patients with stage I disease, 48% for patients with stage II disease, 35% for patients with stage III disease, and 4% for patients with stage IV disease (²⁹). A multivariate analysis from this study identified age >75 years, primary duodenal tumor site, non-cancer-directed surgery, and higher-stage disease as poor prognostic factors. Though significant on a univariate analysis, a poorly differentiated histology was not a significant prognostic factor on multivariate analysis ($P = .089$). In other studies, the histopathologic factors reported to be correlated with poor survival were

poorly differentiated histology, positive margins, lymphovascular invasion, lymph node involvement, and T4 tumor stage (^{26, 34–36}). The 5-year OS rates from various single-institution studies for resected small bowel adenocarcinoma are presented in [Table 23-2](#).

Treatment

Surgical Management

For patients with localized disease, complete removal of the tumor with negative surgical margins and local lymph node removal are critical for a potentially curative resection. For jejunal and ileal lesions, an oncologically successful resection requires a wide local excision

Table 23-2 Reported Overall Survival of Patients With Curatively Resected Small Bowel Adenocarcinoma

First Author	Period	Tumor Location	Number of Patients	Overall Survival	
				Median (Months)	5 Year (%)
Agarawal	1971-2005	Small intestine	30	56	45
Kelsey	1975-2005	Duodenum	25	NR	64
Wu	1983-2003	Small intestine	45	NR	27
Swartz	1994-2003	Duodenum	14	41	44
Dabaja	1978-1998	Small intestine	142	36	29
Czaykowski	1990-2000	Small intestine	19	39	NR
Talamonti	1977-2000	Small intestine	26	40	42

Cunningham	1970-1991	Small intestine	19	23	32
Frost	1960-1989	Small intestine	22	NR	32

NR, not reported.

with lymphadenectomy. Lesions located in the duodenum generally require a pancreaticoduodenectomy; however, for small distal lesions in the third and fourth portions of the duodenum, a wide local excision may be an option. In a surgical series of 68 patients with duodenal adenocarcinoma, no differences in the 5-year OS rates, local recurrence rates, or margin-negative resection rates were seen between the 50 patients who underwent pancreatic resections and the 18 patients who underwent distal duodenal segmental resections⁽³⁷⁾. The presence of locoregional lymph node involvement should not deter surgical intervention because well over one-third of patients will survive long term^(29, 38). This is in contrast to patients with lymph node–positive pancreatic cancer, of whom only 7% survive 5 years⁽³⁹⁾. As is seen with colon cancer, the total lymph nodes (TLNs) assessed during surgery and the number of positive lymph nodes (PLNs) have prognostic implications in small bowel adenocarcinomas. In a SEER registry retrospective review of 1,991 patients, the 5-year DSS for patients with stage II disease appeared to be associated with the TLNs assessed (44%, 69%, and 83% for 0 TLNs, 1 to 7 TLNs, and >7 TLNs, respectively)⁽⁴⁰⁾. Furthermore, the 5-year DSS with stage III disease was associated with the number of PLNs (58% and 37% for <3 PLNs and ≥3 PLNs, respectively)⁽⁴⁰⁾.

Patterns of Recurrence

Recurrence after potentially curative resection of small bowel adenocarcinoma occurs most commonly at distant sites. In a series of 146 patients who underwent

resection for small bowel adenocarcinoma, 56 patients relapsed at a median of 25 months, with the sites of relapse reported as distant in 59%, peritoneum in 20%, abdominal wall in 7%, and local in 18%⁽⁴¹⁾. In a second study of 30 patients who underwent potentially curative resection for small bowel adenocarcinoma, 21 patients experienced a relapse, with the sites of relapse being the liver in 67% of the patients, lung in 38%, retroperitoneum in 29%, and peritoneum in 25%⁽³⁴⁾.

Patients with duodenal adenocarcinoma have a higher rate of locoregional failure than for jejunal and ileal adenocarcinoma, with one study reporting a 39% rate of locoregional failure among 31 patients after curative resection of duodenal adenocarcinoma⁽⁴²⁾. In that study, positive margin status was the strongest predictor of local recurrence, with 4 of the 5 patients who had a margin positive resection developing a local recurrence. However, distant recurrences are still predominant, with a retrospective review of recurrence patterns in 67 patients with resected duodenal adenocarcinoma revealing local recurrences in 33% of the patients and distant recurrences in 67%⁽⁴³⁾.

Adjuvant Therapy

Currently, there is no evidence demonstrating a benefit from adjuvant therapy in patients with small bowel adenocarcinoma who undergo potentially curative resection. However, owing to the rarity of small bowel adenocarcinoma, only a limited number of primarily small retrospective studies have been conducted (Table 23-3). Selection bias is the major limitation of these

Table 23-3 Reported Overall Survival of Patients Who Received Adjuvant Therapy After Resection of Small Bowel Adenocarcinoma

First Author	Time Period	Study Type	Tumor Location	Type of Adjuvant Therapy	Number of Patients				Median Overall Survival (Months)		
					Total	No Adjuvant Therapy	Adjuvant Therapy	No Adjuvant Therapy	Adjuvant Therapy	P Value

5-FU, 5-fluorouracil; NR, not reported.

^aFive-year overall survival rate.

retrospective studies because the patients selected to receive adjuvant therapy were the patients believed to be at highest risk for disease recurrence. One prospective phase III study conducted by the European Organization for Research and Treatment of Cancer randomized 93 eligible patients with periampullary carcinoma (defined as adenocarcinoma of the distal common bile duct, ampulla of Vater, or duodenum) to receive either no adjuvant therapy or concurrent 5-fluorouracil (5-FU) and radiation therapy (⁴⁴). The 5-year OS rates were similar in the two groups, but 30% of the patients assigned to receive adjuvant therapy did not actually receive it, and no description of the results in the duodenal adenocarcinoma subgroup were reported.

In a series by Kelsey et al, no differences in the 5-year OS rates were seen between the patients who did or did not receive adjuvant therapy after resection of duodenal adenocarcinoma. However, in the subgroup of patients who had undergone a margin-negative resection, the 5-year OS rate was 53% in the patients who underwent resection only and 83% in the patients who had resection and adjuvant chemoradiation therapy ($P = .07$) (⁴²). A trend toward improvement of disease-free survival and OS was seen in patients receiving adjuvant therapy in a retrospective series at MD Anderson Cancer Center ($n = 54$) (⁴⁵). However, in the subgroup analyses in patients with high-risk disease, defined by a lymph node ratio $\geq 10\%$, adjuvant therapy was associated with significant improvement in OS (⁴⁵). In contrast, in a single-institution retrospective review at Mayo Clinic, no benefit of adjuvant chemotherapy or chemoradiotherapy was seen in patients with resected small bowel adenocarcinoma (⁴⁶).

Limited data are available regarding a neoadjuvant (preoperative) treatment approach for duodenal adenocarcinoma. In one report in which 11 patients underwent neoadjuvant chemoradiation therapy followed by resection for duodenal adenocarcinoma, a complete pathologic response was seen in 2 patients, and none of the 11 patients had histopathologic nodal involvement at the time of surgery (⁴²).

The MD Anderson Approach to Nonmetastatic Disease

At the University of Texas MD Anderson Cancer Center, patients with high-risk, resected small bowel adenocarcinoma are typically offered postoperative adjuvant chemotherapy. In general, patients who are considered to be at high risk are those with lymph node involvement and positive resection margins. The lack of proven benefit from adjuvant chemotherapy for this tumor type must be discussed with the patient. However, the rationale for considering adjuvant chemotherapy is based on

1. The known poor prognosis of patients with high-risk disease
2. The predominantly systemic relapse pattern for small intestinal adenocarcinoma
3. The proven activity of chemotherapy in the treatment of metastatic small intestinal adenocarcinoma
4. The known benefit of adjuvant chemotherapy in large intestinal adenocarcinoma, which appears to have a number of similarities to small intestinal adenocarcinoma
5. The extremely limited amount of high-quality data to support or refute the role of adjuvant therapy for small bowel adenocarcinoma

Based on the substantial activity of a 5-FU and platinum combination in the metastatic disease setting, we generally utilize the combination of capecitabine and oxaliplatin (CAPOX) as adjuvant therapy for nonmetastatic small bowel adenocarcinoma. In addition to systemic chemotherapy, radiation therapy is considered for patients with duodenal adenocarcinoma who are at high risk for a local recurrence based on the presence of positive margins or T4 disease.

Metastatic Disease

In general, chemotherapy for metastatic small bowel adenocarcinoma has been based on the principles used for treating colon cancer. Several single-institution retrospective series have demonstrated a survival benefit in patients with metastatic or unresectable small bowel adenocarcinoma who received chemotherapy when compared to patients who did not receive chemotherapy (^{41, 47}).

Most of the studies evaluating chemotherapy for small bowel adenocarcinoma have been retrospective, with only four prospective phase II studies reported (Table 23-4). One multicenter study conducted by the Eastern Cooperative Oncology Group reported on the combination of 5-FU, doxorubicin, and mitomycin C (FAM) in 39 patients with adenocarcinomas of the duodenum, jejunum, ileum, or ampulla of Vater. The overall response rate was 18%, with a median OS time of 8 months (⁴⁸). A single-institution study conducted at MD Anderson evaluated CAPOX in 30 patients with metastatic or locally advanced small bowel or ampullary adenocarcinomas. The overall response rate was 50%, with a median time to progression of 9.8 months and an OS time of 20.3 months (⁴⁹). An example of a response to CAPOX chemotherapy in a patient treated in that study is shown in Fig. 23-1. In 33 patients treated with continuous infusional 5-FU and leucovorin in combination oxaliplatin (modified 5-FU and oxaliplatin [FOLFOX] regimen), the objective response rate was 48.5%, and the median OS was 15.2 months (⁵⁰). Another prospective, multicenter,

CAPOX, capecitabine and oxaliplatin; CAPOXIRI, capecitabine, oxaliplatin, and irinotecan; ECF, 5-FU, epirubicin, and cisplatin; FAM, 5-FU, doxorubicin, and mitomycin C; FOLFOX, 5-fluorouracil and oxaliplatin; 5-FU, 5-fluorouracil; LAD, locally advanced, unresectable disease; NS, not significant.

first-line study (n = 23) using CAPOXIRI (capecitabine, oxaliplatin, and irinotecan) showed a response rate of 39% and a median survival of 12.7 months⁽⁵¹⁾.

Several retrospective studies have confirmed the substantial activity of 5-FU combined with a platinum agent for metastatic small bowel adenocarcinoma, with response rates of 18%–46%^(52–55). In one of the largest retrospective studies to date, a total of 80 patients with metastatic small bowel adenocarcinoma were treated with various regimens: 29 received 5-FU with a platinum (19 received cisplatin, 4 received carboplatin, and 6 received oxaliplatin); 41 received 5-FU–based therapy without a platinum (32 received 5-FU alone, 3 received FAM, 3 received 5-FU and mitomycin,

and 3 received other 5-FU combinations); and 10 received non-platinum–based and non-5-FU–based therapy⁽⁵⁵⁾. Patients who received 5-FU combined with a platinum agent had a higher overall response rate (46% vs 16%; $P < .01$) and longer median progression-free survival (PFS) time (8.7 vs 3.9 months; $P < .01$) than patients who received other chemotherapy regimens. Although not statistically significant, there was also a trend toward improved median OS times in patients who received 5-FU plus a platinum agent (14.8 vs 12.0 months; $P = .1$). A French multicenter study in SBA receiving frontline chemotherapy with LV5FU2 (n = 10), FOLFOX (n = 48), FOLFIRI (n = 19), and LV5FU2-cisplatin (n = 16) demonstrated a median PFS

FIGURE 23-1 Radiographic response to capecitabine and oxaliplatin (CAPOX) chemotherapy in a patient with locally advanced small bowel adenocarcinoma. Pretreatment (A) and posttreatment (B) computed tomographic scans shown.

of 7.7, 6.9, 6.0, and 4.8 months, respectively⁽⁴⁷⁾. The corresponding median OS was 13.5, 17.8, 10.6, and 9.3 months, respectively⁽⁴⁷⁾. In the subgroup analysis, patients treated with LV5FU2-cisplatin had poorer PFS ($P < .01$) and OS ($P = .02$) compared with oxaliplatin-based chemotherapy⁽⁴⁷⁾.

Irinotecan-based chemotherapy is also active against metastatic small bowel adenocarcinoma. One retrospective study reported that 5 of 12 patients responded to irinotecan-based therapy (3 patients responded to 5-FU plus irinotecan, 1 responded to capecitabine plus irinotecan, and 1 responded to single-agent irinotecan)⁽⁵³⁾. A second study of salvage therapy with irinotecan in the second-line setting noted stable disease in 4 of 8 treated patients⁽⁵⁴⁾. Among the 19 patients in the AGEO study treated with 5-FU plus irinotecan, 1 had a partial response, and stable disease was seen in 7 patients⁽⁴⁷⁾. Responses to gemcitabine-based therapy have also been noted, although the number of patients treated has been small. The role of targeted therapies against the vascular endothelial growth factor (VEGF) or epidermal growth factor receptors (*EGFRs*) has not been studied in small bowel adenocarcinoma.

The MD Anderson Approach to Metastatic Disease

The substantial response rates and prolonged OS times recently reported with modern-day chemotherapy combinations in small bowel adenocarcinomas strongly argue for an aggressive approach in treating patients with metastatic small bowel adenocarcinoma.

Given the extremely encouraging results with CAPOX and FOLFOX for metastatic small bowel adenocarcinoma, we generally recommend these regimens at MD Anderson. Following frontline CAPOX or FOLFOX chemotherapy, patients are then treated with an irinotecan-based regimen. In addition, patients with limited metastatic disease who respond to initial chemotherapy are considered for surgical resection if all disease sites can be successfully excised. Investigations are ongoing at MD Anderson to evaluate the role of *EGFR* inhibition in addition to CAPOX chemotherapy for small bowel adenocarcinoma. More effective treatments for small bowel adenocarcinoma remain needed, and participation in clinical trials for this rare tumor type is strongly encouraged. A proposed treatment algorithm for small bowel adenocarcinoma is presented in Fig. 23-2.

PART B: APPENDICEAL TUMORS

Appendiceal tumors encompass a rare and diverse group of neoplasms. With an age-adjusted incidence of about 0.12 cases per 1 million individuals per year, appendiceal tumors represent only 1% of all CRCs diagnosed each year in the United States^(56,57). Historically, appendiceal tumors have been grouped together with CRCs. However, appendiceal tumors, in which outcomes are strongly determined by histologic subtype, tend to have a biology very different from that of CRC. Appendiceal tumors comprise two types: appendiceal carcinoid tumors and appendiceal epithelial

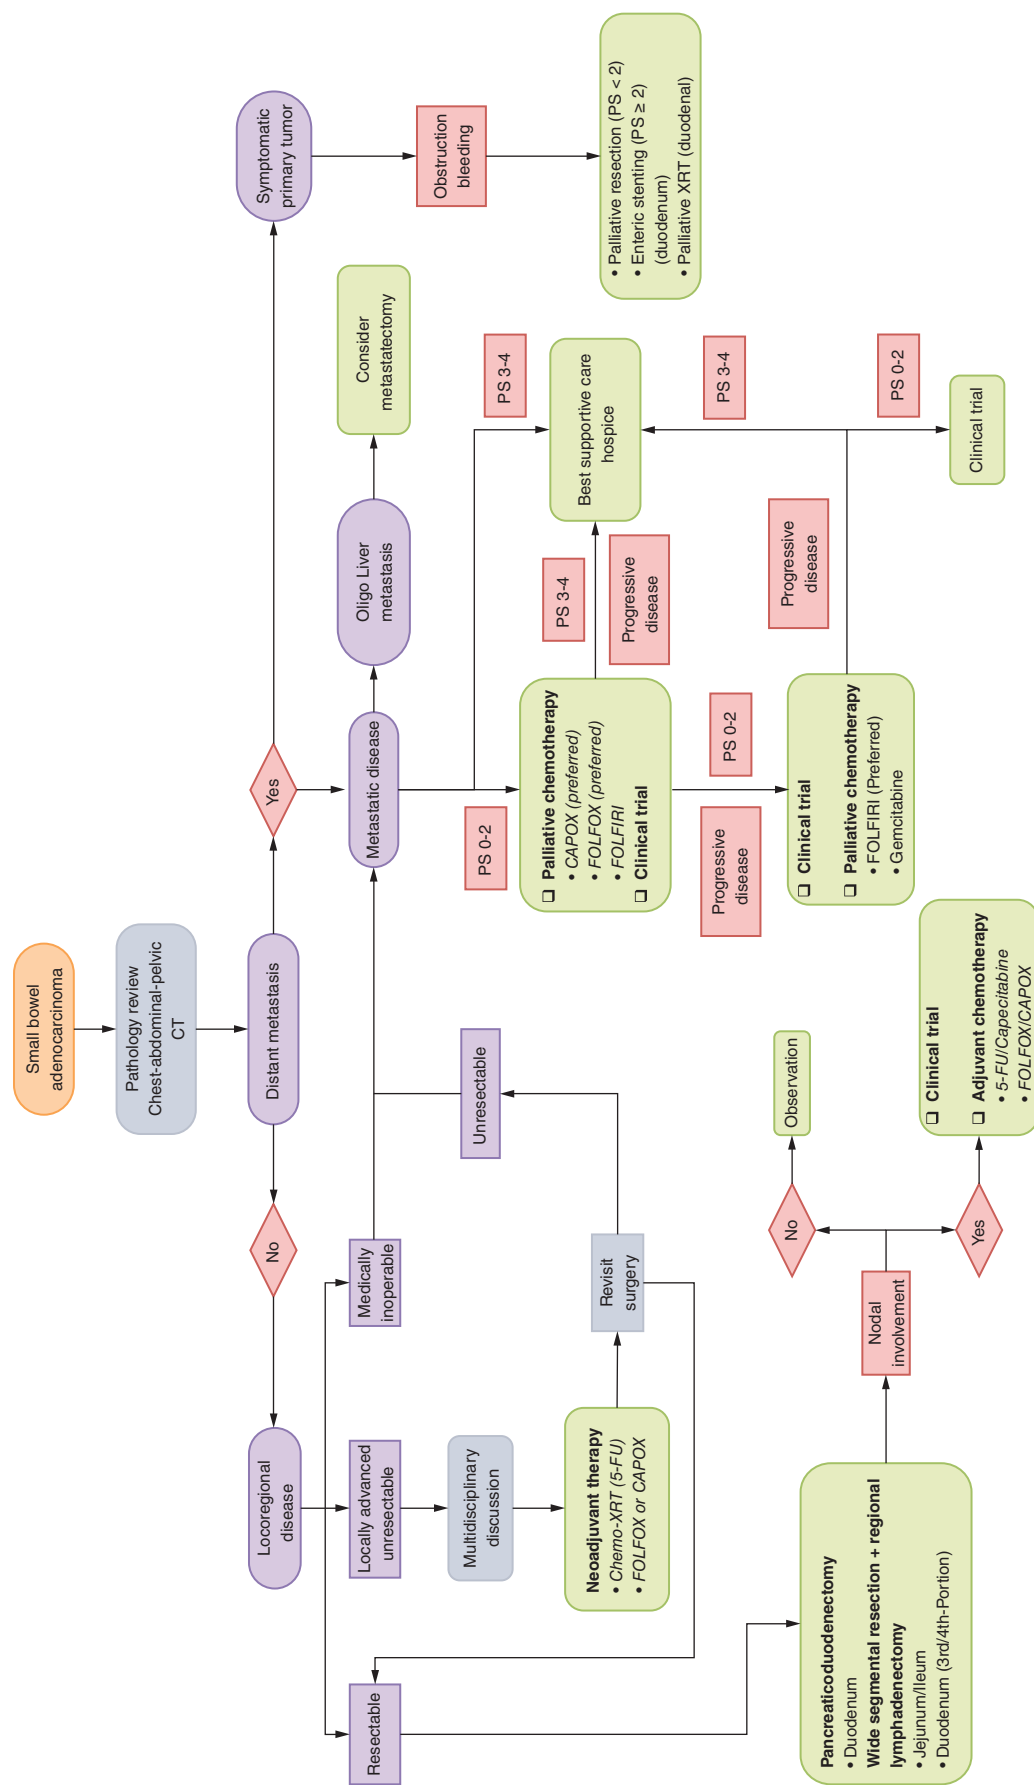

FIGURE 23-2 Treatment algorithm for small bowel adenocarcinoma. (Reproduced with permission from Raghav K. and Overman M. J. Small bowel adenocarcinomas—existing evidence and evolving paradigms. *Nat Rev Clin Oncol*. 2013;10:534.)

tumors. Appendiceal carcinoid tumors account for approximately 50% of all appendiceal neoplasms, and appendiceal epithelial tumors represent the remaining 50%⁽⁵⁸⁾. This chapter on appendiceal tumors discusses the management of these two tumor types (carcinoid and epithelial) and, in particular, the unusual clinical syndrome of pseudomyxoma peritonei (PMP).

Incidence

Data derived from the SEER database of the National Cancer Institute between 1973 and 1998 revealed that the most common histologic subtypes of malignant tumors of the appendix were adenocarcinomas (67%) and carcinoids (33%)⁽⁵⁶⁾. However, this analysis captured neither adenomatous tumors nor benign carcinoids. The subtypes of adenocarcinoma were mucinous type (56%), nonmucinous intestinal type (38%), and signet ring cell type (6%). Alternatively, in a separate study of 7,970 appendectomy specimens, tumors were identified in 1% of specimens, with carcinoids representing 57% of all tumors identified⁽⁵⁸⁾. Adenomas and adenocarcinomas represented 18% and 11% of the identified tumors, respectively.

Presentation and Prognosis

The majority of appendiceal tumors are identified incidentally at the time of pathological review of appendectomy specimens. Symptoms of appendicitis are most often the presenting symptom, especially with tumors located at the base of the appendix, where obstruction is more likely to occur. Other symptoms

seen with more advanced appendiceal disease can reflect the nonspecific abdominal symptoms associated with peritoneal involvement: abdominal pain and distention, altered bowel motility, and early satiety. Metastatic carcinoid tumors may also present with symptoms related to the carcinoid syndrome, with episodic flushing, wheezing, and diarrhea. Patient age at presentation differs depending on histologic subtype of the tumor, with the mean age of 38 years for patients with carcinoid tumors and the mean age of 60 years for those with adenocarcinomas⁽⁵⁶⁾.

Prognosis for appendiceal cancer is strongly dependent on the histopathologic subtype of the tumor, with patients who have carcinoids having a significantly better survival than do patients with adenocarcinomas (Fig. 23-3)⁽⁵⁶⁾. In addition, patients with early-stage tumors identified incidentally at the time of appendectomy have a better prognosis than patients who are diagnosed once symptoms develop.

Prognosis for patients with epithelial tumors is also strongly dependent on histopathology of the tumor. Staging for appendiceal carcinomas is based on the TNM seventh edition staging system and incorporates histological grade in the differentiation between stage IVA and IVB (Table 23-5)⁽³³⁾.

For metastatic epithelial tumors of the appendix, prognosis is excellent for those with low-grade mucinous tumors, termed disseminated peritoneal adenomucinosis (DPAM), whereas appendiceal adenocarcinomas with high-grade histological features such as poor differentiation or signet ring cell morphology have a much poorer survival. Presence of lymph node

metastases is a predictor of recurrence in early-stage tumors⁽⁵⁹⁾. Stage IV mucinous appendiceal adenocarcinomas are categorized as either mucinous low grade (well differentiated) or mucinous high grade (moderate and poor differentiation) by the American Joint Committee on Cancer (AJCC) seventh edition. However, recent population-based efforts utilizing the SEER database have demonstrated that mucinous moderate-differentiated adenocarcinomas appear to have a prognosis more akin to mucinous well-differentiated carcinomas as opposed to mucinous poorly differentiated carcinomas⁽⁵⁹⁾.

Appendiceal Carcinoid Tumors

Similar to other intestinal carcinoid tumors, appendiceal carcinoid tumors arise from neuroendocrine cells within the lamina propria and submucosa. Appendiceal carcinoid tumors can secrete serotonin and vasoactive substances responsible for the carcinoid syndrome, although this is rarely seen in patients in the absence of extensive liver metastases. Appendiceal carcinoid tumors are usually seen in young patients and are seen slightly more often in women^(60, 61).

A rare histological variant of carcinoid tumors, termed goblet cell carcinoids or adenocarcinoids, is characterized by malignant cells that demonstrate both exocrine and neuroendocrine characteristics. This histological subtype has outcomes in between that of a carcinoid and that of an adenocarcinoma (see Fig. 23-3).

Management of Appendiceal Carcinoids

As most appendiceal carcinoid tumors are discovered incidentally from an appendectomy specimen, a critical and somewhat-controversial oncologic question relates to the need for performing a more complete surgical staging procedure. For appendiceal cancers, a complete surgical staging procedure would entail a right hemicolectomy with complete removal of the base of the appendix, mesoappendix, and draining lymph nodes.

The most useful criteria for determining the need for a complete right hemicolectomy are tumor size (≥ 2 cm in diameter) or mesoappendix involvement⁽⁶²⁾. In a retrospective study of appendiceal carcinoids, Moertel et al reported no metastases in 127 patients with tumors < 2 cm, whereas metastatic disease was seen in 3 of the 14 patients with tumors 2 to 3 cm and 4 of the 9 patients with tumors ≥ 3 cm⁽⁶³⁾. Patients with an adenocarcinoid histological variant are generally treated as having an appendiceal adenocarcinoma.

For patients with metastatic disease, the use of somatostatin analogues can alleviate the symptoms of the carcinoid syndrome but rarely causes objective tumor regression. Given the slow-growing nature of

appendiceal carcinoid tumors, local modality therapies such as hepatic embolization or surgical resection may also be beneficial in selected patients with metastatic disease. For additional information on management of this type of tumor, please refer to Chapter 23.

Appendiceal Epithelial Tumors

Little is known about the risk factors or etiology of epithelial tumors of the appendix. Although generally viewed as a subset of CRC, most epithelial tumors of the appendix have a markedly different biology and natural history than do adenocarcinomas of the colorectum. In particular, a subset of appendiceal epithelial tumors that have disseminated peritoneal mucinous deposits derived from a ruptured appendiceal mucinous adenoma can demonstrate excellent long-term survival with aggressive cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC)^(64, 65).

Most appendiceal epithelial tumors begin as a mucinous adenoma with appendiceal distention caused by excessive mucin production. On gross inspection or radiographic evaluation, this dilated mucin-filled appendix is frequently referred to as a mucocele. With progressive growth, the appendiceal lumen can become obstructed and result in increased intraluminal pressure within the appendix, which can cause the appendix to rupture. Appendiceal rupture represents the critical step in the dissemination of the mucinous appendiceal tumor to the peritoneal cavity. For this reason, it is critical that care is taken when surgically removing an appendiceal mucocele to prevent rupture and peritoneal seeding during a routine appendectomy⁽⁶⁶⁾. When resecting an appendiceal mucocele, the peritoneum should be inspected closely to evaluate any evidence of dissemination to the peritoneal cavity. During pathological examination of the appendix, any fluid or mucus in the peritoneal spaces surrounding the appendix should undergo cytologic examination⁽⁶²⁾. In patients with localized disease, the presence of carcinoma requires a completion right hemicolectomy for oncologic staging.

Molecular Profile

The molecular characterization of appendiceal adenocarcinomas is limited. Mutations are frequently seen in these tumors and include *KRAS*, *GNAS*, *AKT*, *MET*, *PIK3CA*, and *TP53* genes⁽⁶⁷⁻⁷⁰⁾. In a cohort of 149 patients with appendiceal adenocarcinomas at MD Anderson Cancer Center, *KRAS*, *PIK3CA*, and *BRAF* mutations were seen in 55%, 17%, and 4% of patients, respectively⁽⁷¹⁾. The study also demonstrated that well- and moderately differentiated appendiceal adenocarcinomas were molecularly distinct from poorly differentiated appendiceal adenocarcinomas⁽⁷¹⁾.

Pseudomyxoma Peritonei

Pseudomyxoma peritonei, or false mucinous tumor, is a term originally described by Werth in 1884, who described the pathological findings in a patient with a ruptured ovarian cystadenoma who had copious gelatinous intraperitoneal ascites (Fig. 23-4) (72). This term has been applied broadly to include any mucinous tumor type involving the peritoneal cavity with any histologic grade of differentiation. However, this imprecise definition has resulted in the grouping of patients with dramatically different outcomes and has generated considerable confusion for patients and even among clinicians. A better understanding of disease biology has shown that this clinical term is most appropriately applied to the pathological subtype of appendiceal tumors called disseminated peritoneal adenomucinosis (73).

However, the term *PMP* is frequently utilized to refer to the clinical syndrome of mucinous peritoneal deposits resulting from any mucinous appendiceal tumor. When used in this fashion, this term encompasses both DPAM and the appendiceal epithelial tumor subtype termed peritoneal mucinous carcinomatosis (PMCA). However, the inclusion of these two histological subtypes combines two appendiceal epithelial tumor types with markedly different OSs (Table 23-6) (73, 74).

Histopathologic Subtypes of Epithelial Appendiceal Tumors

Disseminated Peritoneal Adenomucinosis

Disseminated peritoneal adenomucinosis is characterized by peritoneal lesions composed of abundant

FIGURE 23-4 Peritoneal mucin in a patient undergoing surgical cytoreduction for peritoneal mucinous carcinomatosis (PMCA). (Reproduced with permission from Ronnett BM, Zahn CM, Kurman RJ, et al. Disseminated peritoneal adenomucinosis and peritoneal mucinous carcinomatosis. A clinicopathologic analysis of 109 cases with emphasis on distinguishing pathologic features, site of origin, prognosis, and relationship to “pseudomyxoma peritonei.” *Am J Surg Pathol.* 1995;19:1390-408.)

extracellular, mucin-containing, scant, simple to focally proliferative mucinous epithelium with little cytologic atypia or mitotic activity, with or without an associated appendiceal mucinous adenoma (73). In essence, the underlying epithelium in DPAM may have low-grade adenomatous changes but may not have any evidence of invasion or carcinoma. This subgroup of tumors (DPAMs) demonstrates the classic PMP clinical syndrome of massive amounts of benign-appearing mucinous ascites that over time slowly fill the entire

Table 23-6 Overall Survival for Appendiceal Epithelial Tumors Stratified by Histology Subtype of Disseminated Peritoneal Adenomucinosis (DPAM) or Peritoneal Mucinous Carcinomatosis (PMCA)

FIGURE 23-5 Histology from a patient with disseminated peritoneal adenomucinosis (DPAM) and the clinical syndrome of pseudomyxoma peritonei (PMP): (A) adenoma-like epithelium with acellular mucin pools dissecting through the fibrous stroma with chronic inflammation, $\times 40$; (B) adenoma-like epithelium with abundant acellular mucin, $\times 400$.

peritoneal cavity (Fig. 23-5). Although spread to the peritoneal cavity is present, these tumors do not metastasize to regional lymph nodes or via hematogenous spread to the liver or other distant sites.

Patients with DPAM typically present with gradually increasing abdominal girth. For women, DPAM may present as a new ovarian mass, and for men it may present as a new-onset hernia. In women, secondary involvement of the ovaries is common, and because histopathological features of DPAM from a primary ovarian tumor are extremely rare, a thorough pathological examination of the appendix should be conducted (⁷⁵). When molecular and immunohistochemical evaluations have been performed on cases with both appendix and ovarian involvement, these evaluations have uniformly demonstrated the primary site of disease as the appendix (^{76–78}).

Peritoneal Mucinous Carcinomatosis

If evidence of invasion and carcinoma is present, then the pathological diagnosis of PMCA should be used (⁷³). Peritoneal mucinous carcinomatosis is characterized by peritoneal lesions composed of more abundant mucinous epithelium with the architectural and cytologic features of carcinoma, with or without an associated primary mucinous adenocarcinoma. A subset of PMCA tumors that demonstrate features of both DPAM and PMCA have been termed PMCA with intermediate or discordant features (PMCA-I/D) (⁷³). In an analysis of 109 patients with clinical features of PMP, 60% were classified as DPAM, 27% were classified as PMCA, and 13% were classified as PMCA-I/D (^{73,79}). In this study, the 5- and 10-year survival rates for patients with DPAM were 75% and 68%, respectively. This was significantly higher than patients with PMCA, who demonstrated 5- and 10-year survival rates of 14% and 3%. Those patients with PMCA-I/D had survival more closely associated with that of PMCA patients (Fig. 23-6).

Although appendiceal PMCAs are invasive tumors with distant metastatic potential, the majority of these tumors will remain localized to the peritoneal cavity. Even in the subset of patients with very aggressive-appearing histologies, the rate of distant hematogenous metastases remains low. In one retrospective study of 90 appendiceal adenocarcinomas with either poor differentiation or signet ring cell morphology, the rate of extraperitoneal metastases was only 17% (⁸⁰).

Nonmucinous/Colonic-Type Adenocarcinoma

Occurring less frequently, nonmucinous or colonic-type adenocarcinomas of the appendix demonstrate a different tumor biology than mucinous appendiceal tumors. These cancers are more aggressive and appear to behave more like colonic adenocarcinomas. In a study by Kabbani et al, 43% of patients with nonmucinous appendiceal adenocarcinoma had evidence of extraperitoneal metastases (⁸¹). The patients with nonmucinous carcinomas in this study had a significantly worse OS and disease-free survival than those with mucinous carcinomas.

Treatment

Cytoreductive Surgery

Because of the relative rarity of this disease, prospective randomized clinical trials studying the treatment of appendiceal epithelial tumors are lacking. The majority of data evaluating the various treatment modalities in this disease have been derived from retrospective, single-institution studies. Surgical cytoreduction has

FIGURE 23-6 Overall survival for 109 cases with the clinical syndrome of pseudomyxoma peritonei (PMP) according to histological subtype.

been the primary mode of therapy for these tumors based on the following factors:

1. Lack of extraperitoneal disease spread
2. Primarily mucinous nature of peritoneal deposits
3. Indolent growth rate
4. Limited activity of systemic chemotherapy
5. Lack of an effective systemic mucolytic agent

The goal of surgical cytoreduction is complete tumor removal from the peritoneal cavity. Because of the large surface area of the peritoneum, surgical cytoreduction to remove all visible sites of disease can be challenging. Optimal CRS may involve removal of the appendix, right colon, intraperitoneal tumor debulking, resection of multiple abdominal and pelvic organs with peritoneal tumor studding, and stripping of all involved parietal peritoneum⁽⁸²⁾. Following successful surgical cytoreduction, patients with the DPAM or PMCA tumors can experience reaccumulation of mucinous peritoneal implants, which may be complicated by fibrosis from prior surgery, requiring repeated surgical cytoreductive procedures.

In a 97-patient series from Memorial Sloan Kettering Cancer Center, in which surgical resection alone represented the primary treatment modality in over two-thirds of the patients, the 5-year OS rate was 90% for patients with DPAM and 50% for patients with PMCA⁽⁶⁴⁾. In the 55% of patients who underwent a complete cytoreduction of all visible tumors, 91% had recurrent disease. The average number of surgical cytoreductions that patients underwent in this study was 2.2, with a range of 1 to 6⁽⁶⁴⁾. In patients who develop recurrence after CRS, repeat CRS should be

attempted because survival in these patients is prolonged with repeat CRS⁽⁸³⁾.

Hyperthermic Intraperitoneal Chemotherapy

In an attempt to diminish the rate of disease recurrence following CRS, the administration of intraperitoneal chemotherapy following a surgical cytoreduction has been used to try to treat any residual microscopic disease in the peritoneal cavity. Historically, a number of methods of delivering intraperitoneal chemotherapy have been utilized, although the most commonly utilized method is HIPEC administered at the time of cytoreduction.

At MD Anderson, following complete CRS, administration of heated mitomycin C at a dose of 25 mg/m² for patients who are chemo-naïve or 20 mg/m² for patients who have received previous chemotherapy in a volume of 5 to 6.5 L of electrolyte solution at a flow rate of 3 to 3.5 L/min. Intraoperative hemodynamic monitoring and thermal monitoring are essential for optimal outcomes in these patients. The HIPEC is continued for 90 minutes with vigorous shaking of the closed abdomen. On completion of HIPEC, necessary bowel anastomoses are performed, and gastrostomy and jejunostomy tubes are placed for postoperative management of nutritional deficiencies and prolonged gastric ileus.

Intraperitoneal administration of chemotherapy offers an advantage of providing high concentrations of drug directly to the target, while hyperthermia provides a synergistic antitumor effect when combined with chemotherapy⁽⁸⁴⁾. However, as a locally applied modality, the maximum penetration into tumor tissue is usually limited to 2 to 5 mm from the surface⁽⁸⁵⁾. At present, no randomized study has compared the benefit

of adding HIPEC to surgical cytoreduction, although single-institution series have indirectly suggested a benefit when disease-free survival rates of patients treated with surgical cytoreduction and HIPEC (37%-57%)^(74,76) are compared with the historical rates of surgical cytoreduction alone (9%-12%)^(64,77).

Cytoreductive surgery with HIPEC represents an aggressive treatment requiring significant surgical expertise and should only be conducted at centers experienced in performing peritoneal cytoreduction. Operation time is approximately 8 to 12 h, with an average hospital stay of 20 to 25 days. The 30-day postoperative mortality and morbidity range from 0% to 12% and 12% to 56%, respectively^(76,78).

In one of the largest retrospective multi-institutional registry-based study of 2,298 patients with PMP originating from an appendiceal mucinous neoplasm undergoing CRS, the reported median OS was 16.3 years, with a 10-year survival rate of 63%⁽⁸⁶⁾. The treatment-related mortality was 2%, and major operative complications occurred in 24% of cases⁽⁸⁶⁾. A high PCI, lack of complete cytoreduction, and lack of HIPEC were associated with poorer PFS and OS⁽⁸⁶⁾.

Prognosis for patients undergoing CRS with HIPEC is primarily dependent on two critical factors: histologic classification and completeness of surgical resection. A quantitative score, the completeness of cytoreduction score proposed by Sugarbaker and colleagues, categorizes the completeness of cytoreduction (CC) based on the size of nodules remaining at the end of surgery: CC-0 (no visible disease), CC-1 (nodules <0.25 cm), CC-2 (nodules 0.25 to <2.5 cm), and CC-3 (nodules ≥2.5 cm)⁽⁶⁵⁾. In an analysis of 224 patients with DPAM histology, Sugarbaker et al found that patients with complete cytoreduction (CC-0 or CC-1) had a 5-year OS rate of 86%, whereas patients with incomplete cytoreduction (CC-2 or CC-3) had a 5-year OS rate of 20% ($P < .0001$) (Fig. 23-7)⁽⁶⁵⁾. The importance of completeness of cytoreduction has been confirmed by other authors, although various methods of categorizing a complete cytoreduction have been used^(74,76).

Additional prognostic measures include the peritoneal cancer index (PCI), a quantitative measure of the size and distribution of nodules on the peritoneal surface; the previous surgical score (PSS), a measure of the extent of prior cytoreduction; and the extent of disease on the small bowel and small bowel mesentery^(64,65,87,88). The prognostic value of these different factors relates primarily to their ability to predict the likelihood of obtaining a complete cytoreduction.

For patients who cannot undergo complete CRS, the benefit obtained from an incomplete cytoreduction remains unknown. If complete CRS cannot be performed, a surgical cytoreduction is generally considered only if there are particular symptoms that can be palliated by tumor debulking. Given that HIPEC has limited

FIGURE 23-7 Overall survival for 385 cases with the mucinous epithelial tumors of the appendix (disseminated peritoneal adenomucinosis and peritoneal mucinous carcinomatosis) according to completeness of surgical cytoreduction. Complete cytoreduction defined as a completeness of cytoreduction score (CC) of CC-0 or CC-1, and an incomplete cytoreduction defined as a score of CC-2 or CC-3. [Reproduced with permission from Sugarbaker PH. Results of treatment of 385 patients with peritoneal surface spread of appendiceal malignancy. *Ann Surg Oncol*. 1999;6(8).]

tumor penetration, use of HIPEC should be limited to patients with a complete or near-complete CRS.

Systemic Chemotherapy

The role of systemic chemotherapy has not been well delineated in appendiceal epithelial tumors and has generally been utilized in patients who are not candidates for surgical cytoreduction⁽⁸²⁾. The challenges of using systemic chemotherapy to treat appendiceal tumors relate to the slow-growing nature of the disease, the primarily mucinous component of the tumors, and the challenges in radiographically measuring disease response.

Traditionally, PMP has been considered resistant to systemic chemotherapy, although a recently completed phase II study evaluating the use of concurrent mitomycin C and capecitabine in patients with advanced, unresectable DPAM or PMCA has suggested a role for systemic chemotherapy⁽⁸⁹⁾. In this study of 39 patients, a clinical benefit rate of 38% was determined based on the definition of either semiquantitative reductions in mucinous deposition or stabilization of previously progressive disease⁽⁸⁹⁾. In this study, the 2-year cancer-related mortality rate was 39%. Elevations in tumor markers (CEA, CA 19-9, or CA-125) occurred in all patients, and a 50% reduction in one of these markers occurred in 51% of patients⁽⁸⁹⁾. Although limited by the small sample size, tumor marker response did not appear to correlate with radiographically assessed clinical benefit rate⁽⁸⁹⁾.

In an additional study supporting the role of systemic chemotherapy in patients with PMCA, Shapiro et al retrospectively reviewed data collected from

Commentary: Surgical Perspectives in Appendiceal Carcinoma

Once the diagnosis of appendiceal carcinoma has been established, a thorough evaluation must be performed, including CT imaging, colonoscopy, laboratory studies, and a complete medical history to determine the potential resectability of the tumor and the appropriateness and fitness of the patient for aggressive treatment.

In our experience, patients over the age of 70 must be approached with caution because the potential risks of CRS and HIPEC may be greater than the potential benefits. A number of studies have also identified an Eastern Cooperative Oncology Group (ECOG) status of ≤ 2 as essential for patients to tolerate CRS/HIPEC. Similarly, because of the sensitivity of the liver to hyperthermia, patients with evidence of cirrhosis are not offered HIPEC. Likewise, patients with renal insufficiency may prove difficult to manage postoperatively because of significant fluid shifts associated with surgery and HIPEC. Previous surgical procedures and obesity offer the same challenges as in other complex operations but are not contraindications to surgery.

To determine the extent of the tumor and potential for complete cytoreduction, CT scans of the chest, abdomen, and pelvis appear to be the most useful. We do not use MRI or positron emission tomographic scanning routinely as these offer little advantage over CT alone. Imaging findings suggestive of an inability to completely cytoreduce the tumor include a large volume of disease involving the porta hepatis and the retrohepatic vena cava, large volume of tumor involving the small bowel mesentery with a gathering together of this mesentery termed *cauliflowering*, obstruction of more than one segment of small bowel, and evidence for retroperitoneal organ involvement. In these patients, consideration for systemic chemotherapy

should be given with surgery limited to palliation of symptoms.

At MD Anderson, we often see patients who have been evaluated and treated at outside institutions. Many patients have undergone an incomplete cytoreduction or combinations of therapy that we would not consider standard. The approach to these patients begins with an evaluation of the pathology, review of all operative notes to assess the amount of disease present at the time of surgery, and extent of disease left behind at the completion of surgery. Repeat imaging is obtained as necessary. On completion of the workup, an individualized plan is developed. If the patient had what was described as a complete cytoreduction, and CT imaging demonstrates no evidence of disease, repeat imaging is performed at 6-month intervals and consideration is given to diagnostic laparoscopy at the 1-year anniversary of the original surgery. If there is disease identified during these steps, CRS/HIPEC is offered if the patient meets the selection criteria previously outlined.

In patients who have clearly had an incomplete cytoreduction or have evidence of disease on baseline imaging, if the pathology is low- or moderate-grade appendiceal adenocarcinoma, we offer CRS/HIPEC. In the setting of high-grade/signet ring cell appendiceal adenocarcinoma, we typically have the patient evaluated for systemic chemotherapy. If after completing systemic chemotherapy there is stability of disease and the disease is potentially resectable based on imaging studies, we may offer CRS/HIPEC in selected cases.

Keith F. Fournier

54 patients who were suboptimal surgical cytoreductive candidates⁽⁸²⁾. Systemic chemotherapy in this report consisted of a fluoropyrimidine with or without a platinum agent in 69% of patients. Radiographic stabilization or response to therapy was noted in 55% of patients, median PFS was 7.6 months, and median OS was 56 months⁽⁸²⁾. In this study, poorly differentiated histology and signet ring histology were both negative prognostic indicators for OS. Systemic chemotherapy may play a role in the management of poorly differentiated and signet ring cell adenocarcinomas of the appendix. In a retrospective review of 142 patients with these tumors, systemic chemotherapy resulted in a response rate of 44%, a median PFS of 6.9 months, and a median OS of 1.7 years⁽⁹⁰⁾. Patients with response to chemotherapy and complete CRS were associated with improved PFS and OS⁽⁹⁰⁾.

Although data regarding role of targeted therapy is limited in appendix cancers, retrospective data suggest that combining bevacizumab with chemotherapy may improve survival outcomes in surgically unresectable appendiceal epithelial neoplasms^(71, 91).

The studies discussed in this section suggest a role for chemotherapy in patients who are suboptimal candidates for CRS, but further prospective randomized clinical trials will be needed before any definitive statement regarding the exact benefit and timing of chemotherapy use can be made.

The MD Anderson Approach to Epithelial Appendiceal Tumors

Unlike CRC, appendiceal epithelial malignancies have a more indolent natural history that is determined by

their underlying histopathology. At MD Anderson, patients with DPAM and well-to-moderately differentiated PMCA tumors are evaluated initially for CRS. Patients with a complete cytoreduction (CC-0 or CC-1) are treated with HIPEC utilizing intraperitoneal mitomycin at 42°C. If a complete CRS is not obtained, if radiographic imaging indicates that obtaining a complete cytoreduction is highly unlikely, or if medical comorbidities preclude a surgical procedure, then patients are considered for systemic chemotherapy. Also, HIPEC is utilized at MD Anderson for the control of refractory ascites. We have found that the use of HIPEC in patients who have undergone an incomplete CRS can provide long-term control of ascites and should be considered in patients with refractory ascites.

Given the indolent nature of well-to-moderately differentiated PMCA tumors, systemic chemotherapy is generally reserved for patients who either have clear evidence of disease progression on radiographic imaging or have significant tumor-related symptoms. Front-line chemotherapy is fluoropyrimidine based, and additional agents may be added based on the perceived tolerance of more aggressive combinations. Given the general good prognosis of these patients, it is critical that treatment is closely aligned with quality of life and that cumulative toxicities are kept to a minimum.

The use of multiagent systemic chemotherapy, as administered in CRC, is the treatment of choice for patients who have signet ring cells, poorly differentiated tumors, or nonmucinous tumors. Because patients with poorly differentiated or signet ring cell appendiceal adenocarcinomas have consistently shown worse outcomes following aggressive CRS, our approach has been only to consider surgical cytoreduction in these patients following initial treatment with systemic chemotherapy. In a recent retrospective study from MD Anderson, Lieu et al showed that patients with stage IV poorly differentiated or signet ring cell morphology appendiceal adenocarcinomas had a median OS of 24 months, which appears similar to the known OS for metastatic CRC⁽⁸⁰⁾.

Although trials evaluating the benefit of VEGF inhibitors or EGFR inhibitors in appendiceal epithelial tumors are lacking, their effectiveness in CRC suggests a possible role for these agents in appendiceal epithelial tumors. Expression of VEGF has been demonstrated in appendiceal adenocarcinomas, and high levels of expression have been correlated with poor outcome⁽⁹²⁾. Although not well studied, it appears that mutations in the *K-ras* oncogene are common, with 22 of 31 tested samples demonstrating an activating mutation in *K-ras*⁽⁹³⁾.

Due to the rarity of appendiceal tumors, our understanding of these tumors is limited, and further research into the molecular characteristics of these

tumors is needed. The role of CRS is well established for appendiceal epithelial tumors. The use of systemic chemotherapy in appendiceal epithelial tumors needs further study; in particular, the role of newer targeted therapies needs to be determined.

Colorectal Cancer

Van Morris
Ishwaria M. Subbiah
Scott Kopetz
Cathy Eng

Colorectal cancer is a major cause of cancer-related mortality in the world. It is currently the third-most-common cancer in incidence in the United States and accounts for about 8.5% of all cancer-related mortality (nearly 136,000 new cases and 50,000 deaths each year) ⁽¹⁾. This chapter reviews our current understanding of colorectal cancer, describes the known genetic mutations and risk factors, and outlines emerging screening, prevention, and therapeutic strategies, with particular emphasis on the approach taken at MD Anderson Cancer Center (MDACC).

EPIDEMIOLOGY AND ETIOLOGY OF COLORECTAL NEOPLASIA

Carcinogenesis: The Adenoma–Adenocarcinoma Sequence

Colorectal neoplasia results from accumulation of alterations over years, ultimately transforming normal epithelium to intraepithelial neoplasia (dysplasia) and then malignant epithelium. Three different pathways driving carcinogenesis include chromosomal instability, microsatellite instability (MSI), and CpG island methylation. The chromosomal instability pathway identifies early mutations in genes such as the tumor suppressor *APC* and the *K-ras* proto-oncogene and later genetic events, including mutations in the deleted in colon cancer (*DCC*) gene and the tumor suppressor gene *p53*.

Risk Factors

Genetic predisposition and acquired risk factors progress stepwise from normal colonic mucosa to adenomatous polyps to invasive adenocarcinoma in individuals with acquired (somatic) or inherited genetic (germline) mutations, with further environmental, dietary, or other less-well-understood factors. Personal or family histories of colorectal cancer or polyps, older age, and inflammatory bowel disease (IBD) have all been associated with an increased risk of colorectal cancer (Table 24-1).

Diet

A “Western” diet rich in saturated fat has been associated with an increased risk of colon cancer. Fiber may decrease the fecal carcinogen concentration and transit time, thus reducing the period of exposure to colonic mucosa. However, the prospective Nurses Health Study of 88,757 women aged 34 to 59 years found no association between fiber intake and the risk of colorectal cancer after a median follow-up of 16 years ⁽²⁾.

Obesity

Increased body mass index (BMI), and central obesity are emerging as risk factors for colorectal cancer. The Framingham Study found that a BMI >30 increased the risk of colon cancer by 50% among middle-aged (30–54 years) individuals and by 2.4-fold for those aged 55 to 79 years, and waist circumference was a stronger predictor than BMI ⁽³⁾.

Table 24-1 Lifetime Risks of Colorectal Cancer

Characteristic	Incidence
General population	5%
Personal history of colorectal cancer	15%-20%
Inflammatory bowel disease	15%-40%
Adenomatous polyps: personal	Variable
Hereditary nonpolyposis colorectal cancer mutation	70%-80%
Familial adenomatous polyposis	>95%

Adenomatous Polyps

Carcinoma is present in 5% of adenomas, where the potential for malignant transformation is 8 to 10 times higher for villous and tubulovillous adenomas than tubular adenomas. Just over 1% of adenomatous polyps less than 1 cm in size are malignant, whereas up to 40% of adenomas larger than 2 cm are malignant ⁽⁴⁾.

Inflammatory Bowel Disease

Patients with IBD (ulcerative colitis or Crohn disease) are at increased risk of developing colorectal carcinoma based on the duration and extent of active disease, colitis,

and mucosal dysplasia ⁽⁵⁾. Recognizing the increased risk of colorectal cancer for patients with IBD, appropriate screening should be instituted as detailed in Table 24-2.

Familial Syndromes

About 20% of all colorectal cancer cases are attributed to inherited autosomal dominant syndromes, including familial adenomatous polyposis (FAP), Gardner syndrome, and hereditary nonpolyposis colorectal cancer (HNPCC) (Table 24-1). Most genetic abnormalities involve deletion of fragments of chromosomes, known as allelic loss or loss of heterozygosity (LOH), or errors in DNA mismatch repair.

Familial Adenomatous Polyposis

Familial adenomatous polyposis is caused by a mutation of APC leading to the functional loss of both APC alleles, one inherited as a germline mutation and the other mutated in early childhood. Familial adenomatous polyposis has high penetrance, manifesting as thousands of adenomatous polyps—some invariably progress to cancer, thereby warranting a prophylactic colorectal resection. The onset of malignancy in untreated patients occurs at about 42 years, with invasive cancer developing 20 to 30 years later.

Table 24-2 Current Recommendations for Colorectal Cancer Screening

Patient Populations	Screening Tests
General population AND	FOBT annually and sigmoidoscopy every 3-5 years or colonoscopy every 10 years, beginning at age 50
Patient with any distant relative with CRC or polyps	
Patient with first-degree relative with CRC	FOBT annually and sigmoidoscopy every 3-5 years or colonoscopy every 10 years; begin at age 40
Moderate-risk patients	Polyp removal; repeat colonoscopy at 3 years; if normal, extend interval to 5 years
Patient with two first-degree relatives with CRC	Colonoscopy every 3-5 years
	Begin screening at age 40 or 10 years younger than youngest affected relative
OR	
Patient with one first-degree relative with colorectal cancer diagnosed at 50 years of age or younger	
Patient with HNPCC risk	Colonoscopy every 2 years, then yearly after age 40; begin screening at age 25 or 10 years younger than the youngest affected relative; consider genetic counseling and testing
Patient with FAP risk	Sigmoidoscopy every 1-2 years; begin screening at age 12 years; genetic counseling and testing
Patient with personal history of CRC	Total colon examination (TCE: ACBE or colonoscopy) within 1 year after resection; repeat at 3 years; repeat at 5 years if normal
Patient with personal history of adenoma	Polyp removal; repeat at 3 years; repeat at 5 years if normal

ACBE, air contrast barium enema; CRC, colorectal cancer; FAP, familial adenomatous polyposis; FOBT, fecal occult blood test; HNPCC, hereditary nonpolyposis colon cancer.

Hereditary Nonpolyposis Colorectal Cancer

The genetic penetrance of HNPCC (also known as Lynch syndrome) is caused by defects in DNA mismatch repair through germline mutations in the repair genes. Additional mutations involving tumor suppressor genes and oncogenes rapidly accumulate within these DNA repair-deficient cells, leading to malignant transformation in only 3 to 5 years.

MUTYH-Associated Polyposis

MutY Homolog-associated polyposis is caused by biallelic mutation in the base excision repair gene *MUTYH*. Patients with the syndrome are characterized by oligopolyposis, usually more than 15 but fewer than 100 polyps. The onset of adenomas is older than in classic FAP, but similar to attenuated adenomatous polyposis (45-55 years of age).

SCREENING FOR COLORECTAL NEOPLASIA

Researchers have attempted to identify individuals at greatest risk of developing colorectal cancer who would benefit most from screening (see Table 24-2). Despite the benefits associated with screening, the majority of colon cancers continue to be diagnosed in symptomatic patients.

Detection Methods

Fecal Occult Blood Testing

Meta-analysis of four randomized trials investigating the role of fecal occult blood testing (FOBT) demonstrated an increased percentage of early-stage colorectal cancers discovered through FOBT and a reduction in mortality from colorectal cancer (⁶). The current recommendation of the US Preventative Services Task Force is to screen using FOBT, sigmoidoscopy, or colonoscopy in adults from age 50 to 75 years (⁷).

Air Contrast Barium Enema

High-quality air contrast barium enema (ACBE) plus flexible sigmoidoscopy was considered in lieu of a full

colonoscopy but has fallen out of favor due to its lack of sensitivity for small polyps (<1 cm), its highly operator-dependent nature, and reliance on the patient's mobility to optimize imaging.

Sigmoidoscopy

Flexible sigmoidoscopy is a relatively safe and inexpensive procedure that may be suitable for screening large populations at low risk, in combination with FOBT. However, adenomas in the distal colon are not indicative of proximal lesions, and sigmoidoscopy may miss nearly 50% of all colonic lesions (⁸). Patients with adenomas in the distal colon detected by flexible sigmoidoscopy should have a full colonoscopy.

Computed Tomographic Colonography (Virtual Colonoscopy)

Virtual colonoscopy (VC) involves reconstruction of three-dimensional images of the colon from the two-dimensional data obtained by a spiral CT scanner. Bowel preparation is required, but the technique is less invasive and does not require sedation. However, VC lacks the advantage of a colonoscopy for direct access to colonic tissue for biopsies.

Colonoscopy

Colonoscopy not only enables full visualization of the entire colon but also allows for biopsy or removal of any suspicious lesions. In one retrospective study, 1,994 patients were examined to determine whether the size and histologic features of distal lesions are predictive of proximal lesions, as identification of these factors would help determine who should undergo full colonoscopy after sigmoidoscopic screening. The findings in the distal and proximal colon are shown in Table 24-3 (⁹).

Despite widespread use, the colonoscopy for the purposes of cancer screening has not been studied in a randomized prospective trial until the Nordic-European Initiative on Colorectal Cancer (NordICC) study. This multinational trial randomizes patients aged 55 to 64 years to either once-only screening colonoscopy with removal of all lesions or no screening, which is the

Table 24-3 Findings in the Distal and Proximal Colon in Cohort of 1,994 Patients

Finding	Distal Colon		Proximal Colon	
	No.	%	No.	%
No polyp	1,564	78.4	1,686	84.6
Hyperplastic polyp	201	10.1	72	3.6
Tubular adenoma	168	8.4	186	9.3
Advanced neoplasm	61	3.1	50	2.5

standard of care in those trial countries⁽¹⁰⁾. After a 15-year follow-up, the primary end points of cumulative colorectal cancer–specific death and incidence will be evaluated. Results are anticipated beyond 2020, given that the study began accrual in 2009.

Genetic Testing and Counseling

Genetic testing for *APC* mutations, *MUTYH* mutations, and DNA mismatch repair gene mutations are now available to identify carriers. A patient with classic FAP or with oligopolyposis but negative *APC* mutation testing should undergo *MUTYH* mutation testing given the incidence (7%-29%) of biallelic *MUTYH* in patients with polyposis with negative *APC* testing⁽¹¹⁾. At MD Anderson, suspected FAP patients are referred to a genetic counselor to discuss screening recommendations, genetic testing, and intervention for themselves and family members.

All patients with colorectal cancer at MD Anderson are screened for HNPCC. Table 24-4 summarizes the Amsterdam Criteria (both original and modified) to assess the risk of HNPCC⁽¹²⁾. Microsatellite instability, which is a hallmark of HNPCC, also occurs in about 15% of spontaneous colon cancers. Histology

Table 24-4 Original and Revised ICG-HNPCC Criteria (“Amsterdam” Criteria I and II)

Original Criteria (Amsterdam Criteria I)	Revised Criteria (Amsterdam Criteria II)
There should be at least three relatives with colorectal cancer; all the following criteria should be present:	There should be at least three relatives with an HNPCC-associated cancer (colorectal cancer; cancer of endometrium, small bowel, ureter, or renal pelvis):
One should be a first-degree relative of the other two.	One should be a first-degree relative of the other two.
At least two successive generations should be affected.	At least two successive generations should be affected.
At least one colorectal cancer should be diagnosed before age of 50.	At least one should be diagnosed before age of 50.
Familial adenomatous polyposis should be excluded.	Familial adenomatous polyposis should be excluded in the colorectal in cancer case(s) if any.
Tumors should be verified by pathological examination.	Tumors should be verified by pathological examination.

FIGURE 24-1 Photomicrograph of a tumor with microsatellite instability. Upper arrows point to poorly differentiated malignant cells with some glandular differentiation and mucin. Lower arrow shows peritumoral lymphocytes clustering near areas of malignant cells and permeating the local stroma.

that suggests an MSI tumor may include mucinous features, poor differentiation, or the presence of tumor-infiltrating lymphocytes (Fig. 24-1). In female patients less than 50 years of age with proximal tumors, poorly differentiated histology, or mucinous tumors, HNPCC should be considered even when the patient’s family history is not suggestive.

Immunohistochemical (IHC) stains done on sections from the diagnostic biopsy assess tumors for loss of heterozygosity in hMSH2, hMSH6, or hMLH1 gene loci. At MD Anderson, we test all patients with surgically resection for MSI status as a predictive and prognostic marker. Further testing for germline mutations may follow an uninformative IHC stain. In particular, the absence of the MLH1 protein on IHC staining calls for the testing of the *BRAF* gene, where a *BRAF* mutation signifies the downregulation of *MLH1* gene expression not through a germline mutation, but rather somatic promoter hypermethylation⁽¹³⁾. Furthermore, 10% to 15% of all MSIs are not detected through conventional IHC methods, highlighting standardized MSI testing by polymerase chain reaction (PCR) as is done at MD Anderson⁽¹⁴⁾. Thus, genetic counseling and testing are strongly recommended.

PREVENTION STRATEGIES

Primary Prevention

Prevention of colorectal neoplasia is usually considered primary or secondary. In primary prevention, broad-based interventions may decrease the risk of colorectal cancer for those at average risk. Americans currently

have a 1-in-20 lifetime risk of developing colorectal cancer. Consequently, primary preventive strategies may have a significant impact on the overall incidence of colorectal cancer.

Nonsteroidal Anti-Inflammatory Drugs

For over 20 years, data suggested that nonsteroidal anti-inflammatory agents such as sulindac slow or prevent the formation of adenomatous polyps, particularly in patients with FAP (¹⁵). Prostaglandin E₂ (PGE₂), an important modulator of cell proliferation and malignant transformation, is formed by the catalytic activity of two predominant isoforms of cyclooxygenase. Cyclooxygenase 1 (COX-1) is constitutively active and widely expressed; it appears to regulate tissue repair and homeostasis. Cyclooxygenase 2 is an inducible enzyme that appears to play a role in inflammation and tumor promotion. In a study of patients with FAP, the selective COX-2 inhibitor celecoxib at a higher dose significantly reduced the number of adenomas when compared with placebo or a lower dose of celecoxib (¹⁶).

However, the increased incidence of stroke and myocardial infarctions make the use of COX-2 inhibitors as primary chemoprevention unclear (¹⁷). Aspirin has primary chemopreventive properties, with the risk of colorectal cancer substantially reduced among women who were regular users of aspirin for at least 20 years (¹⁸). An additional prospective cohort study of male physicians followed over 4 years showed that regular users of aspirin (≥ 2 times per week) had a lower risk of developing colorectal cancer during the study period (RR = 0.68; 95% CI, 0.52-0.92) (¹⁹).

Secondary Prevention

Outside the clinical trial setting, patients with FAP are treated with celecoxib 400 mg twice daily. Recognizing the cardiovascular risk associated with COX-2 inhibitors, patients with cardiovascular disease or risk factors need aggressive risk management (eg, hypertension, diabetes, hyperlipidemia) or forgo therapy with celecoxib.

Aspirin also has secondary chemopreventive benefits. In a large randomized, placebo-controlled trial, aspirin demonstrated a benefit for patients with a prior history of colorectal cancer, showing a significantly reduced risk of developing adenomatous polyps compared to the placebo group (RR = 0.65; 95% CI, 0.46-0.91) (²⁰). In a separate study, 1,121 patients with recent adenomatous polyp removal were randomized to receive aspirin 81 mg daily, aspirin 325 mg daily, or a placebo. Both groups receiving aspirin had a reduced risk of subsequent colorectal adenomas, with the 81-mg dose superior to the 325-mg dose (²¹). In a prospective cohort study of 1,279 patients with

stage I to III colorectal cancer, after a median follow-up of 11.8 years, participants who regularly used aspirin had lower colorectal cancer-specific mortality, including those who initiated aspirin after diagnosis.

DIAGNOSTIC EVALUATION AND STAGING

Clinical Presentation

Colonic lesions in any location can cause change in bowel habits and bleeding, which may manifest as melena, hematochezia, a positive hemoccult test, or iron deficiency anemia in addition to weight loss, anorexia, and other constitutional symptoms. Unexplained iron deficiency anemia warrants an evaluation of the gastrointestinal tract.

Staging Studies

Preoperative evaluation is not always possible, particularly in the setting of acute bowel obstruction, and the staging evaluation in these cases should be completed within several weeks of surgery. Accurate postoperative staging may be confounded by the preceding surgery and therefore should not be obtained for at least 3 to 6 weeks after the operative procedure. Patients at MD Anderson are advised to wait a minimum of 4 weeks after surgery before undergoing imaging and a colonoscopy to allow wound healing and minimize risk to the surgical anastomosis.

Preoperative Staging for Colonic Neoplasms

In patients found to have a colonic neoplasm not requiring urgent surgery, a complete history, physical exam, and full colonoscopy with biopsies should be performed. Laboratory evaluation should include a complete blood cell count with differential, electrolytes, liver function studies, carcinoembryonic antigen (CEA) level, serum urea nitrogen (BUN), and creatinine. Imaging studies should include CT of the chest and CT scan or magnetic resonance imaging (MRI) of the abdomen/pelvis.

Rectal Cancer Staging

Patients with newly diagnosed rectal cancer at MD Anderson are staged with an endorectal ultrasound (EUS) or pelvic MRI. The EUS is more accurate than CT for assessing the depth of tumor invasion into the bowel wall and perirectal lymph node involvement. A pelvic MRI to evaluate the mesorectal planes and perirectal lymph nodes allows improved accuracy of preoperative staging. At MD Anderson, all patients with rectal cancer are staged with a CT scan of the chest and

abdomen, with a dedicated MRI of the pelvis in the preoperative setting.

The Role of Positron Emission Tomography in Staging Cancers of the Colon and Rectum

Positron emission tomographic (PET) scanning using (18F)-fluorodeoxyglucose (FDG-PET) is obtained in patients with a rising CEA without clinical or radiographic evidence of disease or in the setting of equivocal CT findings. However, inflammation may increase 18FDG uptake, thus confounding accurate assessment. At MD Anderson, FDG-PET is not part of routine staging for newly diagnosed colon or rectal cancer.

Pathology

More than 95% of all colorectal malignancies are adenocarcinomas that are well differentiated, moderately differentiated, poorly differentiated, and undifferentiated. Other subtypes include mucinous and signet ring cell, which confer a poorer prognosis. These tumors are more likely to be present in younger patients and more commonly spread to the peritoneum. Treatment, however, does not differ from the more typical adenocarcinoma subtypes.

Pathologic Staging

Currently, the widely accepted system is the American Joint Committee on Cancer (AJCC) TNM classification system (Table 24-5) to guide treatment.

Importance of Lymph Node Dissection and Sampling

At the time of resection, tumor removal should involve segmental resection of the involved colon or rectum

FIGURE 24-2 Computed tomographic image of a 54-year-old woman with a history of T3N0M0 adenocarcinoma of the sigmoid colon found incidentally at the time of hysterectomy for benign disease. Surgical resection of the sigmoid mass was performed by her gynecologist. The patient received adjuvant therapy for 6 months but subsequently developed a rising serum CEA level and a nodal mass at the base of the inferior mesenteric artery (IMA). After a course of chemotherapy for metastatic disease, she underwent repeat laparotomy with the finding of an isolated nodal mass, which was removed and was positive for adenocarcinoma. In retrospect, inadequate resection of the sigmoid mesentery to the level of the IMA was thought to explain the recurrence.

along the appropriate vascular pedicles with careful removal of all regional lymph nodes. Failing to do so may lead to relapse in lymph nodes draining the affected segment of bowel, as shown in Fig. 24-2.

Table 24-5 TNM Staging of Colorectal Cancer

TNM Stage	Primary Tumor	Lymph Metastasis	Distant Metastasis
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
II	T3	N0	M0
	T4	N0	M0
IIIA	T1, T2	N1	M0
IIIB	T3, T4	N1	M0
IIIC	Any T	N2	M0
IV	Any T	Any N	M1

M1, any distant metastatic site; N1, metastases to 1-3 regional lymph nodes; N2, metastases in 4 or more regional lymph nodes; Tis, tumor in situ; T1, tumor invades submucosa; T2, tumor invades muscularis propria; T3, tumor invades through muscularis mucosa to subserosa or pericolic or perirectal tissues; T4, tumor perforates the visceral peritoneum or directly invades other organs. Reproduced with permission from Edge SB, Byrd DR, Compton CC (eds): *AJCC Cancer Staging Manual*, 7th ed. New York, NY: Springer; 2010.

Therefore, tumors are considered high-risk stage II (T3N0M0 or T4N0M0) unless at least 12 lymph nodes are negative for metastatic disease ⁽²²⁾.

THERAPEUTIC APPROACHES

Local and Regional Control

Almost half of the patients undergoing curative resection will ultimately die of metastatic disease as a result of residual microscopic disease not evident at the time of surgery. Patients with stage II colon cancer at high risk of relapse have been defined by the National Comprehensive Cancer Network (NCCN) as those individuals with T4 tumors (stage IIB/IIC); poorly differentiated history (excluding MSI-H cancers); lymphovascular invasion; perineural invasion; bowel obstruction; localized perforation; margins that are close, indeterminate, or positive; and inadequate sampling of lymph nodes (<12 nodes examined) ⁽²³⁾.

Surgical Management of Colon Cancer

Resection for localized colon cancer removes the affected segment of bowel, the adjacent mesentery, and the draining lymph nodes. Asymptomatic patients with stage IV disease with their primary malignancy intact do not require surgical resection of their primary except for impending bowel obstruction. Laparoscopic colectomy was noninferior to an open colectomy in several prospective randomized studies, with the laparoscopic surgery group having a shorter perioperative recovery, hospital stay, duration of parenteral narcotic use and oral analgesics, as well as comparable intraoperative complications and postoperative mortality ⁽²⁴⁾.

Evidence Regarding Adjuvant Therapy for Colon Cancer

Patients with stages II and III colon cancer have a risk of relapse after surgical resection of macroscopic disease. Systemic chemotherapy has been employed to eradicate micrometastases. Currently, patients with stage III colon cancer (node positive without clinically detectable metastases) receive 6 months of adjuvant chemotherapy. The MOSAIC (Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer) trial demonstrated an improved 5-year disease-free survival (DFS) from 67% to 73% for patients receiving FOLFOX (5-fluorouracil [5-FU], leucovorin calcium, and oxaliplatin) versus 5-FU and leucovorin alone ⁽²⁵⁾ with the DFS and overall survival (OS) benefits achieving statistical significance in patients with stage III disease.

The evidence for adjuvant therapy for stage II disease is less robust. To date, the largest study of patients with stage II disease, QUASAR (Quick and Simple and Reliable), showed a modest survival benefit of 3.6% in patients receiving adjuvant 5-FU versus observation following surgical resection ⁽²⁶⁾. The 2012 subset analysis of the 889 patients with stage II disease in the MOSAIC (Multicenter International Study of Oxaliplatin/5FU-LV in the Adjuvant Treatment of Colon Cancer) trial showed no statistically significant benefit in either OS or DFS with the addition of oxaliplatin to 5-FU in the adjuvant setting for stage II ⁽²⁷⁾. Furthermore, the analysis of the patients with low- and high-risk stage II demonstrated that neither subgroup unequivocally derived benefit from the addition of oxaliplatin.

Multigene assays have been in development for prognostic and predictive value in patients with stage II colon cancer. Among the assays furthest along in development is the Oncotype Dx colon cancer assay (Genomic Health, Inc.), which provides a prognostic classification of low, intermediate, or high risk of recurrence based on the expression of seven recurrence risk genes and five reference genes. In two large trials, QUASAR and NSABP C-07, of patients with stage II and III disease, this score was validated as prognostic for recurrence, DFS, and OS but not predictive of benefit from chemotherapy ⁽²⁸⁾.

A second assay, ColoPrint (Agendia), identifies the expression of 18 genes and produces one of two recurrence risk categories, high or low. Although it was studied in stages I-IV, it has emerged to be of the most value in patients with stage II in identifying the risk of recurrence between high- and low-risk groups (hazard ratio [HR] 3.34, $P = .017$) ⁽²⁹⁾. It is currently being prospectively validated in patients with stage II in the PARSC trial, which will predict the 3-year recurrence-free survival using ColoPrint and clinical factors ⁽³⁰⁾. Both assays share limitations particularly the inability to predict clinical benefit from chemotherapy.

Irinotecan has no established role in the adjuvant setting. Three randomized phase III trials failed to show an improvement in DFS or OS in the adjuvant setting ⁽³¹⁻³³⁾. An exploratory analysis of CALGB 89803 (IFL versus bolus 5-FU/LV) indicates that patients with MSI-H may have an improved DFS from irinotecan-based therapy (HR 0.76; 95% CI, 0.64-0.88; $P = .03$). However, the PETACC 3 study confirmed that while patients with stage II disease with MSI-H tumors have a survival advantage over MSS patients with a 5-FU-based treatment, the addition of irinotecan produced no additive benefit, affirming the overall consensus against using an irinotecan-based regimen in the adjuvant setting ⁽³⁴⁾.

Furthermore, data have not supported the addition of bevacizumab, cetuximab, or panitumumab in the adjuvant setting. The NSABP trial C-08 showed no improvement in DFS or OS with the addition of

bevacizumab to adjuvant FOLFOX6 in stage II and III colon cancer⁽³⁵⁾. A second phase III randomized controlled study, the bevacizumab plus oxaliplatin-based chemotherapy as adjuvant treatment for colon cancer (AVANT) trial of resected stage III or high-risk stage II colon cancer⁽³⁶⁾ also failed to show any improvement in DFS and, in fact, suggested a poorer OS with the addition of bevacizumab.

The IDEA (International Duration Evaluation of Adjuvant Chemotherapy) Collaboration is a prospective combined analysis of phase III trials investigating duration of adjuvant chemotherapy (3 vs 6 months) for stage III colon cancer⁽³⁷⁾. The ongoing US CALGB/SWOG 80702 colon trial, which is among the six trials that are part of the IDEA collaboration, further randomizes patients beyond the duration of adjuvant therapy to 3 years of celecoxib versus placebo⁽³⁷⁾. Overall, few therapeutic changes appear to

be on the horizon for the treatment of adjuvant colon cancer.

The MDACC Approach to Nonmetastatic Colon Cancer

When patients present to MDACC with a diagnosis of colon cancer, a detailed history, including family history; routine laboratory tests, including CEA level; and imaging (CT chest, CT or MRI abdomen, pelvis) are obtained. Previous endoscopic findings and pathology are reviewed and are tested for MSI by IHC or by PCR. Patients without metastatic disease or contraindications to surgery should undergo primary resection with curative intent (Fig. 24-3). If there is an obstruction, colonoscopy is usually performed. Surgery may consist of segmental resection or subtotal colectomy, depending on the underlying colonic pathology

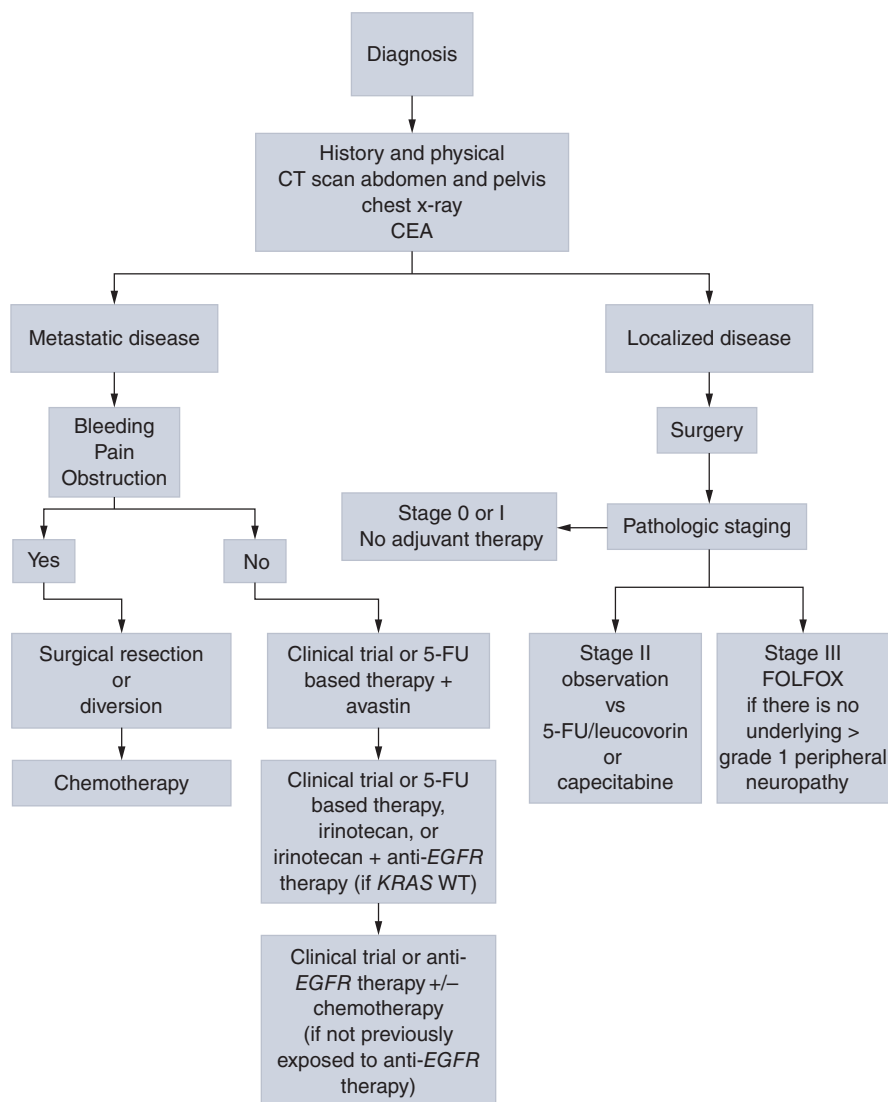

FIGURE 24-3 Diagnostic and therapeutic algorithm for colon cancer.

(multifocal cancer, FAP, HNPCC, etc.); pathologic staging is then determined from the surgical specimens, which is the standard for all such resections at MD Anderson irrespective of age. Patients with stage 0 or I tumors are placed on surveillance only. Patients with stage II colon cancer have a 75% to 80% chance of long-term DFS with surgical resection alone. Patients with stage II colon cancer are referred for discussion of adjuvant chemotherapy with full consideration provided to all patients with stage III disease.

Our current approach favors FOLFOX or XELOX (Table 24-6) for 6 months for all stage III patients unless

chemotherapy is contraindicated. Those who are better candidates for a single-agent fluoropyrimidine are offered capecitabine over intravenous 5-FU. Adjuvant therapy should begin within 4 to 8 weeks after surgery, unless postoperative complications warrant a delay.

Surveillance for Patients With Resected Colon Cancer

Once active therapy is completed, patients undergo clinical evaluations every 3 to 4 months for the first 3 years during the period of highest risk of recurrence, then

Table 24-6 Summary of Common Chemotherapy Regimens Used at MDACC for Colorectal Cancer

Adjuvant Chemotherapy
<i>Capecitabine</i> : 1,000 mg/m ² by mouth twice daily on days 1-14 (3-week cycle, total 8 cycles)
<i>5-Fluorouracil/leucovorin</i> : Leucovorin 400 mg/m ² IV on day 1; 5-fluorouracil 400 mg/m ² IV bolus on day 1, followed by 5-fluorouracil 2,400 mg/m ² IV continuous infusion over 46 hours (2-week cycle, total 12 cycles)
<i>Modified FOLFOX 6</i> : Oxaliplatin 85 mg/m ² IV on day 1; leucovorin 400 mg/m ² IV on day 1; 5-fluorouracil 400 mg/m ² IV bolus on day 1, followed by 5-fluorouracil 2,400 mg/m ² IV continuous infusion over 46 hours (2-week cycle, total 12 cycles)
<i>XELOX</i> : Oxaliplatin 130 mg/m ² on day 1; capecitabine 850 mg/m ² by mouth twice a day on days 1-14 (3-week cycle, total 8 cycles)
Therapy for Metastatic Disease
<i>Capecitabine</i> : 1,000 mg/m ² by mouth twice a day on days 1-14 (3-week cycle)
• With or without bevacizumab (7.5 mg/kg IV every 3 weeks)
<i>5-Fluorouracil/leucovorin</i> : Leucovorin 400 mg/m ² IV on day 1; 5-fluorouracil 400 mg/m ² IV bolus on day 1, followed by 5-fluorouracil 2,400 mg/m ² IV continuous infusion over 46 hours (2-week cycle)
With or without bevacizumab (5 mg/kg IV every 2 weeks)
<i>Modified FOLFOX 6</i> : Oxaliplatin 85 mg/m ² IV on day 1; leucovorin 400 mg/m ² IV on day 1; 5-fluorouracil 400 mg/m ² IV bolus on day 1, followed by 5-fluorouracil 2,400 mg/m ² IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
• With or without cetuximab ^a (400 mg/m ² IV first infusion followed by 250 mg/m ² IV weekly or 500 mg/m ² IV every 2 weeks) or panitumumab ^a (6 mg/kg IV every 2 weeks)
<i>XELOX</i> : Oxaliplatin 130 mg/m ² on day 1; capecitabine 850 mg/m ² by mouth twice a day on days 1-14 (3-week cycle)
With or without bevacizumab (7.5 mg/kg IV every 3 weeks)
• With or without cetuximab ^a (400 mg/m ² IV first infusion followed by 250 mg/m ² IV weekly or 500 mg/m ² IV every 2 weeks) or panitumumab ^a (9 mg/kg IV every 3 weeks)
<i>Modified FOLFIRI</i> : Irinotecan 180 mg/m ² IV on day 1; leucovorin 400 mg/m ² IV on day 1; 5-fluorouracil 400 mg/m ² IV bolus on day 1, followed by 5-fluorouracil 2,400 mg/m ² IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
• With or without cetuximab ^a (400 mg/m ² IV first infusion followed by 250 mg/m ² IV weekly) or panitumumab ^a (6 mg/kg IV every 2 weeks)
<i>Irinotecan</i> : 180 mg/m ² IV on day 1 (2-week cycle) or 300-350 mg/m ² IV on day 1 (3-week cycle)
<i>Cetuximab^a/Irinotecan</i> :
• Cetuximab ^a 400 mg/m ² IV first infusion followed by 250 mg/m ² IV weekly + irinotecan 350 mg/m ² IV on day 1 (3-week cycle) or 180 mg/m ² IV on day 1 (2-week cycle)
• Cetuximab ^a 500 mg/m ² IV every 2 weeks ± irinotecan 180 mg/m ² IV every 2 weeks
<i>Panitumumab^a</i> : 6 mg/kg IV every 2 weeks or 9 mg/kg IV every 3 weeks

^aCetuximab and panitumumab are indicated only in patients with *KRAS* wild-type tumors.

Concurrent chemotherapy and radiation therapy (rectal cancer)

Continuous infusion 5-fluorouracil: 250-300 mg/m² IV daily (Monday-Friday on days of radiation therapy only)

Capecitabine: 825 mg/m² by mouth twice a day (Monday-Friday on days of radiation therapy only)

every 6 months for the following 2 years, and annually thereafter. Of all recurrences, 80% occur within the first 3 years following surgical resection⁽³⁸⁾. Colonoscopy is recommended 1 year after surgery and every 3 years thereafter at a minimum. Laboratory studies, including CEA level, are checked every 3 to 6 months; abdominopelvic CT or MRI and a chest x-ray/CT of the chest are obtained at 12 months. At 5 years, patients are followed with surveillance colonoscopy (every 3 years), annual physical examination, and CEA level.

Local Therapy for Rectal Cancer

In general, over two-thirds of the patients with rectal cancer will be able to have a sphincter-saving procedure whether it is a low anterior resection or a proctectomy with a coloanal anastomosis (CAA). An abdominoperineal resection (APR), which includes removal of the rectum, anus, sphincter muscles, and a permanent colostomy is reserved for patients with tumor involvement of sphincter muscles or with poor preoperative sphincter function. A sharp mesorectal excision should be performed; there is no role for blunt dissection in the pelvis in rectal cancer surgery.

Radiotherapy

Radiotherapy improves survival in patients with locally advanced rectal cancer. Standard radiotherapy doses are 45 Gy in 25 fractions, followed by a 5.4-Gy boost. Concurrent protracted venous infusional (PVI) 5-FU provides similar efficacy with lower gastrointestinal and hematologic toxicity rates than bolus 5-FU or a high-dose infusion of 5-FU⁽³⁹⁾. A phase III intergroup trial demonstrated inferiority for bolus 5-FU during radiation therapy versus prolonged infusional 5-FU and resulted in higher OS rates ($P = .005$)⁽²²⁾.

Preoperative Therapy for Rectal Cancer

Two European studies have supported the use of preoperative therapy for resectable rectal cancer. The German Arbeitsgemeinschaft Internistische Onkologie (AIO) trial comparing preoperative and postoperative chemoradiation in T3 or T4 tumors showed a lower pelvic recurrence rate in the preoperative chemoradiation arm (6% vs 13% postoperative, respectively, $P = .0006$)⁽⁴⁰⁾. In patients who, based on pretreatment clinical evaluation, were believed to require APR, chemoradiation also led to increased sphincter preservation rates (39% vs 19%, $P = .004$). Only 54% of patients in the postoperative arm received the full radiation dose, and 50% received full-dose chemotherapy, compared with 92% and 89%, respectively, in the preoperative arm ($P < .001$).

Neoadjuvant chemotherapy with concurrent radiotherapy has been extensively studied. NSABP R-04, a four-arm phase III trial of 5-FU, capecitabine,

5-FU/oxaliplatin, and XELOX showed no improvement in locoregional recurrence, DFS, or OS with the addition of oxaliplatin⁽⁴¹⁾. Two phase III trials (Studio Terapia Adjuvante Retto and Action Clinique Coordonnées en cancérologie Digestive [STAR and ACCORD, respectively] 12) did not have higher rates of pCR with the addition of weekly oxaliplatin^(42, 43).

Another treatment principle under investigation is *induction chemotherapy*, defined as administration of chemotherapy prior to chemoradiotherapy and surgery in resectable stage II or III rectal cancer. One small study out of the United Kingdom evaluated neoadjuvant capecitabine and oxaliplatin followed by synchronous chemoradiation and total mesorectal excision in patients with MRI-defined poor-risk rectal cancer⁽⁴⁴⁾. Overall, 77 patients received neoadjuvant capecitabine and oxaliplatin, with 88% demonstrating a radiologic response and 86% a symptomatic response after just one cycle of therapy. The response rates increased to 97% on completion of chemoradiation. Then, 66 of 67 patients who then underwent a TME had R0 resection, with a pathologic complete response seen in 16 patients and only microscopic disease noted in 32 patients (48%).

To investigate the sequence of therapies, the randomized phase II study from Spain, the Grupo cancer de recto 3 (GCR-3) study, randomized 108 patients into two arms: arm A for preoperative concurrent chemoradiation with capecitabine and oxaliplatin followed by surgery and four cycles of adjuvant capecitabine and oxaliplatin or arm B for induction capecitabine and oxaliplatin followed by chemoradiation and surgery⁽⁴⁵⁾. Rates of pathologic complete response, which was the study's primary end point, were not significantly different in the arms; however, patients who received induction capecitabine/oxaliplatin combination had fewer grade 3 or 4 adverse events occur during the induction period when compared to those in the adjuvant chemotherapy arm.

The addition of the neoadjuvant bevacizumab was also investigated in a randomized, noncomparative phase II study in locally advanced T3 resectable rectal cancer⁽⁴⁶⁾. Arm A incorporated bevacizumab plus FOLFOX4 as induction prior to bevacizumab-5-FU-RT and then TME; arm B did not have the induction component but did include bevacizumab-5-FU-RT prior to surgery. While the pathologic CR end point was not met in arm B, arm A did show a statistically significant improvement in pathologic CR (23.5%; 95% CI, 12.1% to 39.5%) when compared to a defined standard rate of 10% ($P = .015$).

In studies incorporating cetuximab, the EXPERT-C trial was a multicenter randomized phase II clinical trial comparing neoadjuvant oxaliplatin, capecitabine, and preoperative radiotherapy with or without cetuximab followed by total mesorectal excision in high-risk rectal cancer, with high risk defined by the high-resolution, thin-slice MRI (3 mm) finding of tumor within 1 mm of

mesorectal fascia, T3 tumor at or below levators, extramural extension of 5 mm or greater, T4 tumor, or presence of extramural venous invasion^(47, 48). This study showed higher response rates and OS with cetuximab in KRAS/BRAF wild-type (WT) rectal cancer; however, the primary end point of improved pathologic or radiologic complete response was not met.

A potentially pivotal ongoing study led by the Alliance (N0148) is a phase II/III trial that evaluates the need for chemoradiation therapy versus induction FOLFOX in patients with mid-high-lying rectal cancers (NCT01515787).

Adjuvant Therapy for Rectal Cancer

Since the mid-1970s, studies have shown that combined-modality therapy offers a clear benefit for patients with stage II or III rectal cancer. The Gastrointestinal Tumor

Study Group (GITSG) performed a randomized trial in patients with rectal cancer undergoing surgery with curative intent. Patients were randomized to four arms: observation, chemotherapy alone, radiotherapy alone, or chemoradiotherapy. The rates of DFS and OS were higher in the combined-modality therapy group than in the other arms⁽⁴⁹⁾. Currently, standard adjuvant therapy for patients with stage II or III rectal cancer should consist of fluoropyrimidine-based chemotherapy and external-beam radiotherapy of the pelvis.

The MDACC Approach to Nonmetastatic Rectal Cancer

Preoperative Chemoradiation

The approach to rectal cancer is outlined in Fig. 24-4. At MD Anderson, patients see a multidisciplinary team of radiation, medical, and surgical oncology specialists

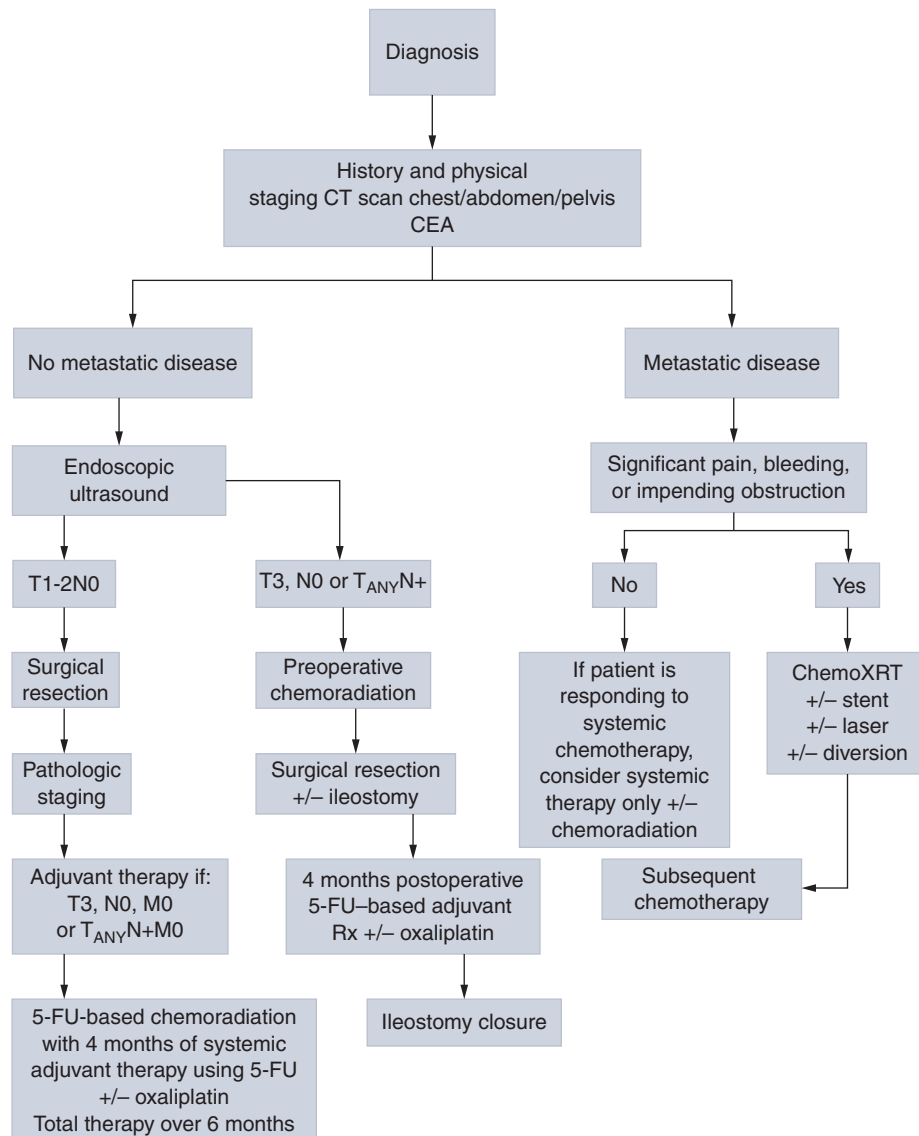

FIGURE 24-4 Diagnostic and therapeutic algorithm for rectal cancer.

for a thorough history, including family cancer history, physical exam with a digital rectal exam, inguinal lymph node exam, rigid proctoscopy, and staging studies. The patency of the colonic lumen is evaluated by proctoscopy, flexible sigmoidoscopy, or colonoscopy before starting systemic chemotherapy.

For patients with nonmetastatic disease, EUS and MRI of the pelvis are obtained as pretreatment staging. Capecitabine is given as the radiation sensitizer (825 mg/m² twice daily, Monday-Friday, on days of radiation therapy only). Bowel exclusion techniques during simulation minimize the small bowel in the field. We conduct a toxicity evaluation every 1 to 2 weeks during radiation to ensure symptom control. Electrolytes, renal function, and hematologic parameters are checked weekly. Topical barrier creams are prescribed for grades 1 to 3 perineal radiation dermatitis. Should grade 2 or higher nonhematologic toxicity develop (excluding radiation dermatitis), concurrent chemotherapy is held until resolution but radiation is continued.

After chemoradiation, perianal pain and ulceration, anorexia, and diarrhea typically subside within 2 to 3 weeks. Approximately 6 weeks after completion, patients undergo repeat physical examination with proctoscopy and then surgical resection. We recommend reversal of the diverting ileostomy after the completion of adjuvant chemotherapy due to erratic bowel managements. For those patients who recover fully from surgery, postoperative chemotherapy is delivered for a total of 4 months.

In the adjuvant setting, patients with stage III rectal cancer and no contraindication to oxaliplatin are advised to receive it as a component of FOLFOX or XELOX. In select cases, a patient with a pCR after preoperative 5-FU-based chemoradiation may receive single-agent 5-FU-based adjuvant therapy rather than FOLFOX. The choice of adjuvant therapy may vary based on degree of response to single-agent fluoropyrimidine-based therapy and the patient's underlying comorbidities.

Postoperative Chemoradiation

Patients who have undergone surgery as their initial intervention may require postoperative chemoradiation and systemic therapy when they present to MD Anderson after surgery. For patients with T3N0M0 or T2N1 disease, radiotherapy is often omitted if the tumor was located in the high pelvis (>10 cm from the anal verge), there is good nodal sampling (>12 lymph nodes)⁽⁵⁰⁾, and the radial margin is negative (>2 mm) because pelvic tumor control is excellent without the use of chemoradiation⁽⁵¹⁾. In all other stage II and III rectal cancer cases, local failure is high enough to warrant the use of chemoradiation. In addition, 4 months of systemic therapy with either capecitabine or 5-FU/

leucovorin is typically integrated with chemoradiation. Patients at higher risk of distant metastasis often receive chemotherapy first with FOLFOX.

Surveillance for Patients With Resected Rectal Cancer

Follow-up for patients with resected rectal cancer is very similar to that for colon cancer. Patients with a sphincter-preserving procedure also require periodic proctoscopies for local relapses and anastomotic strictures. A rising CEA without other clinical or CT evidence of relapse prompts a pelvic MRI or PET/CT particularly for local recurrence.

Patterns of Spread and Recurrence After Primary Therapy

Among patients who undergo surgical resection, at least 25% will have a recurrence, with most (60%) relapsing at multiple sites; the remaining relapse in the liver (15%), lung (4%), and locally (21%)⁽⁵²⁾. Relapse in multiple sites is generally managed with palliative systemic chemotherapy, while surgery can be considered for oligometastatic disease.

Management of Locally Recurrent Disease

Locally recurrent rectal cancer presents a therapeutic challenge for which salvage surgery may not be feasible. The collective experience at MD Anderson suggests that systemic therapy has limited activity against locally recurrent disease with few durable responses. Palliative radiation is delivered as external-beam radiotherapy or brachytherapy catheters. Aggressive use of narcotics and intrathecal analgesics or neurolytic blocks is employed for pain control concurrently with aggressive bowel management.

For the subset of patients who may be surgical candidates, treatment planning is vetted in the weekly multidisciplinary conference at MD Anderson. In our experience, pelvic MRI is superior to CT for distinguishing posttreatment changes from viable tumor while identify resectable disease. Biopsy confirmation of recurrence is always recommended; EUS has not been particularly useful with locally recurrent rectal tumors.

Prior to salvage surgery, additional chemoradiation may be considered using a hypofractionated schedule to a total dose of 39 Gy (if at least 1 year has elapsed since prior pelvic radiation). Radiosensitization with 5-FU or capecitabine is also considered. Approximately 6 to 8 weeks after completion of chemoradiation, a final decision about surgery is made. In most cases, the operative strategy may also include intraoperative radiotherapy or insertion of brachytherapy catheters

for high-dose afterloading. Postoperative chemotherapy after aggressive preoperative chemoradiation is at the discretion of the treating physician. However, there is broad agreement that surgery for locally recurrent disease is not indicated in those patients with unresectable metastatic disease, given the overall poor prognosis, significant morbidity, and prolonged recovery associated with this complex pelvic surgery.

Systemic Therapy for Metastatic Disease: A Rapidly Changing Therapeutic Landscape

Since the late 1950s, systemic chemotherapy with 5-FU has been the mainstay of palliative treatment for patients with metastatic disease not amenable to surgical intervention. During the ensuing decades, a variety of 5-FU schedules have been employed, including bolus injections administered either weekly (Roswell Park regimen) or daily for 5 days (Mayo regimen) and continuous infusion given via central catheter and portable pump. Objective response rates have ranged from 15% to 25% with these schedules. When 5-FU is administered as a bolus injection, leucovorin is often added to enhance binding of 5-FU to its target, thymidylate synthase. After a long period of uncertainty regarding the optimal dose and schedule of 5-FU with leucovorin, infusional 5-FU regimens have been recognized as superior to bolus regimens. However, prior to the advent of irinotecan and oxaliplatin, while infusional delivery of 5-FU led to better response rates compared with bolus therapy, no clear survival advantage was ever demonstrated. Given the barriers to delivery of infusional 5-FU, including the need for a central venous catheter and its associated risks, bolus 5-FU with leucovorin was widely accepted in the United States as frontline therapy for metastatic colorectal cancer well into the 1990s.

Since that time, therapeutic options for metastatic disease have been rapidly evolving, and oncologists now have access to several drugs with activity in the first-, second-, and even third-line settings. In addition to cytotoxic drugs, the targeted agents cetuximab, panitumumab, and bevacizumab have emerged as clinically relevant components of systemic therapy for advanced disease. It is important for oncologists to have a general understanding of these drugs and their roles in the treatment of metastatic disease.

Capecitabine: An Orally Bioavailable Fluoropyrimidine

Capecitabine is an oral fluoropyrimidine that is converted to 5-FU primarily in tumor tissues. It passes through the intestinal mucosa essentially unchanged and is subsequently metabolized by a sequential

three-enzyme pathway⁽⁵³⁾. First, capecitabine is converted to 5'-deoxy-5-fluorocytidine (5'-DFCR) by carboxylesterase (primarily in the liver). The 5'-DFCR is then converted to 5'-deoxy-5-fluorouridine (5'-DFUR) by cytidine deaminase, which is found in both the liver and tumor tissues. The metabolism of 5'-DFUR to the pharmacologically active agent 5-FU is mediated by thymidine phosphorylase (TP), also known as platelet-derived endothelial cell growth factor. Concentrations of TP are relatively higher in tumor tissue than normal tissue, which accounts for the preferential intratumoral release of 5-FU. Two large phase III trials compared capecitabine with a bolus regimen of 5-FU^(54,55), and the results were subsequently pooled. The response rates were superior with capecitabine, and the median survival was equivalent, with less neutropenia and mucositis among those patients receiving capecitabine.

In patients with contraindications to combination chemotherapy, capecitabine monotherapy is a reasonable alternative to 5-FU and leucovorin in the metastatic setting.

Irinotecan

Irinotecan, an inhibitor of topoisomerase I, was originally developed as second-line chemotherapy for patients in whom 5-FU was ineffective⁽⁵⁶⁻⁵⁸⁾. In phase II trials of irinotecan performed in the United States, response rates in patients refractory for 5-FU were approximately 15% superior to those reported prior to the advent of irinotecan; this led the Food and Drug Administration (FDA) to approve the drug as a second-line therapy in patients with advanced 5-FU-refractory disease⁽⁵⁹⁾. The survival benefit of second-line irinotecan was subsequently verified in a European trial, in which patients who had been previously treated with 5-FU were randomized to receive irinotecan every 3 weeks or best supportive care (BSC)⁽⁶⁰⁾. Patients randomized to BSC were allowed to receive infusional 5-FU. This trial demonstrated a survival advantage for patients in the irinotecan arm compared to those in the BSC arm (9.2 vs 6.5 months; $P = .0001$).

Shortly thereafter, studies were performed to investigate the potential benefit of irinotecan as a component of frontline therapy in patients with metastatic colorectal cancer. Two large, randomized trials were conducted in the United States and Europe comparing 5-FU and leucovorin with 5-FU, leucovorin, and irinotecan as first-line treatment of metastatic colorectal cancer^(61,62). Both studies demonstrated that the response and OS rates for the group treated with triple-drug therapy were superior to those for the group treated with 5-FU and leucovorin. The response rates for the triple-drug combination ranged from 35% to 40%, the median time to disease progression was 7 months, and

median survival was prolonged by 2 months. These results prompted the FDA in 2000 to approve the use of these irinotecan-based combinations for first-line treatment of colorectal cancer. For a brief period of time, the IFL regimen (bolus 5-FU at 500 mg/m², leucovorin 20 mg/m², and irinotecan 125 mg/m², administered weekly for 4 weeks on a 6-week cycle) became standard first-line therapy for patients with metastatic colon cancer in the United States. However, as these studies were being performed, a novel platinum analog, oxaliplatin, was also showing impressive activity in combination with 5-FU and leucovorin, generating great interest in the drug.

Oxaliplatin

Oxaliplatin is a third-generation platinum derivative that has shown additive or synergistic antitumor activity in combination with a variety of standard antineoplastic agents, including 5-FU; oxaliplatin is ineffective without 5-FU⁽⁶³⁾. While irinotecan was being studied in the United States, oxaliplatin was already approved in Europe. In 2000, de Gramont and colleagues reported the results of a phase III trial of infusional 5-FU/leucovorin and oxaliplatin (FOLFOX4), versus 5-FU/leucovorin alone, as first-line treatment in advanced colorectal cancer⁽⁶⁴⁾. Four hundred twenty patients were randomized to the study, and progression-free survival (PFS) was the primary end point. Progression-free survival and response rates were significantly better for the FOLFOX arm compared to the 5-FU/leucovorin arm (9.0 months and 50% vs 6.2 months and 22%, respectively). Even though the FOLFOX arm experienced more grade 3 and 4 neutropenia, diarrhea, and neurosensory toxicity, this did not impair quality of life. The primary objective of median OS was not met (14.7 months for the 5-FU/leucovorin arm and 16.2 months for the FOLFOX arm, $P = .12$); consequently, initial approval by the FDA failed.

Goldberg and associates subsequently compared the activity and toxicity of three different drug combinations in untreated patients with metastatic colorectal cancer. Seven hundred ninety-five patients were randomized to receive IFL, FOLFOX, or IROX (irinotecan + oxaliplatin)⁽⁶⁵⁾. The results favored FOLFOX for all end points, including time to progression, response rate, and OS. Median survival in the FOLFOX, IFL, and IROX groups was 19.5, 15.0, and 17.4 months, respectively. The authors concluded that FOLFOX should be considered a standard first-line regimen for advanced colorectal cancer. A limitation of this study was that 60% of the patients treated with oxaliplatin received irinotecan in the second-line setting, but only 24% of patients in the IFL arm could get oxaliplatin as second-line treatment because it was not approved in the United States at the time of the study.

Tournigand and colleagues answered the important question of how to sequence these regimens. They reported the results of a phase III study investigating 5-FU, leucovorin, and irinotecan (FOLFIRI), followed by FOLFOX6 (see Table 24-6) on progression of disease, versus the opposite sequence (FOLFOX6 followed by FOLFIRI)⁽⁶⁶⁾. The two sequences were equivalent in terms of progression-free and OS, although the toxicity profiles were different. Median survival was 21.5 months in the FOLFIRI-FOLFOX arm (109 patients) and 20.6 months in the FOLFOX-FOLFIRI arm (111 patients) ($P = .99$).

An aggressive approach is the combination of oxaliplatin, irinotecan, and 5-FU/leucovorin (FOLFOXIRI)⁽⁶⁷⁾. An impressive response rate of 66% was noted in a phase III trial of FOLFOXIRI versus FOLFIRI, fulfilling the primary end point of PFS. However, a serious adverse toxicity reaction associated with this regimen is severe myelosuppression. Concerns about this regimen are largely due to discussion of limited options for second-line therapy if the patient's disease should progress. Furthermore, an earlier phase III Greek trial failed to note an improvement in OS, perhaps due to the limited second-line chemotherapy options for patients treated with FOLFOXIRI⁽⁶⁸⁾. Common chemotherapy regimens for both colon and rectal carcinoma are listed in Table 24-6.

Monoclonal Antibodies

Therapeutic use of the immune system against cancer has been studied for decades but remained elusive until recently due to technical difficulties. The fact that tumor cells are recognized as a part of the normal host makes the development of vaccines difficult, and the logical alternative would involve development of foreign antibodies that could be delivered to the patient. The development of those antibodies was not possible until 1975, when the hybridoma technique was perfected by Kohler and others, allowing the development of specific antibodies against antigens restricted to, or overexpressed in, tumor cells⁽⁶⁹⁾. Initially, the development of these antibodies was proposed as a direct immunologic and cytotoxic approach for treatment of malignant disease. While such efforts continue, this strategy has been refined to include the development of antibodies that target specific proteins critical to intracellular signaling, tumor cell function, or the host-tumor interface. Three new monoclonal antibodies have been recently approved in the United States for treatment of metastatic colorectal cancer.

Cetuximab

Cetuximab is a chimeric immunoglobulin G1 (IgG1) monoclonal antibody directed against the epidermal growth factor receptor (*EGFR*), also known as

ErbB-1 (⁷⁰). In the colorectal cancer arena, it was primarily studied in previously treated patients. Cetuximab monotherapy yielded a response rate of 9% and median survival of 6.4 months in a small group of irinotecan-refractory patients (⁷¹). When compared to BSC in a treatment-refractory patient population, single-agent cetuximab resulted in superior OS (6.1 vs 4.6 months) and quality of life. Two phase III randomized trials (Bowel Oncology and *Cetuximab* Antibody, Erbitux Plus Irinotecan for Metastatic Colorectal Cancer [BOND, EPIC]) subsequently confirmed the efficacy of cetuximab in combination with irinotecan in previously treated patients (^{72, 73}), with response rates of approximately 20%. Improvement in OS versus BSC has since been validated in heavily pretreated patients (⁷⁴). The reason for the apparent synergy between cetuximab and irinotecan is not well understood; it is known that *EGFR* mediates not only proliferation signals but also a number of other processes whose inhibition may render cells more sensitive to apoptotic stimuli, such as chemotherapy.

The *EGFR* inhibition is fraught with potential treatment-related toxicities, including a pustular acneiform rash of the upper torso and scalp. Hence, identification of a predictive marker for efficacy of anti-*EGFR* therapy would decrease unnecessary drug exposure and financial burden. It is now recognized that *EGFR* expression does not correlate with efficacy of therapy (⁷⁵). However, mutation of the *KRAS* oncogene is present in 35% to 50% of all patients with colorectal cancer and has an early role in the transition of adenoma to carcinoma, with reported concordance between the primary and the metastatic site (⁷⁶). The mutations are commonly G>A transitions and G>T transversions; codons 12 and 13 are the most frequently affected and rarely codons 61 and 146. In addition to *KRAS*, mutations in *NRAS* have been recently identified as a potential predictive indicator of anti-*EGFR* efficacy. The *NRAS* mutation may be present in 10% of patients and was also associated with reduced response to panitumumab (⁷⁷). Patients with *KRAS* WT and *NRAS* WT tumors had improved PFS (HR = 0.39, 95% CI = 0.27, 0.56) compared with those receiving BSC, whereas those with *NRAS* mutant tumors did not appear to benefit from panitumumab (HR = 1.94, 95% CI = 0.44, 8.44).

The Cetuximab Combined With Irinotecan in First-Line Therapy for Metastatic Colorectal (CRYSTAL) phase III trial randomized nearly 1,200 patients with untreated metastatic colorectal cancer to FOLFIRI with or without cetuximab. Median PFS (8.9 vs 8.0 months) and response rate (47% vs 39%) were modestly improved with cetuximab. Most important, however, investigators later discovered in an unplanned retrospective analysis that clinical benefit was limited to those patients with *KRAS* WT tumors. In this group

of patients, the findings were impressive; cetuximab improved the response rate from 43% to 59% and median PFS from 8.7 months to 9.9 months (⁷⁸). Updated results of the CRYSTAL trial were recently presented, indicating an OS advantage for FOLFIRI and cetuximab in the *KRAS* WT group (23.5 vs 20.0 months) (⁷⁹). This is the first trial to demonstrate an improvement in OS with cetuximab in combination with chemotherapy in treatment-naïve patients. In addition, OPUS, a randomized phase II trial in treatment-naïve patients, compared FOLFOX4 plus cetuximab to FOLFOX4 alone and also showed improvement in response rate and PFS with cetuximab. Once again, analysis revealed that this benefit was restricted to patients without *KRAS* mutations (⁸⁰). Neither study has indicated what percentage of specimens analyzed was from the primary versus the metastatic site and if true concordance existed. Despite the current evidence supporting *KRAS* testing, the FDA delayed mandating *KRAS* testing largely due to the retrospective unplanned analyses. Soon after, the American Society of Clinical Oncology (ASCO) released a provisional clinical opinion advising against use of *EGFR* monoclonal antibodies in colorectal cancer patients with *KRAS* mutant tumors (⁸¹); subsequently, the FDA revised the label of cetuximab and panitumumab in July 2009.

The most significant toxicities associated with cetuximab include diarrhea, hypomagnesemia, hypocalcemia, and an acneiform rash. Traditionally, the risk of an allergic hypersensitivity reaction is reported to be <5%. However, life-threatening anaphylactic hypersensitivity reactions have been reported in up to 30% of patients residing in select geographic locations (⁸²). Immunoglobulin E antibodies against cetuximab have been discovered and may allow screening for patients at risk for this reaction.

Development of the skin rash appears to be a clinical predictor of response and survival, but the mechanisms involved in this process are poorly understood (⁸³). The Dose-Escalation Study of Cetuximab for Metastatic Colorectal Cancer (EVEREST), which was undertaken to address the association between skin rash and clinical response to cetuximab, stratified patients with no or mild rash to standard-dose or dose-escalated cetuximab. Dose escalation increased the response rate from 13% to 30%. Although these results are intriguing, firm conclusions about the dose-response relationship with cetuximab cannot be drawn from this small phase II trial, and the final results have not been reported. Recent data support that the pharmacokinetics of cetuximab is not compromised with administration every 2 weeks rather than weekly (⁸²). Furthermore, a small phase II trial indicated that preemptive dermatological care may improve patient outcome when using *EGFR* inhibitors (⁸⁴).

Cetuximab is currently FDA approved as monotherapy for patients with metastatic colorectal cancer who

are intolerant of irinotecan-based regimens or in combination with irinotecan after progression of disease. The findings of the CRYSTAL trial will likely result in an FDA application for approval for cetuximab in the frontline setting.

Panitumumab

Panitumumab is a fully human IgG2 monoclonal antibody directed against the *EGFR*. In a randomized phase III trial, patients with refractory metastatic disease received BSC with or without panitumumab. The response rate and stable disease rate with panitumumab were 10% and 27%, respectively, compared to 0% and 10%, respectively, with BSC alone. An OS difference could not be demonstrated in this trial, likely due to crossover from the BSC group⁽⁸⁵⁾. Subsequent analysis revealed that only patients with *KRAS* WT tumors benefited from panitumumab⁽⁸⁶⁾. Although cetuximab and panitumumab have not been compared head to head, they appear to have similar efficacy and toxicity in patients. Infusion reactions are uncommon with panitumumab because it is a fully human monoclonal antibody. It is now FDA approved as a single agent for patients failing irinotecan- and oxaliplatin-based chemotherapy. Two phase III trials have recently been reported of FOLFOX or FOLFIRI with or without panitumumab for both treatment-naïve and previously treated patients, respectively^(87, 88). Both studies reported superior response and PFS for the combination and will likely also result in an application for approval in combination with chemotherapy in the front- and second-line setting.

Bevacizumab

In studies dating back more than 40 years, Dr. Judah Folkman demonstrated that tumors cannot grow beyond 1 mm without creating new vessels to deliver oxygen and nutrients. He therefore predicted that a drug capable of blocking angiogenesis would be able to arrest the growth of tumors⁽⁸⁹⁾. Among the several angiogenic factors isolated to date, vascular endothelial growth factor (VEGF) seems to be particularly important, with elevated circulating levels associated with poor prognosis in patients with colorectal cancer^(90, 91). Bevacizumab is a humanized monoclonal antibody that binds all isoforms of circulating VEGF, thereby inhibiting permeability and angiogenesis mediated by this factor⁽⁹²⁾.

Bevacizumab is currently FDA approved in multiple tumor types, including lung, breast, and colorectal cancer. A randomized phase II trial compared weekly 5-FU/leucovorin with the same chemotherapy combined with either 5 mg/kg or 10 mg/kg of bevacizumab. Both experimental arms performed better than the control 5-FU/leucovorin arm⁽⁹³⁾. However, the best results were seen with the lower dose of bevacizumab,

leading the investigators to recommend a dose of 5 mg/kg for a phase III trial in colorectal cancer.

The phase III trial compared the IFL regimen, which was considered the standard regimen for metastatic colorectal cancer at that time, with IFL plus bevacizumab (5 mg/kg)⁽⁹⁴⁾. A third arm with 5-FU/leucovorin plus bevacizumab was added as a precaution, but it was dropped after the first 100 patients were treated safely. Patients on the exploratory arm were allowed to continue bevacizumab with their second-line chemotherapy regimen following progression of disease. When compared to IFL alone, the addition of bevacizumab resulted in a 10% increase in overall response rate (35%-45%). More important, patients randomized to IFL plus bevacizumab had a median survival of 20.3 months, while patients randomized to IFL alone had a median survival of 15.6 months ($P < .0004$). The absolute improvement in OS was superior to any incremental survival advantage observed using conventional combination chemotherapy alone. As a result, bevacizumab became the first drug of its class to receive FDA approval for colorectal cancer.

These promising results in the frontline setting have been confirmed in other trials. In the phase II TREE-2 study, Hochster and colleagues demonstrated the safety and efficacy of bevacizumab in combination with oxaliplatin-based chemotherapy (mFOLFOX6, bFOL, or XELOX)⁽⁹⁵⁾. This trial was not powered for direct comparisons among the three arms, but time to progression (9.9 and 10.3 months, respectively) and OS (26.1 and 24.6 months, respectively) were virtually identical in the mFOLFOX6 and XELOX arms. In the NO16966 trial, untreated patients were randomized in a 2 × 2 design to FOLFOX4 or XELOX (noninferiority) with or without bevacizumab⁽⁹⁶⁾. The pooled analysis revealed superior median PFS (9.4 vs 8.0 months, $P = .002$) in the bevacizumab-containing groups, but a difference in response and OS did not achieve statistical significance. Surprisingly, when PFS was stratified by chemotherapy regimen, the XELOX regimen fared better. In both of these trials, bevacizumab did not increase the toxicities of chemotherapy. However, it may exist when bevacizumab is combined with an oxaliplatin-based regimen, and the use of antiangiogenic therapy in conjunction with oxaliplatin-based chemotherapy is not well understood as originally believed. The most significant adverse events associated with bevacizumab were hypertension, proteinuria, thrombosis, and rare instances of bleeding (mostly epistaxis), delayed wound healing, and gastrointestinal perforation.

The Bolus, Infusional, or Capecitabine With Camptosar-Celecoxib (BICC) trial was a phase III trial that evaluated the role of bevacizumab in combination with irinotecan-based regimens (IFL, FOLFIRI, and CapeIri). During patient enrollment, bevacizumab

was subsequently approved, requiring an amendment to the trial design. An expanded cohort of 117 patients randomized to IFL or FOLFIRI plus bevacizumab was created. No statistical difference in PFS or response was noted, but an impressive median OS was reported for the FOLFIRI plus bevacizumab arm (28.0 vs 19.2 months, $P = .037$).

The efficacy of bevacizumab as an adjunct to chemotherapy has been validated in the second-line setting as well. ECOG 3200 randomized over 800 patients with metastatic colorectal cancer previously treated with 5-FU and irinotecan (but not oxaliplatin or bevacizumab) to one of three arms: FOLFOX4, bevacizumab, or the combination. The arm receiving bevacizumab as monotherapy was closed to accrual after an interim analysis revealed inferior outcomes compared to the other two arms. Ultimately, the addition of bevacizumab to chemotherapy resulted in improved PFS (median 7.3 vs 4.7 months, $P < .0001$) and OS (median 12.9 vs 10.8 months, $P = .0011$)⁽⁹⁷⁾.

A recent large patient registry trial (Bevacizumab Regimens: Investigation of Treatment Effects and Safety [BRiTE]) suggested that continuation of bevacizumab following first-line progression of disease will have a positive impact on patient outcome versus no therapy or continuing second-line chemotherapy without continuing bevacizumab⁽⁹⁸⁾. These data are intriguing but were not collected in a prospective randomized fashion. Regardless, ongoing clinical trials have adopted this methodology of bevacizumab as the control arm. Admittedly in the patient with *KRAS* MT tumor, consideration of continuing bevacizumab is an option given the limitations of biologic therapy in a *KRAS* MT tumor-type patient, but it should be considered with a note of caution given the lack of evidence-based medicine and potential toxicities associated with bevacizumab.

The role of bevacizumab in the adjuvant setting is questionable at this time. A large phase III trial (NSABP C-08) was completed in patients with both stage II and III⁽⁹⁹⁾. Patients were randomized to FOLFOX (6 months) versus FOLFOX plus bevacizumab (5 mg/kg \times 12 months). After a median follow-up of 35.6 months, the investigators failed to meet their primary end point of DFS ($HR = 0.89$, $P = .15$). The AVANT trial is a three-arm randomized study of FOLFOX4 (6 months) versus FOLFOX4 plus bevacizumab (5 mg/kg \times 12 months) versus XELOX plus bevacizumab (7.5 mg/kg \times 12 months) in the adjuvant treatment of patients with stage III or high-risk stage II colon cancer. Preliminary toxicity results have been reported with final efficacy results pending⁽¹⁰⁰⁾.

Unlike the *EGFR* inhibitors, predictive markers for the efficacy of initial anti-VEGF therapy have not been identified. Intriguing data from a phase II study of bevacizumab in treatment-naïve patients has noted

a possible correlation with levels of basic fibroblast growth factor⁽¹⁰¹⁾.

Bevacizumab represents a significant step for the use of antiangiogenesis agents in the treatment of colorectal cancer. It was FDA approved for use in combination with fluorouracil-based regimens as a first- or second-line treatment for metastatic colorectal cancer. Because bevacizumab has essentially no clinical activity as monotherapy in colorectal cancer, it cannot be recommended as a single agent in colorectal cancer and should not be considered for adjuvant therapy outside a clinical trial.

Dual Antibody Anti-Vascular Endothelial Growth Factor and Anti-Epidermal Growth Factor Receptor Therapy

Based on compelling preclinical data suggesting additive antitumor efficacy, the concept of dual inhibition of VEGF and *EGFR* has been investigated in several clinical studies. The BOND-2 trial randomized 83 irinotecan-refractory, bevacizumab-naïve patients to cetuximab plus bevacizumab with or without irinotecan (CB vs CBI). The CBI arm showed a better response rate (37% vs 20%) and time to progression (7.3 vs 4.9 months). In addition, the concurrent use of monoclonal antibodies did not result in any unexpected safety signals. These encouraging data prompted two large phase III trials (Capecitabine, Irinotecan, Oxaliplatin 2 [CAIRO2], Panitumumab Advanced Colorectal Cancer Evaluation [PACCE]) to examine the efficacy of dual biologic therapy in metastatic colorectal cancer. The CAIRO2 trial randomized 755 untreated patients to XELOX/bevacizumab with or without cetuximab. Unexpectedly, the patients receiving cetuximab experienced shorter PFS (9.4 vs 10.7 months, $P = .01$). Furthermore, in subgroup analyses, cetuximab-treated patients with *KRAS* mutant tumors had significantly inferior PFS (8.1 vs 12.5 months, $P = .003$) and OS (17.2 vs 24.9 months, $P = .03$) compared to patients with *KRAS* mutant tumors who did not receive cetuximab. Even in the subset of *KRAS* WT patients, the addition of cetuximab did not produce a PFS benefit⁽¹⁰²⁾.

The PACCE trial investigated dual biologic therapy in the first-line setting by randomizing patients receiving oxaliplatin- or irinotecan-based chemotherapy (investigator's discretion) to bevacizumab plus or minus panitumumab⁽¹⁰³⁾. The panitumumab arms were discontinued after a planned interim analysis of patients in the oxaliplatin cohort revealed inferior PFS (8.8 vs 10.5 months, $P = .04$) with the addition of panitumumab. The final results showed worse OS (19.4 vs 24.5 months) and significant excess toxicity with dual-antibody therapy. The negative clinical impact of panitumumab was seen irrespective of *KRAS* status. In light of the data from PACCE and CAIRO2, dual VEGF and *EGFR* inhibition currently has no role in

the treatment of patients with colorectal cancer and should not be pursued outside a clinical trial.

Decision Making for Potential Surgical Resection in Patients With Metastatic Colorectal Cancer

Despite therapeutic advances, the estimated 5-year OS for a patient unable to be surgically resected will remain at 11%. Therefore, when surgical resection with curative intent is a possibility for a patient with metastatic colorectal cancer, it is best to initiate discussion with your colleagues in the other disciplines. It is imperative discussion regarding each individual patient is initiated early if there is a potential for surgical resection with curative intent to optimize patient outcomes. Maximizing diagnostic imaging capabilities has an important role when considering surgical resection, such as MRI, PET/CT, and volumetric imaging. The use, choice, and duration of neoadjuvant chemotherapy should be determined by the treating medical oncologist and surgeon in a multidisciplinary fashion. Prior studies indicated that patients who have a partial response or stable disease to neoadjuvant therapy will fare better than those with progression of disease⁽¹⁰⁴⁾. Prior studies have indicated a trend in DFS and OS for adjuvant single-agent 5-FU–based chemotherapy versus observation following hepatic resection⁽¹⁰⁵⁾. Hence, clinical trials are under way to modify the neoadjuvant and adjuvant approach for candidates of hepatic resection. Challenges remain in the setting of a patient with a primary rectal cancer and the timing and role of radiotherapy.

In general, it is recommended that patients have *KRAS* testing completed early on in preparation for both immediate and subsequent chemotherapy treatment planning. When considering hepatic resection, it is crucial that patients are not treated until the point of radiographic CR. It is well known that a radiographic CR harbors microscopic disease that is only appreciated on the tissue specimen once surgically resected⁽¹⁰⁶⁾. Furthermore, if patients are not surgically resected following path CR or near-path CR, progression of disease will develop. In addition, prolonged chemotherapy may have a negative impact on surgical mortality⁽¹⁰⁷⁾.

Follow-Up for Patients With Resected Metastatic Colorectal Cancer

Following metastasectomy, patients are followed closely with physician visits, CEA level analysis, and diagnostic imaging. Patients undergo clinical evaluations every 3 to 4 months for the first 3 years, every 6 months for the following 2 years, and annually thereafter. Colonoscopy will continue to be completed every 3 years thereafter (some patients require more frequent examinations based on endoscopic findings

or high-risk status). Computed tomography of chest, abdomen, and pelvis (or MRI) is the standard recommended cross-sectional imaging modality. Use of PET/CT is completed only if inconclusive findings are noted on CT/MRI or if a rising CEA is noted without measurable disease on CT/MRI. All patients are encouraged to maintain a relationship with a primary care physician for optimal surveillance and health care.

The MDACC Approach to Patients With Metastatic Disease

It is difficult to articulate a general treatment algorithm for patients with metastatic disease, but individual consideration of each patient's case is always taken into account. For the majority of patients with metastatic colorectal cancer, surgical resection of metastatic disease will not be technically possible or clinically appropriate. Whenever possible, patients with good performance status and no significant problems related to local tumor are offered therapy as part of a clinical trial.

Once patients fail frontline therapy, a period of observation may ensue, or second-line therapy may be instituted. Previous analyses have suggested a survival advantage for patients treated with all three active conventional cytotoxic agents (5-FU, irinotecan, and oxaliplatin) during the course of their treatment⁽¹⁰⁸⁾, but the precise order of targeted agents in the therapeutic sequence has yet to be fully elucidated. However, *KRAS* tumor mutation status has become a core part of treatment decision making.

Broad principles have emerged as the foundation for therapeutic decisions at MDACC:

1. *Asymptomatic patients with metastatic disease are usually offered systemic chemotherapy treatment.* Systemic chemotherapy has served an integral role in our care of patients with metastatic disease with regard to quality of life, palliation of pain, and improvement in OS. A multidisciplinary approach is always considered when the primary malignancy remains in place. Evaluation of lumen patency is completed before initiating systemic chemotherapy. With the advent of newer agents such as irinotecan, oxaliplatin, and the monoclonal antibodies, OS of patients with metastatic disease has been steadily improving over the last several years. Moreover, frontline therapy is better tolerated and more likely to be beneficial in asymptomatic patients with good performance status. An exception to this principle applies to those patients with known metastatic disease that is either not evaluable or extremely low volume. In these cases, close follow-up with frequent cross-sectional imaging may be an appropriate initial strategy. Therapy is then initiated once measurable disease is evident or, in the

oncologist's judgment, further expectant follow-up is likely to lead to symptoms. Patients with a rising serum CEA level are usually not recommended to undergo treatment in the absence of clear clinical or radiographic evidence of metastatic disease and are followed closely. When deciding between an oxaliplatin- or irinotecan-containing regimen, the choice of chemotherapy is largely based on the objectives of treatment: surgical intent, borderline resectable, and unresectable for palliation. FOLFIRI and FOLFOX are comparable in terms of efficacy, but toxicities are distinctly different. When considering systemic chemotherapy for an unresectable patient, FOLFIRI is commonly selected at our institution given its lack of dose-limiting toxicities.

2. *The initial treatment for metastatic disease may depend on the timing and residual toxicities of prior adjuvant therapy.* Many patients who develop metastatic disease have received prior adjuvant therapy consisting of oxaliplatin, 5-FU, and leucovorin. When patients relapse, they should be considered refractory to this combination if fewer than 12 months have elapsed since the completion of adjuvant therapy. Irinotecan often becomes the primary cytotoxic agent in the treatment of relapsed disease after recent adjuvant therapy.
3. *Patients should be treated to maximal benefit or until therapy becomes intolerable.* When patients are receiving systemic therapy for metastatic disease, we usually continue treatment until the tumor becomes refractory to the regimen, toxicity dictates discontinuation, or patient deferment of therapy. Patients receiving oxaliplatin in conjunction with capecitabine or 5-FU, as part of a FOLFOX or XELOX regimen, may develop unacceptable peripheral neuropathy. A study performed in France suggested that there is no disadvantage to discontinuation of oxaliplatin, provided maintenance therapy with 5-FU and leucovorin continues. Oxaliplatin may be reintroduced as a component of the regimen once neuropathic symptoms subside or the tumor starts to progress⁽¹⁰⁹⁾.

This concept was analyzed in a prospective trial, Optimized 5-FU and Oxaliplatin Study (OPTIMOX1). It demonstrated that switching to a nonoxaliplatin maintenance regimen (5-FU/ leucovorin) after 6 cycles of FOLFOX, with reintroduction of oxaliplatin after 12 cycles of maintenance therapy or at disease progression, did not worsen clinical outcomes when compared to continuous FOLFOX until disease progression. In fact, patients on the maintenance arm experienced less grade 3 and 4 toxicities after the initial six cycles of treatment⁽¹¹⁰⁾. A subsequent trial (OPTIMOX2) randomized patients to maintenance therapy (as in OPTIMOX1) or a chemotherapy holiday after six

cycles of FOLFOX, with similar rules for oxaliplatin reintroduction. The maintenance arm showed superior median PFS (8.6 vs 6.6 months, $P = .0017$) and duration of disease control (13.1 vs 9.2 months, $P = .046$), with a trend toward improved overall⁽¹¹¹⁾. In clinical practice, however, the benefit of maintenance therapy must be weighed against potential toxicity, and patient preference must be considered as well. Therefore, a chemotherapy treatment holiday may be appropriate for patients after prolonged response or stability of disease.

4. *Once frontline therapy has been exhausted, a period of observation may be advantageous.* With newer drugs and combinations creating significant inroads as debulking agents, metastatic colorectal cancer can be viewed as a chronic illness for some patients, rather than a suddenly life-threatening disease. Therefore, immediate initiation of second- or third-line therapy after failing frontline treatment is not always necessary, and punctuating regimens with periods of observation has at least two advantages. First, it provides patients with a chemotherapy holiday, which may improve overall quality of life; second, it allows for more robust physiologic and hematopoietic recovery after prior treatment. Therefore, once a decision is made to restart cytotoxic therapy, timely delivery of full-dose therapy is more likely to proceed without interruption. As described previously, when we follow patients expectantly, restaging studies are performed every 8 to 12 weeks unless the clinical situation requires restaging sooner.
5. *The need for local control should always be considered.* Some patients with metastatic disease may also have intact primary tumors or locally recurrent disease. Recent experience with combination therapies suggested that the primary tumor may respond well to systemic therapy in some cases, obviating the need for local therapies. As a general rule, however, locally recurrent tumor at a site of previous surgery or radiotherapy is not particularly responsive to systemic therapy. Therefore, oncologists must continuously reassess whether local tumor control should take priority over treatment for disseminated disease. Such decisions are usually made with input from a multidisciplinary team, which may include radiotherapists, surgical oncologists, and gastroenterologists.

Challenging Clinical Management Problems

The Malignant Polyp

On occasion, an endoscopically removed polyp may demonstrate invasive adenocarcinoma within a villous or tubular adenoma. Treatment recommendations

in this situation should be individualized based on features, including negative margins, no evidence of invasion beyond the submucosa, well- or moderately differentiated adenocarcinoma, and no evidence of lymphatic or vascular invasion. In this setting, the risk of lymph node metastases is low (5%), and follow-up with periodic colonoscopic examinations is reasonable ⁽⁴⁾. Unfortunately, retrieval of a sessile or bulky polyp distorts the depth of invasion or margin status. Furthermore, if pathology demonstrates poor differentiation, invasion into the muscularis, or lymphovascular invasion, surgical resection is advised. In particular, T2 tumors have a 20% likelihood of lymph node metastases, so continued endoscopic follow-up without further surgical intervention is not appropriate.

A malignant polyp in the distal or midrectum is often not amenable to further local staging because endoscopic rectal polypectomy leads to unreliable EUS imaging. Definitive surgical resection should be considered for a resected rectal polyp without clear margins or with adverse pathologic features. If margins are equivocal without muscle invasion, transanal excision may be feasible. Even when laparotomy is considered, a sphincter-preserving procedure is usually possible. Occasionally, an adequately informed patient will refuse surgery, or medical comorbidities preclude surgery as an option. In these special circumstances, nonstandard combined-modality chemoradiation is an alternative to definitive resection.

Nonsurgical Options for Partially Obstructing Tumors

The clinical diagnosis of bowel obstruction usually is based on an endoscopy or CT that may show obstructing mass(es). However, clinically significant bowel obstruction may not be present without proximal colonic dilation or evidence of perforation.

Bowel resection or diverting ostomy may be appropriate, but in patients with poor performance status, nonsurgical management should be considered, which includes expandable metal stents, especially in the rectosigmoid region. Obstructing sites higher in the colon can pose technical barriers to stent insertion. An endoscopically placed colonic decompression tube *proximal* to the obstruction may provide temporary relief. Endoscopic electrosurgical procedures, including argon plasma coagulation may recanalize the lumen. External-beam radiotherapy may then prevent complete obstruction while alleviating partial obstruction. Radiotherapy in rectal primaries may also relieve sacral plexus pain syndromes. Patients with impending bowel obstruction are hospitalized for bowel rest, nasogastric tube decompression, and intravenous hydration, followed by multidisciplinary evaluation by a gastroenterologist, surgical oncologist, medical oncologist, and

radiotherapist. While stent insertion, photocoagulation of intraluminal disease, or radiotherapy may all rapidly reverse impending bowel obstruction, the use of systemic therapy in a patient with tenuous bowel patency should be discouraged.

Multidisciplinary Management of Poor Bowel Function After Curative Treatment

Segmental bowel resections particularly for rectal cancer lead to permanent alterations in the frequency and character of bowel movements. Loss of the rectal vault and subsequent radiotherapy lead to compromised stool storage and stricture formation at the anastomotic site, while sphincter function may not return to baseline, leading to functional and mechanical dysfunction manifesting as small, frequent bowel movements, with episodic fecal incontinence.

In general, patients are advised that bowel habits may improve for up to 1 year from the time of surgery or up to 6 months after completion of all adjuvant therapy. For patients with more chronic and severe problems (innumerable small bowel movements or fecal incontinence), a multidisciplinary team of surgeons, gastroenterologists, and enterostomal nursing staff recommends a personalized detailed bowel regimen that, with adequate adherence, can improve quality of life and satisfaction with sphincter preservation. On rare occasions, when a sphincter-preserving procedure leads to unbearable dissatisfaction with bowel function, a colostomy or ileostomy may be recommended to improve functional status and quality of life.

Carcinoma With Neuroendocrine Features

Histologically, a colorectal carcinoma may demonstrate neuroendocrine differentiation, which should be readily distinguished from small cell carcinomas or high-grade neuroendocrine tumors by additional stains for chromogranin and synaptophysin. Metastatic gastrointestinal neuroendocrine carcinomas have been treated with irinotecan/cisplatin or irinotecan/oxaliplatin at MDACC, with observed partial responses, but durable responses remain uncommon. Individuals with adenocarcinoma with focal neuroendocrine features are offered standard colorectal cancer chemotherapy.

SUMMARY

Advances in pathogenesis and management of colorectal cancer contribute to continued reduction in mortality as biologic agents are under investigation in the advanced disease setting (Table 24-7). Many of these trials include correlatives to identify predictors of

Table 24-7 Targeted Therapies in Development for Advanced Colorectal Cancer

Mechanism of Action	Example of Agents	Phase of Study ^a
PI3K/Akt/mTOR inhibition	Perifosine, RAD001, MK-2206, GSK690693	Phase III
FGFR inhibition	Brivanib, AZD-4547	Phase III
cMET/HGF inhibition	ARQ-197, AMG-102	Randomized phase II
Apo2L/TRAIL inhibition	AMG-655, CS-1008	Randomized phase II
MEK/BRAF inhibition	AS703026, selumetinib, PLX-4032, XL281	Randomized phase II
IGFR inhibition	MK-0646, AMG-479	Randomized phase II
PARP inhibition	Olaparib, ABT-888	Phase II
Demethylating agent	Decitabine, azacitadine	Phase II
Histone deacetylase	Vorinostat, entinostat	Phase II
Notch/ γ secretase inhibition	RO4929097	Phase II
PPAR- γ inhibition	CS7017	Phase II
PDGFR inhibition	Imatinib	Phase II
Src inhibition	Dasatinib	Phase II
Integrin inhibition	EMD 525797	Phase II

^aFor most advanced agent in development.

clinical benefit to ultimately aid in patient selection. Hence, patient enrollment in clinical trials is highly encouraged.

Anal Cancer

Van Morris
Christopher H. Crane
Cathy Eng

Carcinoma of the anal canal is a rare malignancy representing approximately 2.5% of all gastrointestinal malignancies. It is estimated in 2015 that over 7,200 patients will be diagnosed with carcinoma of the anal canal in the United States, resulting in greater than 1,000 deaths (¹). The incidence of this disease continues to rise steadily. A practicing oncologist will evaluate and treat less than one such patient per year. The majority of anal carcinoma arises within the mucosa of the anus and is of squamous cell histology (²). Traditionally, 74% to 90% of carcinomas of the anal canal are cured with the combined modalities of chemoradiation, reserving an abdominoperineal resection (APR) for salvage therapy of persistent or recurrent disease (³). This chapter focuses on treatment of squamous cell carcinoma of the anal canal and the potential innovative strategies that lie ahead.

ANATOMY/HISTOLOGY

The anal canal is approximately 4 cm wide and is composed of the region extending from the proximal anorectal ring to the distal anal verge (margin) (Fig. 25-1). Because various definitions of the normal anal canal anatomy exist, classifying these tumors by a histologic definition based on the lining mucosa offers a more consistent approach to guide diagnosis and treatment (²).

Malignancies of the anal margin are treated as primary skin cancers and are often surgically excised. The rectal mucosa adjacent to the anorectal ring is composed of columnar epithelium. A transition zone of both cuboidal and columnar epithelium (6-12 mm

in length) extends from the distal rectum to the dentate line. The dentate line separates the columnar epithelium (columns of Morgagni) of the proximal anal canal and the squamous epithelium of the distal canal, which extends to the anal verge. The anal verge is the convergence of squamous epithelium and the anal margin. The anal margin comprises the dermis, located within 5 cm of the anal verge.

The mucosa of the transition zone, formally referred to as the cloacogenic mucosa, represents 66% of the lesions now commonly referred to as nonkeratinizing squamous cell carcinoma (SCC) (Figs. 25-2 and 25-3) (⁴). Tumors distal to the dentate line are usually keratinizing SCC (Figs. 25-4 and 25-5).

The vascular supply of the anal canal consists of the superior, middle, and inferior rectal vessels that originate from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. Lymphatic drainage superior to the dentate line is identical to rectal carcinomas flowing to the perirectal and paravertebral nodes. Tumors located inferior to the dentate line drain to the inguinal and femoral lymph nodes. A complete physical examination should include examination of the lymph nodes of the groin.

ETIOLOGY

Multiple risk factors have been associated with the development of carcinoma of the anal canal. Benign conditions such as hemorrhoids, fissures, and anal fistulas have not been determined to be causal factors (⁵). Rather, it has been postulated that these

FIGURE 25-1 Anatomy of the anal canal.

benign conditions may instead represent the initial symptoms of anal cancer ⁽⁵⁾.

Sexual Activity

The pathogenesis of developing anal cancer is largely related to infection with specific subtypes of human papillomavirus (HPV), most commonly with HPV-16 or HPV-18. Common risk factors associated with anal cancer include a history of more than 10 sexual partners; receptive anal intercourse before the age of 30; and sexually transmitted diseases, including condyloma acuminata (genital warts, attributed to HPV), gonorrhea, herpes virus, hepatitis, *Chlamydia trachomatis*, or a history of infection with human immunodeficiency

FIGURE 25-3 Magnified view of nonkeratinized squamous cell carcinoma of the anal canal.

FIGURE 25-4 Keratinized squamous cell carcinoma of the anal canal.

FIGURE 25-2 Nonkeratinized squamous cell carcinoma of the anal canal.

FIGURE 25-5 Magnified view of keratinized squamous cell carcinoma of the anal canal.

virus (HIV) ⁽⁶⁻⁸⁾. Women with a history of cervical, vaginal, or vulvar cancer are three to five times more likely to develop anal cancer as opposed to stomach or colon cancer, demonstrating the link between sexual activity and likely field cancerization effects from prior high-risk HPV infection ⁽⁹⁾.

Human Papillomavirus

Human papillomavirus is the most common sexually transmitted disease in the United States and has been strongly associated with the development of anal carcinoma ⁽¹⁰⁾. It is estimated that 75% of men and women of reproductive age have been infected with genital HPV.

High-risk subtypes HPV-16 and HPV-18 are associated with anal cancer—and also cervical dysplasia—and may result in anal intraepithelial neoplasia (AIN). Human papillomavirus subtype 16 reportedly results in a greater incidence of high-grade AIN ⁽¹¹⁾. However, unlike cervical dysplasia, AIN is a premalignant condition for which standard screening methods currently have not been universally recommended and have been limited to select high-risk individuals.

A systematic literature review on HPV type distribution in anal cancer showed a combined prevalence of HPV-16 and/or HPV-18 of 72% in invasive anal cancer, with the prevalence of HPV-16 being the highest in these cases, as in cervical cancer ⁽¹²⁾. A cohort of patients with metastatic SCC of the anal canal at the University of Texas MD Anderson Cancer Center (MDACC) revealed the presence of HPV, via detectable HPV DNA and/or expression of the protein p16, in 68 (95%) of 72 tumor samples analyzed ⁽¹³⁾. Therefore, HPV appears to be found in the vast majority of anal cancers.

The presence of HPV also has been reported to be a positive prognostic biomarker for patients with nonmetastatic SCC of the anal canal. In one study of patients with stages I to III anal cancer, HPV was detected in 120 (88%) of 137 tumors analyzed. In a multivariate analysis, p16 expression was determined to be associated with an improvement both in overall survival and disease-specific survival relative to patients with HPV-negative tumors ⁽¹⁴⁾.

Introduction in 2006 and 2009 of the prophylactic vaccines Gardasil and Cervarix, respectively, directed against primary infection by HPV has demonstrated efficacy in reducing precancerous anogenital lesions caused by the targeted subtypes 6, 11, 16, and 18 ⁽¹⁵⁻¹⁷⁾. In late 2014, the US Food and Drug Administration (FDA) approved the introduction of a nonavalent vaccine targeting nine HPV subtypes (6, 11, 16, 18, 31, 33, 45, 52, and 58). A large, double-blind placebo-controlled study of men who have sex with men between 16 and 26 years of age demonstrated that the use of a

quadrivalent vaccine against HPV not only was safe and well tolerated but also decreased the incidence of precancerous AIN ⁽¹⁸⁾. These findings generate early optimism that this preventative approach may decrease the incidence of this disease in the future. Even though initially approved for the vaccination of adolescent females, Gardasil has subsequently received extended FDA approval for males of the same age category after it was shown to be efficacious and may offer a promising primary prevention strategy in both genders ⁽¹⁹⁾.

Human Immunodeficiency Virus

Although a direct relationship between HIV and carcinoma of the anal canal has not been clearly established, a strong correlation exists between HIV and HPV. Compared with HIV-negative patients, HIV-positive patients are two to six times more likely to be diagnosed with HPV regardless of sexual practices and are also more likely to have a persistent infection ^(20, 21). Human immunodeficiency virus-positive men and women exposed to HIV are less likely to clear the virus and become HPV negative ^(21, 22). For patients who are infected with HIV, the prevalence of anal carcinoma is greater and cancer presents at a younger age of onset than in HIV-negative patients ⁽²³⁾.

Chronic Immunosuppression

Solid organ transplantation has been associated with a 10-fold increased risk of developing anal cancer and a 20-fold increased risk for vulvar and vaginal cancers ⁽²⁴⁾. A recent population-based cohort study conducted using the Danish National Patient Registry and the Danish Cancer Registry (DCR) from 1978 to 2005 found that HIV infection, solid organ transplantation, hematologic malignancies, and a range of specific autoimmune diseases were strongly associated with increased risk of anal SCC ⁽²⁵⁾.

Tobacco Use

Prior case-control studies have indicated that chronic tobacco use may result in a two- to five-fold increased likelihood of developing anal cancer ⁽²⁶⁾. Moreover, tobacco smoking appears to be associated with recurrence of anal carcinoma and is related to increased mortality; thus, smoking cessation should be encouraged once a diagnosis of anal carcinoma is made ⁽²⁷⁾.

PRESENTATION AND DIAGNOSIS

The mean age of diagnosis is approximately 62 years ⁽²⁸⁾. The most common presenting complaint is rectal bleeding. Other symptoms may include tenesmus, pain,

FIGURE 25-6 Perianal mass.

local irritation, discharge, or a change in bowel habits. Clinically enlarged lymph nodes are present in 15% to 25% of patients at presentation⁽²⁹⁾. Extreme case presentations may include a fungating perianal mass or a verrucous mass, as seen in Figs. 25-6 and 25-7.

A diagnostic evaluation should consist of a complete physical examination including examination of the inguinal lymph nodes, a digital rectal examination (DRE), and evaluation of the surrounding mucosa of the anus. Diagnostic studies should include proctosigmoidoscopy or anoscopy, chest x-ray, and computed tomography (CT) of the chest, abdomen, or pelvis or magnetic resonance imaging (MRI) of the abdomen and pelvis to rule out distant disease. A transrectal or transvaginal ultrasound may be of added benefit in accurate disease staging⁽³⁰⁻³³⁾. Histologic confirmation is recommended, with a tissue biopsy of the suspected area and/or fine-needle aspiration of any palpable inguinal lymph nodes because this may impact the radiation fields. An HIV test should be considered in all patients, and a one-time test for hepatitis C infection may also be considered for patients born before the year 1965

FIGURE 25-7 Multiple verrucous lesions originating from squamous cell carcinoma of the anal canal.

given the disproportionately high risk of incidence of viral infection for patients in this age range⁽³⁴⁾.

STAGING AND PROGNOSIS

The staging classification system for anal cancer was adopted by the American Joint Committee on Cancer. The T stage, unlike most gastrointestinal malignancies, is not dependent on the degree of tumor tissue penetration but rather on the size of the primary tumor site.

Carcinomas of the anal margin are commonly excised with complete resolution of the tumor. Independent poor prognostic features include tumor size (T stage) with a clear distinction in prognosis between T2 and T3 tumors^(23, 35, 36). Patients with T1 to T2 tumors have an expected 5-year survival of 80%, whereas patient with T3 to T4 tumors have an expected median 5-year survival of <20%⁽²⁸⁾. Inguinal lymph node involvement may reduce the cure rate by 50%, with increased nodal stage also being a significant prognostic factor⁽³⁷⁻⁴⁰⁾. Multivariate analysis of the results from the Radiation Therapy Oncology Group (RTOG) 98-11 trial indicates that tumor-related prognosticators for poorer overall survival included node-positive status (hazard ratio [HR], 1.88), large tumor diameter >5 cm (HR, 1.30), and male sex (HR, 1.38; $P = .031$)⁽⁴¹⁾.

CHEMORADIATION—NIGRO REGIMEN

A pivotal approach led to the anecdotal finding that surgery may not be necessary for curative intent in the treatment of SCC of the anal canal⁽⁴²⁾. The benefits of combined chemoradiation in other gastrointestinal malignancies prompted Nigro and colleagues to consider the use of chemotherapy as a radiation sensitizer. Patients received concomitant 5-fluorouracil (5-FU) and mitomycin C, which was administered along with external beam radiation therapy (EBRT) (30 Gy). The pathologic specimens in three of three patients failed to demonstrate any viable tumor. This observation culminated in the use of chemoradiation as the primary treatment modality for the treatment of anal cancer and revolutionized the approach to its treatment. The Nigro approach of chemoradiation has subsequently been evaluated in several other small phase II studies with radiation doses ranging from 30 to 60 Gy.

A retrospective analysis from the Princess Margaret Hospital reviewed the outcomes of patients who had been treated with (1) radiation alone, (2) 5-FU/mitomycin C, (3) split-course 5-FU/mitomycin C, or (4) split-course 5-FU⁽⁴³⁾. The 5-year disease-free survival (DFS) was significantly improved in the

5-FU/mitomycin C arms versus 5-FU alone (76% vs 64%). Although the combination of 5-FU/mitomycin C was superior in locoregional control (LRC) with the addition of mitomycin C (86% vs 60%), the use of split-course radiation resulted in decreased morbidity, notably acute skin toxicities.

RADIATION VERSUS CHEMORADIATION: THE ROLE OF MITOMYCIN C

United Kingdom Coordinating Committee on Cancer Research

The UK Coordinating Committee on Cancer Research (UKCCCR) created the phase III anal cancer trial (ACT I). Patients were randomized to radiation alone (45 Gy) versus continuous infusion 5-FU (1,000 mg/m² on days 1-4 or 750 mg/m² on days 1-5) during the first and last weeks of radiation (45 Gy) with mitomycin C (12 mg/m² on day 1) (44). After a median follow-up time of 42 months, the 3-year local failure rate was significantly reduced in the chemoradiation arm versus the radiation-alone arm (39% vs 61%, $P < .0001$; Table 25-1).

Notably, the 3-year mortality rate in the radiation-only arm was greater than that of the chemoradiation arm (39% vs 28%). Twenty patients (3%) required a palliative colostomy or anorectal excision due to treatment-related morbidities. Early morbidity was significant in the chemoradiation arm. Subsequently, dose reduction of mitomycin C was recommended if the patient was ≥ 70 years old or if deemed medically necessary. The authors concluded that chemoradiation provided a 46% reduction in local recurrence compared with radiation alone.

European Organization for Research and Treatment of Cancer

A smaller study completed by the European Organization for Research and Treatment of Cancer (EORTC) explored the role of chemoradiation and its potential benefit in LRC and colostomy-free interval (45). A total of 110 patients were randomized to radiation (45 Gy) with or without continuous infusion 5-FU (750 mg/m² on days 1-5 and 29-33) and mitomycin C (15 mg/m² on day 1).

Event-free survival was superior in the combined-modality arm ($P = .03$). The overall 5-year survival was 56% in this patient population. In contrast to the UKCCCR study, this clinical trial was limited to T3 to T4 or node-positive tumors. Chemoradiation contributed 18% actuarial improvement in 5-year LRC and an increase in colostomy-free survival (CFS) (36%).

Table 25-1 Randomized Phase III Studies of Radiation Therapy Versus Chemoradiation

	Radiation	Chemoradiation
UKCCCR	n = 285	n = 292
Complete response	76 (30%)	100 (39%)
Partial response (>50%)	157 (62%)	138 (53%)
Minimal response (<50%)	22 (9%)	21 (8%)
Three-year local failure	164 (61%)	101 (39%)
Three-year overall survival	58%	65%, $P = .25$
EORTC	n = 52	n = 51
Complete response	54%	80%
Five-year locoregional control	—	$P = .02$
Five-year colostomy-free interval	—	$P = .002$
Three-year overall survival	65%	72% ($P = .17$)

Concomitant radiotherapy and chemotherapy is superior to radiotherapy alone in the treatment of locally advanced anal cancer: results of a phase III randomized trial of the European Organization for Research and Treatment of Cancer Radiotherapy and Gastrointestinal Cooperative Groups. *J Clin Oncol*. 1997;15:2040-2049.

In summary, the phase III UKCCCR and EORTC studies established combined chemoradiation as superior to radiation alone for LRC and CFS.

THE INTRODUCTION OF CISPLATIN

Despite the evident benefits of mitomycin C in the treatment of anal cancer, potential treatment-related toxicities may include leukopenia, thrombocytopenia, and, rarely, hemolytic uremic syndrome (HUS) and leukemia. Although a review of prior 5-FU/mitomycin C clinical trials in SCC of the anal canal suggests the potential for superior results, these often come at the cost of treatment-related morbidity and mortality. Therefore, other agents that may reduce treatment-related toxicities without compromising efficacy would be preferable.

Table 25-2 RTOG Study of 5-FU/Radiation Versus 5-FU/Mitomycin C/Radiation

	5-FU/Radiation (n = 145)	5-FU/Mitomycin C/Radiation (n = 146)	P Value
Complete response	115 (86)	119 (92)	.135
Tumor size >5 cm	42 (81)	42 (86)	.02
Tumor size <5 cm	73 (90)	77 (96)	.002
Time to colostomy (4 years)	32 (22)	13 (9)	.002
Colostomy-free survival	89 (61)	109 (75)	.014
Four-year DFS	71 (51)	98 (73)	.0003
Four-year OS	42 (29)	32 (22)	.31

5-FU, 5-fluorouracil; DFS, disease-free survival; OS, overall response; RTOG, Radiation Therapy Oncology Group. Data from Flam M, John M, Pajak TF, et al. Role of mitomycin in combination with fluorouracil and radiotherapy, and of salvage chemoradiation in the definitive nonsurgical treatment of epidermoid carcinoma of the anal canal: results of a phase III randomized intergroup study. *J Clin Oncol*. 1996;14:2527-2539.

The Eastern Cooperative Group (ECOG) 4292 trial attempted to evaluate the combination of 5-FU/cisplatin (Table 25-2) (⁴⁶). The overall response rate was 95%. Thirteen patients (68%) were determined to have a complete response (CR), and five patients (26%) had partial response. Fifteen patients (79%) experienced grade ≥ 3 toxicities. Locoregional control could not be achieved in approximately one-third of patients accrued. This treatment schedule with split-course radiation was identical to that reported in RTOG 92-08. The authors concluded that the delay in radiation treatment likely accounted for the inferior LRC rate and recommended examining this combination further.

A retrospective analysis in 197 patients with T_xN_xM0 SCC of the anal canal was completed at MDACC (⁴⁷). Patients received continuous infusion of 5-FU and cisplatin for the duration of radiation therapy (55 Gy), and median follow-up was 8.6 years. Complete responses after chemoradiation were observed in 185 patients (94%). The local recurrence rate was 11% with the use of 5-FU and cisplatin, and all patients with a local recurrence underwent salvage APR or diverting colostomies. Only 16 patients (8%) developed distant metastases. Overall survival at 5 years was 86%. Grade 4 acute toxicities (diarrhea, dehydration, and skin ulceration) were infrequent. These studies suggest that the use of cisplatin and 5-FU with concurrent radiation is safe and effective in patients with locally advanced anal cancer and may be an acceptable alternative to the traditional 5-FU/mitomycin C regimen.

Neoadjuvant (Induction) Chemotherapy

In place of standard chemoradiation therapy, could the addition of systemic induction treatment provide an improvement in overall survival and decrease the risk of distant disease development?

The phase III Intergroup/ACCORD 03 trial created a 2 × 2 factorial design to compare standard-dose (45 Gy/25 fractions + boost of 15 Gy) versus high-dose radiation therapy (boost of 20-25 Gy) and the potential benefits of induction chemotherapy with 5-FU (800 mg/m² on days 1-4) and cisplatin (80 mg/m² on day 1) for two cycles in locally advanced SCC of the anal canal (⁴⁸). Patients were required to have T2 >4 cm or node-positive disease. Three hundred six patients were allocated to one of four treatment arms: (1) induction with standard-dose radiation therapy, (2) induction with high-dose radiation therapy, (3) control arm of 5-FU/cisplatin plus standard boost, and (4) control arm of 5-FU/cisplatin plus high-dose boost. The results were compared in terms of CFS. After a median follow-up of 43 months, no difference in CFS was noted for the induction arm (P = not significant) or the higher dose radiation therapy arm (P = .67) versus the control arm. Overall, no statistical differences were noted across all arms for local control, CFS, event-free survival, or overall survival.

Radiation Therapy Oncology Group 98-11

The RTOG 98-11 trial was a large phase III multi-institutional randomized trial for locally advanced SCC of the anal canal (⁴¹) that randomized 682 patients with T2 to T4 tumors and any nodal status to receive 5-FU/mitomycin C and concurrent radiation (control arm) or induction 5-FU/cisplatin followed by concurrent 5-FU/cisplatin and radiation. All patients received 45 to 50 Gy of radiation, with an additional 10 to 14 Gy in 2-Gy fractions given to patients with residual evidence of disease, tumors >5 cm, or tumor invasion of adjacent organs. From a recent long-term update, improved outcomes were noted in the group randomized to 5-FU/mitomycin C and concurrent radiation. Five-year DFS was better in this group (68% vs 58%,

$P = .026$) when compared to those receiving induction 5-FU/cisplatin followed by concurrent 5-FU/cisplatin and radiation, as was 5-year overall survival (78% vs 71%, $P = .026$). Trends in CFS, locoregional failure, and colostomy failure all favored the 5-FU/mitomycin C arm as well, although none reached statistical significance. Grade 3 or 4 hematologic toxicity was observed more frequently in patients randomized to the 5-FU/mitomycin C arm (62% vs 42%, $P < .0001$).

Despite the initial appearance that 5-FU/mitomycin C treatment is superior for patients with nonmetastatic SCC of the anal cancer, these findings must be interpreted with caution. This study has since been criticized for the inequality of the two treatment schedules, making a direct comparison of mitomycin C and cisplatin difficult due to the confounding factor of induction chemotherapy in the investigational arm⁽⁴⁹⁾. Additionally, administration of induction chemotherapy delayed the time to initiation of curative chemoradiation and thereby prolonged the overall treatment time, a metric that, when extended, has been associated with worse clinical outcomes in clinical trials for anal cancer. Nonetheless, induction chemotherapy in patients with early-stage SCC of the anal canal is not routinely administered, based on these findings, at MDACC.

Mitomycin Versus Cisplatin and the Role of Adjuvant Therapy

The UK ACT II trial is the largest phase III trial conducted in SCC of the anal cancer and is the first direct analysis of 5-FU/mitomycin C versus 5-FU/cisplatin with concurrent radiation therapy. The ACT II trial also evaluated whether maintenance (adjuvant) chemotherapy following completion of chemoradiotherapy reduces recurrence-free survival (RFS)⁽⁵⁰⁾. Using a 2×2 factorial design, 940 patients with T1 to T4 node-negative and -positive disease were randomly assigned to either 5-FU/mitomycin C or 5-FU/cisplatin administered concurrently with continuous radiotherapy of 50.4 Gy. The second randomization was to two courses of 5-FU/cisplatin (same schedule) consolidation chemotherapy or no further treatment. There was a greater incidence of acute grade 3 or 4 hematologic toxicity on the mitomycin C arm (26% vs 16%, $P = .001$) but no statistical differences in grade 3 or 4 nonhematologic toxicities. Results after a median follow-up of 5 years demonstrated no statistically significant difference for the end point of 6-month CR rate for concurrent chemoradiation with 5-FU/mitomycin C versus 5-FU/cisplatin (90.5% vs 89.6%, respectively), no difference in RFS, and no difference in CFS, respectively. The role of maintenance (adjuvant) 5-FU/cisplatin chemotherapy showed no added benefit for RFS or overall survival.

Although the investigators failed to fulfill the primary end point of superiority for the cisplatin-based regimen, the final results indicate that 5-FU/cisplatin is noninferior to 5-FU/mitomycin C in achieving a CR and is associated with fewer significant hematologic toxicities. Based on these findings, at MDACC, 5-FU/cisplatin remains our preferred regimen due to its efficacy and decreased myelosuppression relative to 5-FU/mitomycin C. This also allows for safer treatment of immunocompromised and elderly patients who otherwise might not tolerate myelosuppressive combinations.

RADIATION TECHNIQUE

Currently, the most commonly used approach in the combined-modality treatment of carcinoma of the anal canal is continuous-course radiation (45 Gy in 1.8-Gy fractions using opposed anterior and posterior treatment fields with a boost to the primary tumor to 5.4 Gy) plus two cycles of concurrent continuous infusion 5-FU plus mitomycin C. This regimen is considered by most to be the standard of care. Review of the literature has shown the gradual increase in radiation from 30 to 59.4 Gy in recent studies. Prior studies have indicated that there is a dose-response relationship between treatment and outcome. An analysis completed at MDACC from 1979 to 1987 revealed a dramatic difference in LRC for patients who received 45 to 49 Gy (50%) versus ≥ 55 Gy (90%)⁽⁵¹⁾.

At MDACC, our initial experience of 55 Gy for all patients indicated that the local failure rate was 25% to 30% in patients with T3-4 tumors⁽⁵²⁾. In 1999, based on this data, the dose was increased to 59 Gy for T3-4 tumors. Definitive evidence that the higher dose improves local tumor control will eventually be determined. It should be noted that radiation dosages >60 Gy result in an unacceptably high risk of anal canal and urethral stricture, ulceration, and fistula formation.

EVALUATION OF RESPONSE

Studies using CT imaging are often relatively insensitive for detecting the total burden of disease in patients during evaluation for anal cancer, and traditionally evaluation for response following definitive treatment for nonmetastatic anal cancer has been based on clinical assessment. Although the literature is scant regarding use of MRI in evaluation of response to anal cancer, MRI may be used to evaluate a concerning lesion of interest noted on CT with relation to the adjacent anatomic structures.

The question arises regarding the duration of time to wait for a complete clinical response before referral to a surgeon for APR. Review of outcomes from ACT II revealed that 29% of patients without CR by week 11 following completion of definitive chemoradiation did achieve a CR by week 26⁽⁵³⁾. Based on these findings, in the presence of improving symptoms and/or continued tumor regression on evaluation, at MDACC patients are allowed 26 weeks to achieve a CR before referral for APR. Should clinical progression become apparent prior to this point, then patients are sent promptly for salvage evaluation. Response is largely based on clinical examination. A tissue biopsy should only be pursued if there is clinical evidence of progression or significant residual disease despite an adequate surveillance period. Because anal cancer tends to remain locoregionally confined, the opportunity will not typically be missed for salvage APR with curative intent even if a clinically concerning area is followed closely without biopsy. Treatment guidelines suggest that a tumor biopsy be performed only if recurrent or persistent disease is suspected after serial DRE (Fig. 25-8)⁽⁵⁴⁾.

RECURRENT DISEASE

Salvage of Recurrent Disease

Abdominoperineal resection is the only effective treatment option for localized recurrent or residual primary disease following chemoradiation for SCC of the anal canal. Fifty to 70% of patients are cured who undergo APR for recurrence at the primary site^(55,56). There is no role for definitive reirradiation for an in-field recurrence, but neoadjuvant chemoradiation (39 Gy in 26 fractions twice daily with chemotherapy) may be used in cases where there are concerns about the radial margin.

The management of nodal recurrences should be individualized based on the extent of disease, prior radiation delivered to the area of recurrence, and performance status of the patient. In cases where patients have been referred to MDACC with nodal recurrence outside of or at the margin of a prior radiation field, salvage chemoradiation has been effective provided that a full dose of reirradiation is possible. For in-field nodal recurrences, we typically use preoperative

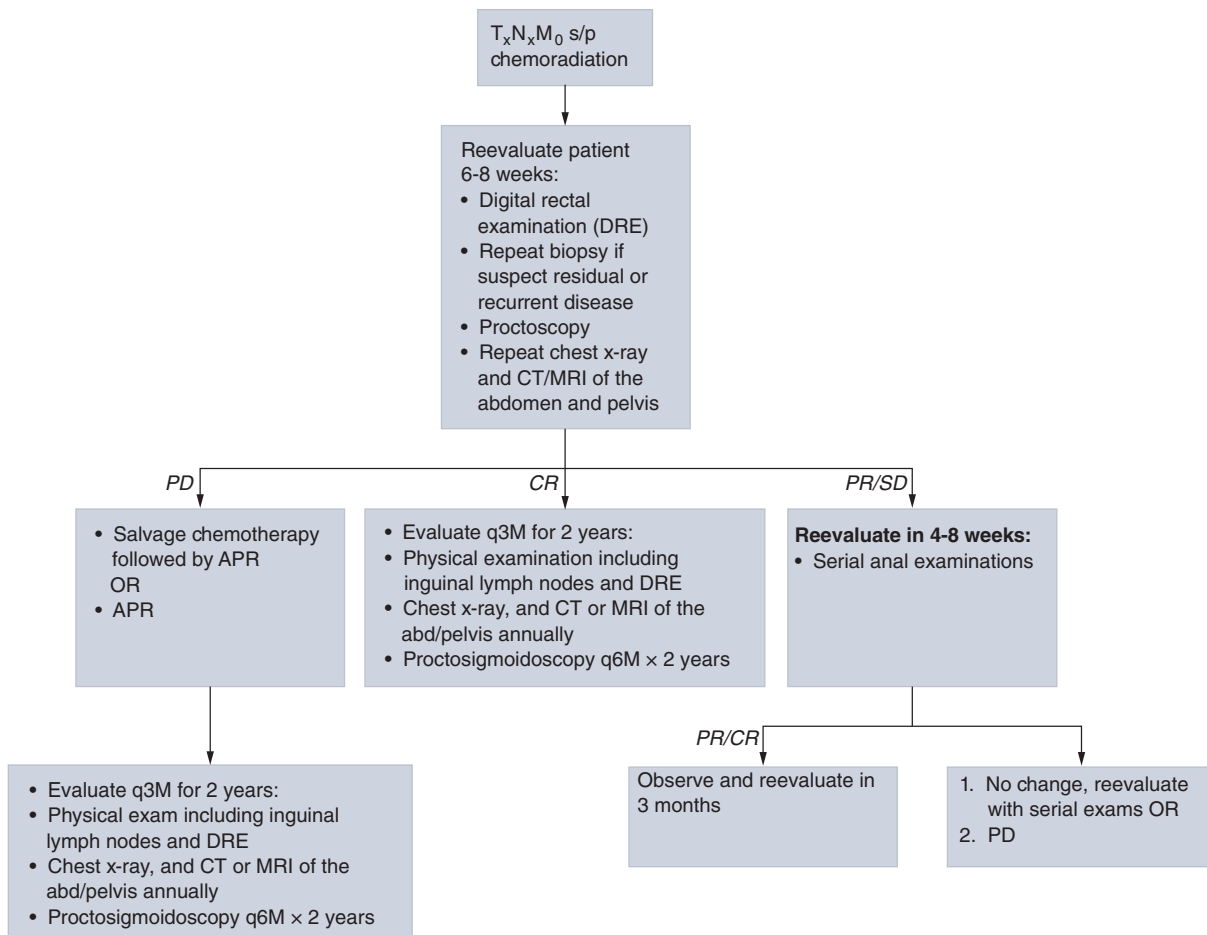

FIGURE 25-8 Postchemoradiation evaluation and surveillance APR, abdominoperineal resection; CR, complete response; CT, computed tomography; MRI, magnetic resonance imaging; PD, progressive disease; PR, partial response; SD, stable disease.

chemoradiation to 39 Gy in 26 fractions twice daily followed by surgical resection.

ADENOCARCINOMA OF THE ANAL CANAL

Adenocarcinomas of the anal canal occur less frequently than SCCs⁽²⁸⁾. Nonetheless, most of the reports overestimate the incidence of adenocarcinoma of the anal canal because they do not exclude contamination by the more common distal rectal cancer. The true incidence is likely less than 10%. Its etiology remains unclear, but like its squamous cell counterpart, it has been linked in the past to chronic inflammatory conditions and HPV^(37,55). The most appropriate management remains to be defined, with no large prospective studies completed to date. The most striking difference between adenocarcinoma and SCC of the anal canal is the high distant metastasis rate, which tends to undermine the impact of local tumor control. Retrospective analysis from the MDACC experience with adenocarcinoma of the anal canal has suggested a benefit of neoadjuvant chemoradiation followed by APR with the consideration of adjuvant chemotherapy analogous to the treatment of rectal cancer⁽⁵⁷⁾.

METASTATIC ANAL CARCINOMA

Although the majority of patients with SCC of the anal canal will be cured with chemoradiation, a minority of patients will develop distant metastatic disease. Overall, 5% of patients initially present with extrapelvic metastases, and 10% to 20% of patients treated with curative intent will develop metastatic disease. Due to the rarity of this disease, a universally accepted treatment paradigm has not been established, with choice and duration of therapy largely based on individual case studies and small case series⁽⁵⁸⁾.

One recent retrospective analysis of our experience at MDACC, the largest series published to date of 72 patients with metastatic anal cancer treated between 2000 and 2012, demonstrated that the majority of patients (55%) with metastatic anal carcinoma receive a 5-FU- and cisplatin-based regimen as first-line therapy⁽⁵⁹⁾. Patients received a median of two lines of cytotoxic chemotherapy, with carboplatin and paclitaxel being the most popular second-line treatment for patients still able to tolerate further therapy following progression on frontline chemotherapy. With a median follow-up period of 42 months, the median overall survival was 22 months. Systemic treatment should be considered in any patient demonstrating a good performance status, with duration of therapy

continued indefinitely for maximal outcome if tolerated well. A subset of patients in this cohort (43%) with oligometastatic disease was able to proceed to surgical resection of distant metastases or chemoradiation to affected regions that had not received prior radiotherapy. For these patients, overall survival was prolonged (53 months vs 17 months, $P < .001$), which was likely a reflection of a lower total burden of disease and favorable clinical characteristics that enabled this group to withstand multidisciplinary management of their metastatic disease. Consideration of surgical resection with curative intent should be encouraged for patients if surgically resectable or borderline resectable.

SURVEILLANCE

When patients are treated with chemoradiation therapy with curative intent, patients should be evaluated every 6 to 8 weeks until a maximal clinical response is achieved. Biopsy should not be performed before 26 weeks following chemoradiation therapy unless there is clear evidence of residual disease or progression is suspected. If clinical CR is achieved, then patients should be evaluated every 3 months for 2 years after diagnosis. Physical examination must include a DRE and assessment for any palpable inguinal lymph nodes. Vaginal dilators may be used three times a week if needed. The critical time for the prevention of vaginal stenosis is 3 to 6 months following completion of chemoradiation therapy. Vaginal hormonal creams and suppositories are also useful for treatment of vaginal dryness and dyspareunia. Proctosigmoidoscopy should be performed biannually following a CR for 2 years. Chest x-ray and CT of the chest, abdomen, and pelvis or MRI of the abdomen and pelvis should be completed annually for 2 years. Pap smears should continue to be performed annually.

FUTURE DIRECTIONS AND CHALLENGES

It is likely that additional chemotherapy agents other than 5-FU, mitomycin C, and cisplatin may provide benefit to patients with SCC of the anal canal. A prospective, randomized trial (InterAACT) comparing cisplatin/5-FU with carboplatin/paclitaxel as frontline therapy for patients with metastatic anal cancer is currently under way and will elucidate the optimal choice of cytotoxic agents to be used in patients with nonresectable disease. Given the tight association between HPV infection and anal cancer, there is interest that these immune checkpoint blockade agents may have efficacy for this virally associated tumor. A phase II

trial of nivolumab, a monoclonal antibody against PD-1, is under way for patients with refractory metastatic anal cancer, and these results will be important in understanding the safety and efficacy of this class of agents in patients with metastatic disease.

Biologic Agents

The role of the anti-vascular endothelial growth factor (VEGF) agent bevacizumab in SCC of the anal canal has not been well defined. However, although this drug has received recent approval by the FDA in combination with paclitaxel and either cisplatin or topotecan in patients with recurrent/metastatic cervical cancer⁽⁶⁰⁾, further investigation in the coming years will clarify the benefit of this anti-VEGF agent in advanced anal cancer.

Anti-epidermal growth factor receptor monoclonal antibodies such as cetuximab have demonstrated efficacy in patients with *KRAS* wild-type metastatic colorectal cancer^(61, 62). This oncogene appears to be mutated infrequently in anal cancer. Data published from the ACCORD 16 phase II trial studying cetuximab in combination with cisplatin/5-FU in patients receiving concomitant radiation for locally advanced anal cancer revealed an unacceptably high frequency of significant adverse events⁽⁶³⁾.

CONCLUSION

Carcinoma of the anal canal is a unique malignancy where chemoradiation therapy is provided with curative intent or failure to respond to therapy will result in an APR. Hence, it is recommended that all patients diagnosed be initially evaluated at a tertiary cancer center or the equivalent given the rarity of the disease and the potential for permanent loss of sphincter preservation. We highly recommend a multidisciplinary team discussion with significant expertise for the most appropriate treatment in this rare malignancy.

Neuroendocrine Tumors

Daniel M. Halperin
James C. Yao

INTRODUCTION

Neuroendocrine tumors (NETs) originate from enterochromaffin cells distributed throughout the body. This chapter focuses on low- to intermediate-grade gastroenteropancreatic NETs (GEP-NETs), although the term *neuroendocrine tumor* also denotes diseases such as small cell carcinoma, medullary thyroid carcinoma, neuroblastoma, and Merkel cell tumor. Pancreatic NETs (PNETs), previously known as islet cell carcinomas, arise from pancreatic ductal progenitors. Extrapaneatic low- to intermediate-grade NETs are generally called carcinoids and most often originate along the aerodigestive tract. These tumors share the capacity for hormone production and usually have an indolent clinical course. Presenting symptoms are caused by secreted hormones, local tumor growth, and/or metastasis. Surgical resection is the curative approach for localized disease. In unresectable or metastatic disease, long-acting somatostatin analogues improve quality of life and progression-free survival. In PNETs, recent randomized studies support the use of targeted therapies such as everolimus and sunitinib, with older prospective and retrospective data supporting the use of alkylating chemotherapy such as streptozocin and temozolomide. This chapter presents a comprehensive overview of the diagnosis and management of pancreatic and extrapancreatic NETs.

EPIDEMIOLOGY

The overall incidence of NETs in the United States is rising and presently estimated at 5.25 cases per 100,000 (¹). Most NETs progress slowly and may remain undiagnosed for years or even a person's entire natural life. Small bowel NETs are found in 0.65% to 1.2% of patients during unselected necropsy (^{2,3}). These tumors are usually diagnosed in the sixth and seventh decades of life (^{1,4}). The gastrointestinal tract is the most common primary site of NETs, accounting for 58% of NETs (¹). The distribution of NETs is illustrated in [Table 26-1](#).

PROGNOSIS

The prognosis for patients with NETs varies by histologic grade, stage, and primary site. High-grade NETs demonstrate similar biology and prognosis to small cell lung carcinoma. Low- to intermediate-grade NETs have a more favorable prognosis. The median overall survival of patients with localized low- to intermediate-grade NET is 223 months, according to a recent analysis of the Surveillance, Epidemiology, and End Results (SEER) database of patients registered from 1973 to 2004. For patients with regional disease, defined as involvement of regional lymph nodes, extension to adjacent tissue, or both, the median overall survival is 111 months. For metastatic disease, the median overall

Data from analysis of Surveillance, Epidemiology, and End Results 17 Registry, 2000 to 2004 (¹).

survival is 33 months (¹). The prognoses of NETs by anatomic site are discussed subsequently.

PATHOGENESIS AND MOLECULAR BIOLOGY

Sporadic and hereditary tumors have yielded insights into NET biology. The *MEN1* gene, mutated in multiple endocrine neoplasia, type 1, was mutated in 44% of patients with resected sporadic PNETs in a recent exome sequencing study, with 43% having mutations in the *DAXX/ATRX* complex and 14% harboring mutations in the mammalian target of rapamycin (mTOR) pathway (⁵). Menin, the protein product of the *MEN1* gene, suppresses tumorigenesis by multiple mechanisms, including transcription regulation via interaction with histone methyltransferases, direct cell cycle regulation via interaction with the genetic loci of cyclin dependent kinase inhibitors, and facilitation of apoptosis by increased caspase 8 production (⁶). Genomic analyses of small intestinal NETs revealed rare mutation events, with alterations in *CDKN2B* observed in nearly 10% of cases (⁷). Multiple older techniques, such as comparative genomic hybridization (⁸) and single-nucleotide polymorphism-based array technology (⁹), have confirmed chromosome 18 loss in up to 43% of midgut NETs. Therefore, the somatic genomic alterations in pancreatic and extrapancreatic NETs are qualitatively and quantitatively different, aligning their genetic and clinical heterogeneity. By immunohistochemistry, vascular endothelial growth factor (VEGF) has been associated with poorer clinical outcomes in GEP-NETs (¹⁰), generating significant interest in antiangiogenic therapies, as discussed later.

A significant minority of NETs (5%-10%) occur in the context of multiple endocrine neoplasia, type 1 (MEN1), an autosomal dominant disorder characterized by pituitary tumors, hyperparathyroidism, and PNETs. Neuroendocrine tumors related to MEN1 demonstrate a unique pattern of symptomatic and asymptomatic lesions. Duodenal gastrinomas, causing the Zollinger-Ellison syndrome of peptic ulcers, gastroesophageal reflux, and diarrhea, afflict nearly 60% of MEN1 patients. Characteristic asymptomatic lesions include small duodenal foci of somatostatin expression and pancreatic adenomas secreting glucagon or pancreatic polypeptide. Roughly 20% of MEN1-associated pancreatic macroadenomas are “insulinomas,” causing hyperinsulinemic hypoglycemic syndrome. Notably, approximately 10% of PNETs are associated with MEN1 syndrome (¹¹). Neurofibromatosis type 1, von Hippel-Lindau syndrome, and tuberous sclerosis complex 2 also predispose to NETs, but with very low penetrance, and these diseases account for far fewer NETs than MEN1 (¹¹).

PATHOLOGIC CLASSIFICATION

NETs are characterized by monotonous sheets of small round cells with uniform nuclei and cytoplasm (Fig 26-1). Neuroendocrine cells store secreted substances in membrane-bound vesicles. Malignant neuroendocrine cells have minimal mitotic activity, cytologic atypia, or nuclear polymorphism. Immunohistochemical markers used to confirm a NET diagnosis include neuron-specific enolase, CD56, chromogranin A (CgA), and synaptophysin (Table 26-2).

FIGURE 26-1 Histologic appearance of neuroendocrine tumors (NETs). Microscopic appearance of low-grade NET. **A.** Standard microscopy showing few mitoses, no necrosis, and large numbers of tumor vessels. **B.** Immunohistochemical staining for chromogranin A.

Table 26-2 Immunohistochemical Markers of Neuroendocrine Tumors

Marker	Significance
Neuron-specific enolase	Cytoplasmic glycolytic enzyme, a less specific neuroendocrine marker
Synaptophysin	Presynaptic vesicle membrane glycoprotein, present on normal and neoplastic neuroendocrine cells
Chromogranin A	Acidic protein, universal marker for neuroendocrine tissue
CD56	Neural adhesion molecule
Cytokeratin(s)	Lack of cytokeratin expression suggests the tumor is either an anaplastic neoplasm or may not be a carcinoma

Assessing tumor grade is critical in all NETs. Modern grading schemes distinguish principally between high-grade (grade 3) tumors, with mitotic count >20/10 high-powered fields or Ki-67 proliferation index >20%, and low- or intermediate-grade (grade 1-2) tumors. Clinical behavior and therapy are largely determined by this distinction⁽¹²⁾. However, a large retrospective analysis revealed a Ki-67 index of 55% or greater to better predict responsiveness to the platinum-based chemotherapy recommended for high-grade NETs⁽¹³⁾. Therefore, it is likely that grading systems will evolve with our biological understanding and therapeutic options.

CLINICAL PRESENTATION, DIAGNOSTIC WORKUP, AND CLINICAL STAGING

Although NETs are well known for their hormonal syndromes, many malignant PNETs are nonfunctional, and carcinoid syndrome is typically present only in the setting of metastases. Symptoms can be insidious and present for years before diagnosis. Symptoms of local and regional extrapancreatic and nonfunctional pancreatic NETs are often vague, relating to obstruction, mesenteric fibrosis, or vascular compromise.

Neuroendocrine Tumor Laboratory Tests and Markers

Although general serum and urine biomarkers are useful for tumor monitoring, they are insufficient for NET diagnosis, which requires pathologic evaluation.

Frequently measured tumor markers in carcinoid disease include serum CgA and 5-hydroxyindoleacetic acid (5-HIAA) levels in a 24-hour urine sample. False-positive results occur with consumption of tryptophan- or serotonin-rich foods (bananas, butternuts, kiwis, mockernuts, pecans, pineapples, plantains, plums, shagbark, sweet pignuts, tomatoes, and walnuts). Common medications affecting urinary 5-HIAA levels include guaifenesin, acetaminophen, and salicylates. Serum CgA level is a sensitive, but nonspecific, marker for NETs, and is elevated among patients receiving proton pump inhibitors or with impaired renal, hepatic, or cardiac function.

In addition to CgA and 5-HIAA, NETs can synthesize other bioactive amines and peptides including 5-hydroxytryptamine (5-HTP), 5-hydroxytryptophan (5-HT), serotonin, insulin, gastrin, glucagon, somatostatin, vasoactive intestinal polypeptide (VIP), adrenocorticotrophic hormone, melanocyte-stimulating hormone, pancreatic polypeptide, and pancreastatin⁽¹⁴⁾.

Imaging

Endoscopy

Endoscopic techniques localize tumors and facilitate biopsy. Esophagogastroduodenoscopy (EGD) can often locate gastric and duodenal NETs. Colonoscopy can identify colorectal NETs. Double-balloon enteroscopy and capsule endoscopy may assist in localizing small bowel NETs. Disadvantages of endoscopy include the requirement for patient sedation and the difficulty in visualizing small submucosal lesions. Endoscopic ultrasound is useful in the assessment, visualization, and biopsy of pancreatic and some small duodenal NETs.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are the preferred initial imaging studies for localizing NETs. However, the utility of cross-sectional imaging for diagnosing typical small bowel NETs is limited; usually their presence must be inferred from luminal narrowing, adenopathy, and mesenteric fibrosis. Computed tomography and MRI technologies are far more useful in detection of hepatic metastases, which frequently present convenient sites for diagnostic biopsy. Computed tomography and MRI are helpful in the detection of PNETs, for which the sensitivities of CT and MRI are up to 82% and 100%, respectively⁽¹⁵⁾.

Somatostatin Receptor Scintigraphy

Somatostatin receptor scintigraphy (SRS) has improved the visualization of NETs. Somatostatin receptor

scintigraphy uses a somatostatin analogue, ¹¹¹In-labeled diethylenetriamine penta-acetic acid octreotide (DTPA-D-Phe¹-octreotide), to visualize tumors expressing somatostatin receptors 2 and 5. Compared with CT or MRI, SRS detects additional metastases in about one-third of patients. Moreover, SRS may help to identify small tumors when conventional scans are unrevealing. The overall sensitivity of SRS is 80% to 90% (¹⁶).

Positron Emission Tomography

Because ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) identifies tumors with significant proliferative activity, it is unreliable in NETs. Gallium-68 (⁶⁸Ga)-DOTA-NOC PET, which uses labeled octreotide to detect somatostatin-avid tumors, had a sensitivity of 78.3% and a specificity of 92.5% in an initial study (¹⁷). Ongoing studies are evaluating alternative ⁶⁸Ga-labelled somatostatin analogues, and this technology may emerge as more convenient than SRS, with potentially improved test characteristics.

Other Nuclear Scintigraphy Techniques

Metaiodobenzylguanidine (MIBG) is absorbed by carcinoid tumor cells. Iodine-131-labeled MIBG (¹³¹I-MIBG) has an overall sensitivity of 55% to 70% in detecting NETs (¹⁸). Although ¹³¹I-MIBG is less sensitive than SRS, it may be used in patients receiving long-acting octreotide, which competitively inhibits uptake of radiolabeled somatostatin analogues.

Clinical Staging

The American Joint Committee on Cancer (AJCC) has proposed site-specific staging systems for grade 1 to 2 NETs using the TNM system (¹⁹). The details vary, particularly with respect to the T stage, which can depend on depth of invasion or involvement of critical structures. This staging is prognostic, but not predictive of the benefit with any therapy. The relevant distinction is therefore between resectable and unresectable/metastatic disease. High-grade NETs are described with a

TNM stage according to guidelines for carcinomas of the primary site but are summarized as limited stage or extensive stage disease, defined by the ability of the cancer to be treated in a single radiation port, based on the staging of the biologically analogous small cell lung cancer (²⁰).

CARCINOID CLINICAL BEHAVIOR BY SITE

Gastric Carcinoid

Gastric carcinoid tumors are divided into three types. Type 1 (75%) is associated with chronic atrophic gastritis, type 2 (5%-10%) is associated with Zollinger-Ellison syndrome, and type 3 (15%-25%) is sporadic (²¹). Conceptually, type 1 and 2 gastric carcinoids arise as a physiologic response to excessive gastrin secretion, with the gastrin being physiologic in type 1 gastric carcinoids and pathologic in type 2 gastric carcinoids. Because they are independent of known stimuli, type 3 gastric carcinoids have the worst prognosis, frequently presenting with metastatic disease. A SEER analysis revealed a median overall survival of 13 months for patients with metastatic gastric carcinoid (¹). Clinical features of the three groups of gastric carcinoid are summarized in Table 26-3.

Small Intestine Carcinoid

Small intestine NETs, most frequently associated with carcinoid syndrome, are often found in the distal ileum within 60 cm of the ileocecal valve. At diagnosis, multiple putative “primary” lesions may be present. Analysis of SEER data from 1973 to 2004 demonstrates that jejunum and ileum NETs (30%) were far more likely than duodenal (9%), rectal (5%), or appendiceal (9%) lesions to be metastatic at diagnosis. The median overall survival times of patients with duodenal and jejunum/ileum carcinoids were 107 and 111 months, respectively, for localized

Table 26-3 The Clinical Features of Gastric Carcinoid by Group

Group	Clinical Feature	Tumor Size	Metastasis	Prognosis
Group 1	Chronic gastritis	<1 cm	10%	Good
Group 2	ZES, gastrinoma	<1.5 cm	25%	Intermediate
Group 3	Atypical	>1 cm	Frequent	Poor

ZES, Zollinger-Ellison syndrome.

disease and 57 and 56 months, respectively, for metastatic disease (¹).

Appendiceal Carcinoid

Neuroendocrine tumors are found incidentally in 1 of 200 to 300 appendectomies in young adults. For appendiceal NETs under 1 cm in diameter, surgical resection is sufficient. For tumors over 2 cm, the risk of metastasis is significantly higher, and a right hemicolectomy is recommended (²²). Histologic subtype also influences surgical management; right hemicolectomy is recommended for goblet cell (including signet ring) NETs, regardless of size, because of their aggressiveness (²²). The median overall survival of patients with NET restricted to the appendix is over 360 months. In contrast, individuals with metastatic disease at diagnosis have a median overall survival of 27 months (¹).

Rectal Carcinoid

Rectal NETs occur most frequently in middle-aged adults. They are found incidentally in approximately 1 in 2,500 proctoscopies as a small yellow-gray submucosal nodule in the rectal wall. Most rectal NETs are under 1 cm in diameter and rarely metastasize, whereas 60% to 80% of lesions over 2 cm metastasize. Local excision is adequate for rectal NETs smaller than 1 cm. Lesions measuring 1 to 1.9 cm without evidence of high-risk features such as muscularis, lymphovascular, or perineural invasion can be excised locally (²³). A tumor displaying any of these high-risk features should prompt consideration of a more aggressive segmental rectal resection, preferably sphincter sparing. In patients with metastatic disease at diagnosis, palliative excision may still be required. The median overall survival of patients with metastatic rectal NET is 22 months (¹).

CLINICAL FEATURES OF PANCREATIC NEUROENDOCRINE TUMORS

Insulinoma

Insulinoma is the most common type of PNET. The incidence of insulinoma peaks in patients between 30 and 60 years of age and is more frequent in women. Insulinoma is usually benign (90%), intrapancreatic (nearly 100%), solitary, and small (<2 cm). About 5% of insulinomas are associated with the MEN1 syndrome; screening of family members of an MEN1 index case should be considered (²⁴). Hyperinsulinemia causes a classic “Whipple triad” of hypoglycemia,

neuroglycopenic symptoms, and resolution with eating.

The insulinoma diagnosis is made by detection of inappropriately high serum concentrations of insulin and C-peptide at a symptomatic blood glucose level <50 mg/dL. Although single imaging modalities fail to localize an insulinoma in about 40% of cases, over 90% sensitivity can be achieved with combinations of MRI, pancreatic protocol CT scan, and endoscopic ultrasound. Somatostatin receptor scintigraphy is another noninvasive modality available to assist in localization. Portal venous sampling and arterial calcium stimulation are technically demanding, invasive procedures that are not widely available. When preoperative studies cannot definitively localize the insulinoma, surgical exploration with intraoperative ultrasonography can be considered (²⁵). At some institutions, radiologic innovations have eliminated blind surgical exploration.

Gastrinoma

Gastrinoma causes Zollinger-Ellison syndrome, marked by multiple recurrent peptic ulcers. Most gastrinomas are located in the “gastrinoma triangle,” encompassing the duodenum, pancreatic head, and hepatoduodenal ligament. Duodenal gastrinoma is often submucosal and difficult to visualize during routine EGD; gastrinoma of the pancreas can exceed 1 cm in size (²⁶).

The diagnostic workup for gastrinoma often involves two steps. Elevated fasting serum gastrin and increased basal gastric acid output (>15 mEq/h) suggest hypergastrinemia, with a secretin stimulation test differentiating gastrinoma from other causes. Somatostatin receptor scintigraphy has 77% sensitivity for gastrinoma. Sixty percent of gastrinomas are malignant, and 50% of those have metastases at diagnosis. The median survival of patients with gastrinoma is 3 to 6 years. Roughly one-fifth of gastrinomas occur in the context of MEN1 syndrome (²⁶).

Glucagonoma

Glucagonoma is a rare α -cell tumor that typically occurs in people age 50 to 70 years. These tumors are located primarily within the pancreas; most are malignant. Symptoms may not appear until the tumor is over 5 cm in diameter. At diagnosis, up to 80% of these tumors have metastasized. Serum glucagon levels are usually elevated (>1,000 pg/mL; normal range, 150-200 pg/mL), assisting in diagnosis.

Mild glucose intolerance is the most common clinical feature of glucagonoma. A characteristic red-brown maculopapular skin rash of the face, abdomen, perineum, or extremities called necrolytic migratory erythema may precede the diagnosis by up to 5 years.

The erythematous areas form bullae that eventually break and encrust. Thromboembolic disease and psychiatric disturbances are also seen. Anticoagulation therapy is recommended ⁽²⁷⁾.

Somatostatinoma

Somatostatinoma is very rare. Most occur in the pancreas or duodenum. Patients often present with diabetes mellitus, cholelithiasis, steatorrhea, hypochlorhydria, anemia, and/or weight loss. These tumors are typically metastatic at diagnosis ⁽²⁷⁾.

VIPoma

VIPoma is characterized by watery diarrhea (>3 L/d), mediated by vasoactive intestinal peptide (VIP) and other tumor-secreted peptides. VIPomas are located in the pancreas in adults. They are often metastatic at diagnosis. Their syndrome, known as “pancreatic cholera,” manifests as secretory diarrhea with potassium and bicarbonate wasting, causing hypokalemia and metabolic acidosis. Diagnosis is made from the typical clinical presentation, the presence of a large pancreatic mass on imaging, and the elevated plasma VIP levels. Somatostatin analogues can effectively control the hormonal syndrome ⁽²⁷⁾.

Pancreatic Polypeptidoma

Pancreatic polypeptide is synthesized and released from pancreatic polypeptide cells in the normal pancreas. Pancreatic polypeptidoma is often found unexpectedly in patients with symptoms produced by metastases ⁽²⁸⁾.

CARCINOID SYNDROME, HEART DISEASE, AND CRISIS

Carcinoid Syndrome

Carcinoid syndrome often occurs with metastatic disease or when the primary tumor site allows secreted amines to escape the enterohepatic circulation (Table 26-4). Common symptoms include flushing, diarrhea, abdominal cramping, and, less frequently, wheezing, heart valve dysfunction, and pellagra, resulting from 5-HTP metabolites, kinins, and prostaglandins. The incidence of carcinoid syndrome ranges from 10% in localized carcinoid to 50% in advanced tumors. Somatostatin analogues are the mainstay of medical therapy.

Carcinoid Heart Disease

Carcinoid heart disease is due to right heart endocardial fibrosis, occasionally causing tricuspid regurgitation and right heart failure. However, the relationship between carcinoid heart disease and frank heart failure in the somatostatin analogue era is unclear. A study of 150 patients with carcinoid syndrome described a 20% prevalence of carcinoid valvulopathy on echocardiography. Of those with valvulopathy, 53% had minimally symptomatic heart failure. Over 70% of the patients received a somatostatin analogue, but no relationship was demonstrated between somatostatin analogue use and carcinoid heart disease or heart failure. Patients with carcinoid heart disease exhibited increased urine 5-HIAA and serum CgA levels ⁽²⁹⁾. Currently, echocardiography is recommended for patients with carcinoid syndrome and clinical evidence of heart failure or in whom major surgery is planned ⁽³⁰⁾.

Table 26-4 Symptoms of Carcinoid Syndrome

Symptom	Frequency (%)	Characteristics	Involved Mediators
Flushing	85-90	Foregut: long-lasting, purple	Kallikrein, 5-HTP
			Histamine, substance P
Diarrhea	70	Midgut: short-lasting, pink	PGs
		Secretory	Gastrin, 5-HTP, histamine, PGs, VIP
Abdominal pain	35	Progressive	Small bowel obstruction, hepatomegaly, ischemia
Telangiectasia	25	Face	Unknown
Bronchospasm	15	Wheezing	Histamine, 5-HTP
Pellagra	5	Dermatitis, diarrhea, dementia	Niacin deficiency

5-HTP, 5-hydroxytryptophan; PGs, prostaglandins; VIPs, vasoactive intestinal peptide.

Carcinoid Crisis

Carcinoid crisis is caused by a massive release of bioactive products to the systemic circulation and is characterized by hypotension, diarrhea, and abdominal cramps. Carcinoid crisis is often precipitated by a procedure; treatment consists of prompt initiation of octreotide infusion, typically beginning at 50 to 100 $\mu\text{g}/\text{h}$. Premedication of carcinoid patients with octreotide in subcutaneous or intravenous form is often used as prophylaxis against perioperative carcinoid crisis⁽³¹⁾.

GENERAL APPROACH TO TREATMENT

Treatment is largely dependent on the tumor grade and the primary site. Grade 3 NETs are treated similarly to small cell lung cancer, with platinum-based chemotherapy or chemoradiotherapy, depending on the disease stage. For grade 1 or 2 NETs, surgical removal of all gross disease is advocated whenever feasible. For advanced grade 1 or 2 NETs, regional therapeutic options are largely similar, whereas systemic therapies diverge for pancreatic and extrapancreatic NETs.

Somatostatin analogues are the primary medical treatment for advanced NETs. When carcinoid syndrome persists despite somatostatin analogue or mass effect symptoms worsen, debulking surgery can provide effective palliation. Liver-directed therapy, such as hepatic artery embolization and radiofrequency ablation, should be considered for bulky disease, progression, or symptom palliation. Targeted therapies, such as everolimus and sunitinib, as well as alkylating chemotherapy, such as streptozocin and temozolomide, are also options for systemic therapy in PNETs, with our preference being to use chemotherapy when cytoreduction of larger-volume disease is desired. A general approach to the therapy of advanced disease is depicted in Fig. 26-2.

TREATMENT OF RESECTABLE NEUROENDOCRINE TUMORS

Surgery offers the only potential cure for NETs. Principal considerations include the site and histology of the primary tumor, the extent of detectable disease, and the clinical presentation. Types I and II gastric carcinoids under 2 cm can be removed endoscopically, whereas partial gastrectomy should be considered for larger tumors. Type III gastric carcinoids are more aggressive, requiring excision even when small. Small bowel NET should be managed with resection of the intestinal segment and its associated mesentery because of the risk of nodal involvement. The rest of the intestinal tract should be examined carefully because 20% of tumors

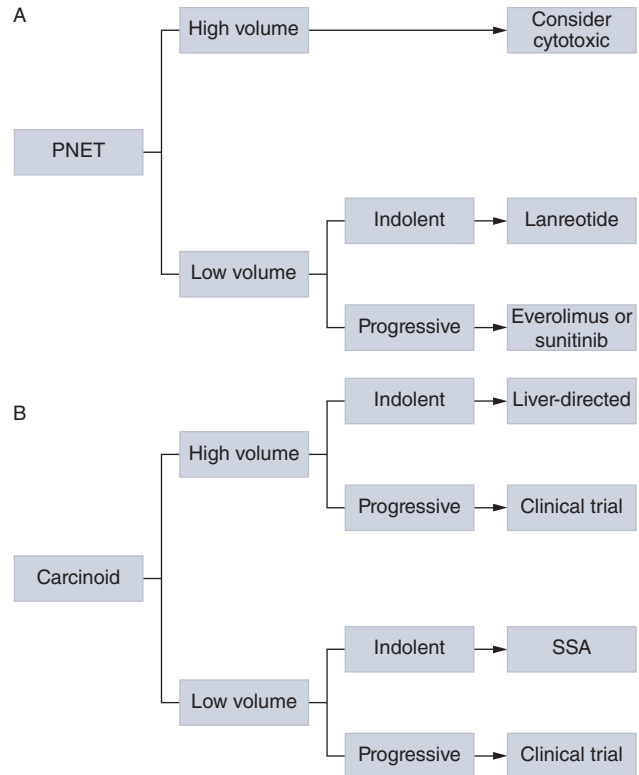

FIGURE 26-2 Approach to therapy for advanced neuroendocrine tumors. **A.** Approach to initial therapy for advanced pancreatic neuroendocrine tumors. PNET, pancreatic neuroendocrine tumor. **B.** Approach to initial therapy for advanced extrapancreatic neuroendocrine tumors. SSA, somatostatin analogue. (Modified with permission from Halperin DM, Kulke MH, Yao JC. A tale of two tumors: treating pancreatic and extrapancreatic neuroendocrine tumors. *Ann Rev Med.* 2015;66:1-16.)

are accompanied by a second primary malignancy⁽³²⁾. Low-risk appendiceal NETs under 2 cm can be treated with appendectomy; larger and high-risk lesions are treated with right hemicolectomy. Colorectal NETs are successfully treated with formal hemicolectomy, adhering to the usual techniques of mesenteric lymphadenectomy as with colon adenocarcinoma. Grade 3 NETs are rare and aggressive, seldom benefit from resection, and are usually treated with chemotherapy.

TREATMENT OF ADVANCED NEUROENDOCRINE TUMORS

The current goal of treatment of advanced unresectable NET is improvement of symptoms and survival. Tumor burden reduction is desirable insofar as it is subsumed in these goals. The current standard of care for hormone-related symptom control remains a somatostatin analogue. Other therapies, including surgical resection of hepatic metastases, hepatic

artery embolization/chemoembolization, and peptide receptor radionuclide therapy, are useful adjuncts. For PNETs, additional systemic treatment options are also available.

Somatostatin Analogues

Somatostatin analogues such as octreotide and lanreotide are the primary medications for control of symptoms from hormonally active NETs. Octreotide is an intermediate-acting somatostatin analogue that can be administered subcutaneously every 6 to 12 hours. It provides complete or partial relief of flushing or diarrhea in about 85% of patients with carcinoid syndrome and produces a biochemical response rate of up to 72%⁽³³⁾. The dose of octreotide varies from 50 to 500 µg.

Long-acting somatostatin analogues have obviated the need for multiple daily injections in most patients. Depot octreotide (10, 20, or 30 mg) is given intramuscularly once a month⁽³⁴⁾. An intermediate-acting somatostatin analogue should be used to supplement long-acting agents until steady state is reached. Rarely, somatostatin analogue can cause sinus bradycardia or cardiac conduction abnormalities. Caution is advised in patients with preexisting cardiac disease. Cholelithiasis may develop with long-term use of somatostatin analogues. Hypoglycemia or, more commonly, hyperglycemia may occur, especially among patients with brittle diabetes. Steatorrhea may occur but can be managed with pancreatic enzymes. Lanreotide is an alternative somatostatin analogue and, in extended release form, is administered subcutaneously monthly in doses of 60, 90, or 120 mg.

Somatostatin analogues also have anticancer activity. Interim analysis of the phase III randomized trial of depot octreotide 30 mg monthly in untreated metastatic midgut NET (PROMID) demonstrated a significantly longer time to progression with octreotide compared with placebo (14.3 vs 6 months, $P < .001$)⁽³⁵⁾. An international, double-blind, placebo-controlled, phase III trial of lanreotide (120 mg every 28 days) in patients with a nonfunctioning NET (CLARINET) also demonstrated significantly improved progression-free survival with lanreotide compared with placebo (median, not reached vs 18 months, $P < .001$)⁽³⁶⁾.

Surgical Resection of Hepatic Metastases

Liver metastases are generally resectable if: (1) all tumors in the liver can be completely resected and (2) an adequate volume of liver (20% of the standardized total liver volume) with adequate biliary drainage, arterial inflow, and venous outflow can be preserved. If the locoregional and hepatic tumor burden is completely resectable, then this is the preferred management of metastatic NETs, whether functional

or nonfunctional. Hepatic resection is most effective for low-grade NETs⁽³⁷⁾. Debulking at least 90% of the hepatic tumor burden in patients with functional metastases improves endocrine symptoms and may prolong survival⁽³⁸⁾.

Radiofrequency Ablation

Local ablative therapies such as radiofrequency ablation (RFA) are being used increasingly for treatment of liver tumors. Radiofrequency ablation involves placing a probe in the liver tumor percutaneously or intraoperatively using image-guidance techniques. The radiofrequency waves increase the intratumoral temperature, resulting in tumor destruction.

Radiofrequency ablation has been used for the treatment of hormone-related symptoms in selected patients with NET liver metastases, alleviating symptoms in up to 80% of cases⁽³⁹⁾. Furthermore, RFA may achieve local control of liver metastases in up to 74% of patients. The use of RFA is generally limited to patients with five or fewer lesions in the liver, with each tumor measuring less than 3 cm in size. The largest reported series using RFA in NET patients with liver metastases included 34 patients with 234 tumors treated in 42 sessions with laparoscopic RFA. "Complete" or "significant" symptom relief was achieved in 80% of the symptomatic patients and lasted an average of 10 months (range, 6-24 months)⁽³⁹⁾.

Hepatic Arterial Embolization and Chemoembolization

Liver metastases from NETs are hypervascular, receiving over 80% of their blood supply via the hepatic artery, whereas liver parenchyma receives 60% to 70% of its perfusion from the portal vein. Thus, embolizing the hepatic artery targets tumor metastases while leaving parenchyma relatively unharmed. The addition of a chemotherapeutic agent to the embolic material, also known as transcatheter arterial chemoembolization (TACE), allows delivery of relatively larger doses of chemotherapy to the tumor, combining local cytotoxicity and ischemia. The most frequently used chemotherapeutic agents for NET TACE include doxorubicin, cisplatin, mitomycin C, and streptozocin^(40, 41).

Potential benefits include symptom relief, slowing progression, and reducing tumor burden before resection or ablation. Many retrospective reports in markedly heterogeneous populations have shown that either technique can reduce tumor burden, hormone levels, and symptoms in NET patients. No study has clearly demonstrated one technique to be superior. The primary risk is postembolization syndrome, which is typically self-limited and characterized by

gastrointestinal distress, fever, leukocytosis, and transaminitis. Major complications such as liver and/or renal failure, gallbladder perforation, cholangitis, peptic ulcer hemorrhage, and abscess formation are rare ⁽⁴²⁾. Embolization can occasionally precipitate carcinoid crisis as well.

In patients with extensive liver tumor burden, multiple embolization sessions may be required, starting with the hepatic lobe with greatest tumor burden. Embolization of the whole liver in one session runs the risk of prolonged postembolization syndrome or liver failure. The timing of subsequent embolizations is determined primarily by symptoms, tumor behavior, and patient tolerance.

The timing of embolizations in the disease course remains controversial. Although some investigators advocate early embolization to reduce tumor burden before initiating systemic therapy, late embolization can also be effective. In a randomized study, NET patients treated with initial liver embolization followed by interferon therapy had a higher objective response rate after 1 year (86%) than patients who received interferon only (42%), without altering survival ⁽⁴³⁾. In contrast, when embolization or chemoembolization was performed at a median of 37 months after diagnosis, the median survival after embolization was 80 months, indicating that later embolization is still effective ⁽⁴⁴⁾.

Selective Internal Radiation Therapy

Intra-arterial radioembolization with yttrium-90 (⁹⁰Y) microspheres is an emerging technique being used increasingly in patients with unresectable liver lesions. Yttrium-90 is a pure β emitter with a mean soft tissue penetration of 2.5 mm and a maximal depth of 1.1 cm. Radioembolization with ⁹⁰Y has a significantly lower incidence of postembolization syndrome than embolization or chemoembolization, allowing it to be performed as an outpatient procedure. However, great care must be taken with ⁹⁰Y radioembolization to avoid nontarget delivery of radioactive microspheres to organs, making an angiogram with selective embolization of all extrahepatic arteries essential before treatment.

There is limited literature on the use of radioembolization for treatment of neuroendocrine liver metastases. In a retrospective review of 148 patients with NET liver metastases treated with 185 separate ⁹⁰Y radioembolization procedures, complete response was observed in 3% of patients, and a partial response was observed in 66.7%. The median survival duration was 70 months ⁽⁴⁵⁾. Further investigation, long-term follow-up, and prospective clinical trials are warranted to determine the exact role of this treatment method in the management of NET.

Peptide Receptor Radionuclide Therapy

Radiolabeled somatostatin analogues have also been developed. A prospective study of ⁹⁰Y-DOTA-Tyr³-octreotide in 90 patients with metastatic, symptomatic carcinoid tumors refractory to octreotide treated showed subjective improvement in over 50% of patients and objective radiologic responses in 4% of patients ⁽⁴⁶⁾. In another report of 310 patients treated with ¹⁷⁷Lu-DOTA-Tyr³-octreotate, the reported radiologic response rate was 30%, but without intent-to-treat analysis incorporating the additional 194 patients accrued to the protocol, meaningful interpretation is challenging ⁽⁴⁷⁾. The ongoing phase III NETTER-1 study, comparing ¹⁷⁷Lu-DOTA-Tyr³-octreotate to high-dose octreotide long-acting release (60 mg intramuscularly every 28 days) in patients with advanced small bowel NETs should allow clearer conclusions to be drawn.

Chemotherapy

High-grade NETs are responsive to platinum-based chemotherapy ⁽¹³⁾. Well-differentiated extrapancreatic NETs respond poorly to cytotoxic chemotherapy. Pancreatic NETs respond better. The authors' group noted radiographic response rates of 39% in a series of 84 PNET patients using a regimen of 5-fluorouracil, doxorubicin, and streptozocin (FAS) ⁽⁴¹⁾. This regimen is derived from prior streptozocin-based chemotherapy regimens observed in randomized studies to achieve biochemical responses ^(48,49).

Targeted Therapy

The NET field has made significant progress over the past 5 years, principally in the area of targeted therapy. Building on the observation that increased VEGF portends poor survival in NET patients, the VEGF receptor (VEGFR) inhibitor sunitinib was tested in a phase III study ⁽⁵⁰⁾. An interim analysis demonstrated a hazard ratio for progression or death of 0.42 favoring sunitinib over placebo ($P < .001$) in 154 PNET patients with advanced and progressive disease. This resulted in the regulatory approval of sunitinib for the indication. Simultaneously, the mTOR inhibitor everolimus was studied in RADIANT-3. This randomized phase III trial investigated everolimus versus placebo in 410 patients with advanced, progressive PNET. The hazard ratio for progression or death was 0.35 ($P < .001$) favoring everolimus over placebo ⁽⁵¹⁾.

The phase II study of sunitinib showed limited evidence of benefit in extrapancreatic NET patients ⁽⁵²⁾. The RADIANT-2 study of everolimus in extrapancreatic NET patients, although limited by randomization

imbalance and informative censoring in central radiology review, also failed to demonstrate statistically significant benefit⁽⁵³⁾. It is hoped that RADIANT-4, a randomized study of everolimus in nonfunctional extrapancreatic NET patients buttressed against informative censoring, will convincingly answer the question of whether mTOR inhibition has a role in a broader range of NETs.

Additional Symptom Control Methods

Carcinoid symptoms can be exacerbated by epinephrine, exercise, emotions, eating tryptophan-rich foods, and ethanol and may be controlled through modulating these factors or supplementing dietary nicotinamide. Medical management of carcinoid symptoms can include a bronchodilator for bronchospasm, loperamide or diphenoxylate for diarrhea, and diuretics for fluid overload secondary to valvular dysfunction. A proton pump inhibitor can manage gastric hypersecretion in gastrinoma patients. Since our initial report, multiple groups have confirmed the efficacy of everolimus for the management of malignant hypoglycemia due to insulinoma⁽⁵⁴⁾.

CONCLUSION

Multidisciplinary diagnosis and management of NETs is mandatory. For localized disease, clear communication between the surgeon and the pathologist is required for appropriate prognostication and treatment. Advanced NETs present different challenges, and surgeons, interventional radiologists, medical oncologists, and endocrinologists may all play roles in improving the quality and quantity of life for the patient. Despite recent advances in targeted therapy for PNET, extrapancreatic NETs remain challenging to treat, and NETs remain life-limiting diseases for many patients. Ongoing studies of targeted agents, peptide receptor radionuclide therapy, and immunotherapy will hopefully continue to advance our understanding of the biology of these diverse diseases while bringing needed therapies to this growing patient population.

EPIDEMIOLOGY

Incidence

Breast cancer is the second most common cause of death for women and is the most common cause of death for women age 45 to 55. In 2015, it is estimated that 231,840 American women would be diagnosed with breast cancer and that 40,290 would die from this disease, making breast cancer the second most common cause of cancer-related mortality in the United States, with lung cancer being the most common (¹).

In the early 1980s, the rates of breast cancer diagnosis rose sharply, likely related to increased mammographic screening, because it was the incidence of stage 0 and I carcinomas that rose most sharply. Data from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute demonstrate that although the incidence of breast cancer has been stable since the late 1980s, there has been an increase in the percentage of breast cancers that are hormone receptor positive, which is thought to be due either changes in receptor assays or an increased use of hormone replacement therapy by women (^{2,3}). The incidence of primary breast cancer then decreased around 2003, shortly after the publication of the Women's Health Initiative (WHI) results, which prompted many healthy postmenopausal women to stop using hormone replacement therapy (⁴).

Worldwide Trends

Breast cancer incidence has long varied in different regions of the world. Incidence is highest in Northern

Europe and North America and lowest in Asia and Africa. Data suggest that this variability is due not only to environmental factors but also to lifestyle. This is supported by the observation that breast cancer incidence is higher in second-generation Asian immigrants in the United States (⁵).

Mortality

Breast cancer overall mortality rates have been stable for more than 50 years prior to 1989. Starting in the 1990s, there has been a steady decrease in breast cancer deaths every year. Mortality rates declined by 1.4% per year from 1989 to 1995 and by 3.2% per year thereafter. This is thought to be due in part to increased use of mammography, resulting in earlier diagnosis, and the use of effective treatments. Mortality rates continue to be higher for African American women. This is due in part to disparities in health care access that exist both for diagnosis as well as treatment (⁶).

RISK FACTORS

Hereditary

Family History

Although it is known that family history is an important risk factor for breast cancer, only 25% of newly diagnosed patients have a positive family history. The Gail model was the first to incorporate the number of first-degree relatives into a comprehensive model of breast cancer risk assessment (⁷). Claus then assessed

the estimated risk of breast cancer based on the number of familial cases and their ages of diagnosis⁽⁸⁾. It is now well known that the risk for each patient with a positive family history is affected by the age of the family member at diagnosis, the total number of first-degree relatives affected, and the patient's age. Based on data from a large meta-analysis, the risk of breast cancer for a patient with one affected first-degree relative increased 1.80-fold; if there were two affected first-degree relatives, that risk increased 2.93-fold. This risk was then further modified by the age of the patient, such that a woman's risk of breast cancer prior to age 40 was increased to 5.7-fold if one relative was diagnosed prior to age 40⁽⁹⁾.

Genetic Mutations

The overall prevalence of specific genetic mutations accounting for breast cancer is rare, accounting for only 5% to 10% of all cases. Risk can be further subdivided based on a patient's history. The most commonly studied mutations are on the *BRCA1* and *BRCA2* genes, although multiple other mutations exist on genes such as *p53*, *ATM*, *CHEK2*, *PTEN*, *MLH1*, *MSH2*, and *PALB2*⁽¹⁰⁾. In a study that analyzed 10,000 individuals, excluding those with Ashkenazi ancestry, the prevalence of *BRCA1* and *BRCA2* mutations varied, with a low of 2.9% if the patient and all first- or second-degree relatives had no prior history of breast cancer or ovarian cancer at less than 50 years of age. A maximum prevalence of 81.3% was noted if the patient and any first- or second-degree relative had breast cancer diagnosed at less than 50 years of age and ovarian cancer at any age⁽¹¹⁾. Because genetic testing often leads to complicated medical decisions both for the patient and other family members, it is important to determine whom it is most appropriate to screen by taking into account population-dependent positive and negative predictive values of the test, using statistical models.

Conditions of the Breast

Ductal Carcinoma In Situ and Lobular Carcinoma In Situ

There has been a rapid increase in the literature concerning the epidemiology, natural history, and treatment of ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). (See detailed information in Chapter 30).

With DCIS, the 10-year risk of invasive breast cancer is 5% in the contralateral breast. Lobular carcinoma in situ has been regarded as a risk factor for ipsilateral and contralateral breast cancer. Recent research supports that LCIS is a direct precursor of both invasive lobular and ductal carcinoma. For patients diagnosed

with LCIS, the risk of developing breast cancer in either breast is 1% a year⁽¹²⁾.

Natural Hormonal Factors

Age at Menarche

A later age of menarche is protective. One study has reported that for every 2-year delay in menarche, there was a 10% reduction in breast cancer risk⁽¹³⁾.

Age at First Pregnancy

There is a favorable risk reduction associated with earlier age of pregnancy. Women who give birth for the first time at age 35 have a 1.6-fold higher risk of breast cancer compared with women who were 26 to 27 at time of first birth. Women who are over age 30 at the time of first birth are at higher risk than nulliparous women⁽¹⁴⁾.

Age at Menopause

Late menopause is associated with a higher risk of breast cancer. Oophorectomy before age 40 will decrease the lifetime risk of breast cancer by 50%⁽¹⁵⁾.

Pregnancy

Breast cancer is the second most common cancer associated with pregnancy, with its incidence being 1 in 3,000. The incidence of pregnancy-associated breast cancer is likely related to the delay of childbirth until after age 30. There are controversial data from two reports suggesting that pregnancy might cause a transient rise in breast cancer risk. However, a clearly documented decreased risk of breast cancer occurs 10 to 15 years after childbirth⁽¹⁶⁾. (See detailed information in Chapter 30.)

Exogenous Hormonal Use

Oral Contraceptives

Most studies have not shown an increased risk of breast cancer with oral contraceptive use^(17, 18). However, a meta-analysis showed a significant but small increase in relative risk of breast cancer⁽¹⁹⁾. A concern about the meta-analysis is that follow-up was limited.

Hormone Replacement Therapy

The WHI showed that the relative risk of breast cancer was increased to 1.26 for women who took combined treatment with estrogen and progesterone for a mean of 5.2 years as compared to placebo⁽²⁰⁾. Although long-term hormone replacement therapy was associated with a higher risk of breast cancer, short-term use did not seem to significantly increase the risk of breast cancer.

STAGING OF BREAST CANCER

2010 TNM Revisions

The 2010 seventh edition of the *Cancer Staging Manual* published by the American Joint Committee on Cancer (AJCC) was modified from the prior staging criteria, published in 2002 (Tables 27-1 and 27-2) ⁽²¹⁾.

The changes were based on continuing developments in breast cancer diagnosis and management. Specifically, isolated tumor cells and micrometastases in axillary lymph node staging and M0(i+) for tumor cells in circulation and bone marrow were added. The AJCC also recommended that all specimens have a histologic tumor grade and description of estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) status.

PROGNOSTIC FACTORS

There is interest in the assessment of prognostic factors in breast cancer. About 30% of patients with node-negative disease will die from a breast cancer–related cause. Thus, there is a great thrust of research to determine markers that could further identify which patients would benefit most from available adjuvant treatment.

Predictive Versus Prognostic Factors

With the growing array of articles in this field, it is important to distinguish predictive prognostic factors. A predictive factor is one that can provide information on the likelihood of response to a given therapeutic intervention. A prognostic factor is one that can provide information on outcome at the time of diagnosis, independent of treatment ⁽²²⁾. Lymph node status is an example of a prognostic factor; ER status is an example of a prognostic and predictive factor.

Pathologic Factors

Prognosis is still determined in large part by histopathology. Multiple studies showed that the most powerful prognostic factor is the extent of disease in the axillary lymph nodes ^(23, 24). Other important pathologic factors are hormone receptor status, HER2 status, histologic grade, tumor type, and lymphovascular invasion.

Axillary Lymph Nodes

More than 30 years ago, it was established that the number of involved lymph nodes could be used to predict disease-free survival (DFS) and overall survival (OS). The 5-year DFS was 62% with 1 to 3 positive

axillary lymph nodes, 58% for 4 to 9 positive lymph nodes, and 29% for ≥ 10 positive lymph nodes ⁽²⁴⁾.

Nuclear Grade

Nuclear or histologic grade describes the degree of tumor differentiation and is based on a pathologist's assessment of nuclear size and shape, number of mitoses, and degree of tubule formation. Although a nuclear grade of 1 (most differentiated) to 3 (least differentiated) is reported with every breast cancer pathology report, its use in predicting outcome is still debated ⁽²⁵⁾. This is in part secondary to interobserver variation in the classification of differentiation. The Nottingham combined grading system seems to be most useful because of its semiquantitative approach and is currently recommended by the College of American Pathologists.

Hormone Receptor Status

Estrogen receptor and PR positivity correlate with prolonged DFS and OS. The importance of hormone receptor status has been documented more consistently in node-positive than in node-negative disease. Immunohistochemical assays have now become the favored approach because they can be used with a variety of specimens. A “positive” specimen is defined as at least 1% of positive cells ⁽²⁶⁾.

Proliferative Rate

This can be evaluated by a variety of methods including mitotic figure count, S-phase fraction (the fraction of cells synthesizing DNA) as determined by flow cytometry, thymidine labeling index, and monoclonal antibodies to antigens in proliferating cells. A high S-phase fraction is usually associated with poor differentiation and lack of ER positivity. Antibodies to Ki-67 can be used to determine a proliferative rate that corresponds with the S-phase fraction. A recent meta-analysis showed a positive correlation between high Ki-67 and poor prognosis ⁽²⁷⁾.

HER2/neu Overexpression

The *HER2/neu* oncogene codes for a 185-kDa transmembrane glycoprotein that has intracellular tyrosine kinase activity and is a member of the family of epidermal growth factor receptors. This group of receptors has an important role in the activation of epidermal signal transduction pathways controlling for epithelial growth and differentiation. Overexpression of the *HER2/neu* oncogene is present in up to 30% of invasive breast cancers.

The current standard is to perform either fluorescence in situ hybridization (FISH) by single or dual

Table 27-1 TNM Staging System for Breast Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget)	Paget disease of the nipple with no tumor
	Note: Paget disease associated with a tumor is classified according to the size of the tumor.
T1	Tumor ≤20 mm in greatest dimension
T1mi	Microinvasion ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to
	(a) chest wall or
	(b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma with typical skin changes involving a third or more of the skin of the breast
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed (eg, previously removed)
N0	No regional lymph node metastases
N1	Metastases in movable ipsilateral axillary level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases
N2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases
N3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected ^a ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral infraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)
Regional Lymph Nodes (pN)	
pNX	Regional lymph nodes cannot be assessed (eg, previously removed or not removed for pathologic study)
pN0	No regional lymph node metastases histologically Note: Isolated tumor cell clusters (ITC) are defined as small clusters of cells not greater than 0.2 mm, or single tumor cells, or a cluster of fewer than 200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by IHC methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluate
pN0(i-)	No regional lymph node metastases histologically, negative IHC

(Continued)

Table 27-1 TNM Staging System for Breast Cancer (Continued)

Regional Lymph Nodes (pN) (cont.)	
pN0(i+)	Malignant cells in regional lymph node(s) no greater than 0.2 mm (detected by H&E or IHC including ITC)
pN0(mol-)	No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
pN0(mol+)	No regional lymph node metastases histologically, positive molecular findings (RT-PCR)
pN1	Micrometastases; or metastases in 1–3 axillary lymph nodes; and/or in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected
pN1mi	Micrometastases (>0.2 mm and/or >200 cells, but none >2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis greater than 2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected ^a
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN2	Metastases in 4–9 axillary lymph nodes; or in clinically detected ^b internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastases in clinically detected ^b internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases in 10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected, or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm); or metastases to the infraclavicular (level III axillary lymph) nodes
pN3b	Metastases in clinically detected ^b ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN3c	Metastases in ipsilateral supraclavicular lymph nodes
Distant Metastases (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

H&E, hematoxylin and eosin; IHC, immunohistochemistry; RT-PCR, reverse transcription polymerase chain reaction.

^aNot clinically detected is defined as not detected by imaging studies (excluding lymphoscintigraphy) or not detected by clinical examination.

^bClinically detected is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.

probe or immunohistochemistry (IHC). Breast cancer is defined as HER2-positive overexpressed if IHC is noted to be 3+, which is defined as >10% of membrane staining. By FISH, for single probe, the average copy number is ≥ 6.0 signals per cell. For dual probe, the *HER2/CEP17* ratio should be ≥ 2.0 or if *HER2* copy number is ≥ 6.0 signals/cell regardless of *HER2/CEP17* ratio. Equivocal results include IHC 2+ or dual probe FISH *HER2/CEP17* ratio <2.0 and an *HER2* copy number between 4.0 and 6.0 signals/cell. These results should be confirmed with the other approved diagnostic tests.

If results continue to be equivocal, repeat testing or a new biopsy should be considered (²⁸).

Prior to the introduction of HER2-targeted therapy, overexpression of *HER2/neu* was associated with shorter DFS and OS (²⁹). A large single-institution study reviewed all women with T1a and T1b disease diagnosed between 1990 and 2002. Multivariate analysis of 965 patients showed that patients with HER2-positive tumors had 5.09 times the rate of recurrence and 7.81 times the rate of distant recurrence at 5 years compared to patients with hormone receptor-positive,

HER2-negative tumors ⁽³⁰⁾. The predictive response with HER2 has been demonstrated in prospective randomized controlled trials (discussed later in the “Adjuvant Therapy” section) ^(31, 32).

Future Thoughts

DNA microarrays classify breast cancer into five major subtypes defined as luminal A, luminal B, basal, HER2 positive, and normal-appearing breast tissue. In a retrospective analysis, these subtypes were associated with differing prognoses ⁽³³⁾. At present, microarrays for these classifications are too expensive to be performed routinely. Cheaper and more cost-effective diagnostics may change the approach.

ADJUVANT THERAPY

After definitive local therapy is completed, it is important to plan for adjuvant systemic therapy. The use of chemotherapy, hormonal therapy, and targeted therapy before or after definitive local therapy has had a significant effect on the management and outcomes of

breast cancers. All women with node-positive disease and a significant percentage of node-negative women with tumors that are hormone receptor negative or >1 cm in size benefit from chemotherapy. The choice of agents to be used for chemotherapy and hormonal therapy should be guided by the patient’s age, concomitant medical issues, positive or negative axillary lymph node involvement, and the status of the hormone receptors and HER2. Estimation of risk of recurrence and death should be assessed. Adjuvant! Online is a validated model that estimates DFS and OS based on age, comorbidity, tumor size and grade, hormone receptor status, and number of involved lymph nodes ⁽³⁴⁾. Additionally, Oncotype Dx, Mammaprint, and other assays can help stratify risk for hormone receptor-positive, node-negative patients ⁽³⁵⁾.

Chemotherapy

Historical Perspective

Studies in the 1960s and 1970s evaluated whether single-agent chemotherapy after local therapy had any benefit compared with observation alone. The single agents studied included cyclophosphamide, thiotepa, and melphalan. Most reports documented that single agents have modest or no effect on DFS. Subsequently, the focus shifted to polychemotherapy, with most trials evaluating variations of the three-drug regimen of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) or similar anthracycline-containing regimens ^(36, 37).

These polychemotherapy regimens clearly showed a greater benefit in DFS and OS, but it was often unclear to clinicians which regimens were superior or equivalent. The Oxford Overview in 1998 helped clarify this issue by reviewing data from about 18,000 women in 47 trials that compared polychemotherapy or no chemotherapy, about 6,000 women in 11 trials that compared longer versus shorter polychemotherapy, and about 6,000 women in 11 trials of anthracycline-containing regimens versus CMF ⁽³⁸⁾. The final interpretation concluded that adjuvant polychemotherapy for patients under 50 years of age resulted in an absolute improvement in 10-year survival of 7% to 11%, whereas the overall 10-year survival benefit was 2% to 3% for patients age 50 to 69 years.

Anthracyclines

The 1998 Oxford Overview further demonstrated that anthracycline-containing regimens were superior to CMF. There was a statistically significant 12% reduction in risk of recurrence for anthracycline-containing regimens, a 2.7% decrease in mortality, and a 3.2% decrease in relapse. The information gained from this

important systematic analysis began a shift toward administration of anthracycline-based regimens for adjuvant therapy of breast cancer.

Official recommendations have been made based on the above data. These were presented at the National Institutes of Health Consensus Development Conference in 2000 and suggested an anthracycline be included as part of breast cancer adjuvant therapy. Several studies have investigated the role of *HER2/neu* in the positive response to anthracyclines. Both the Cancer and Leukemia Group B (CALGB) 8082 and National Surgical Adjuvant Breast and Bowel Project (NSABP) B-11 studies have shown a benefit in DFS in patients who overexpressed *HER2/neu* and received anthracycline therapy^(39, 40).

Evaluation of 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC) began in 1974 at the University of Texas MD Anderson Cancer Center (MDACC). For 1,107 women with node-positive disease, the results were favorable. The 10-year DFS was 72% for patients with 1 to 3 positive nodes, 55% for patients with 4 to 10 positive nodes, and 36% for those with >10 positive nodes⁽⁴¹⁾.

Investigations addressing accelerating the delivery of anthracyclines in a dose-dense manner are discussed later.

Taxanes

The role of taxanes for breast cancer treatment was first investigated in metastatic disease. In randomized trials, paclitaxel and docetaxel improved response rates, duration of response, and OS⁽⁴²⁾. These positive results prompted their investigation in early-stage breast cancer. Several major studies contributed to the current use of taxanes in the adjuvant setting. The CALGB 9344 study evaluated the addition of paclitaxel to doxorubicin and cyclophosphamide (AC) and showed improvements versus placebo in DFS and OS at 69 months of 70% versus 65% and 80% versus 77%, respectively.

The use of docetaxel was evaluated by the Breast Cancer International Research Group (BCIRG) 001 trial, which compared TAC (docetaxel plus AC) versus FAC for the adjuvant treatment of node-positive breast cancer. There was a significant difference in DFS and a trend in OS suggesting docetaxel could reduce the risk of recurrence of breast cancer in the adjuvant setting compared to the standard FAC regimen. However, with the higher rates of myelosuppression and febrile neutropenia seen with TAC, the use of this regimen requires extensive supportive care, including utilization of granulocyte colony-stimulating growth factor^(43, 44).

The Eastern Cooperative Oncology Group (ECOG) E1199 trial attempted to define the more effective adjuvant

taxane and the optimal schedule of administration⁽⁴⁵⁾. All patients received a standard dose and schedule of doxorubicin and cyclophosphamide and were randomized to receive paclitaxel (175 mg/m²) every 3 weeks for four cycles, paclitaxel (80 mg/m²) every week for 12 doses, docetaxel (100 mg/m²) every 3 weeks for four cycles, or docetaxel (35 mg/m²) every week for 12 doses. Weekly paclitaxel compared to every 3 weeks was better, with an odds ratio of 1.27 for DFS ($P = .006$) and 1.32 for OS ($P = .01$). No significant difference existed between paclitaxel and docetaxel. Paclitaxel every 3 weeks was no longer recommended after this trial (Fig. 27-1).

The US09735 trial was a randomized study that compared four cycles of standard-dose AC with four cycles of docetaxel (75 mg/m²) and cyclophosphamide (TC) (600 mg/m²). Most patients (84.3%) were younger than 65 years old, and 48% were node negative. At a median follow-up of 7 years, there was a significant difference in DFS between TC and AC (81% vs 75%; hazard ratio, 0.74). Additionally, there was a significant difference in OS (87% vs 82%). Febrile neutropenia in older patients was 8% with TC and 4% with AC⁽⁴⁶⁾. This indicates that TC is a treatment option but should be used with caution in higher risk cancers given the large percentage of young node-negative patients in the study.

Endocrine Therapy

The correlation between the endocrine system and breast cancer was first recognized more than 100 years ago. Beatson first described bilateral oophorectomy in treating inoperable cases of breast cancer⁽⁴⁷⁾. However, the true understanding of the biological mechanisms that cause estrogen to stimulate the growth of

FIGURE 27-1 Results of Eastern Cooperative Oncology Group E1199: Optimal adjuvant taxane and optimal schedule of administration. D, docetaxel; DFS, disease-free survival; HR, hazard ratio; OS, overall survival; P, paclitaxel. (Data from Sparano JA, Wang M, Martino S, et al. Weekly paclitaxel in the adjuvant treatment of breast cancer. *N Engl J Med*. 2008;358:1663-1671.)

hormone receptor–positive tumors is more recent. Jensen first identified the ER and led subsequent cloning of ER and PR. This knowledge has enabled the development of multiple therapies. Many of these therapies have varying mechanisms of action, but all have the common goal of decreasing estrogen availability for hormone receptor–positive malignancies.

Tamoxifen

Monotherapy

In the late 1970s, tamoxifen was shown to be effective for the treatment of metastatic breast cancer. This form of treatment was well received, because data from trials showed that patients experienced fewer side effects than they did with traditional chemotherapy or with old fashioned endocrine therapy (high-dose estrogens, androgens, adrenalectomy, or hypophysectomy). The proven efficacy of tamoxifen in the metastatic setting enabled its study for adjuvant use.

Tamoxifen was the first targeted drug to be used as an endocrine treatment for early breast cancer. An early placebo-controlled trial of tamoxifen as adjuvant therapy for early breast cancer, NATO, showed that 2 years of tamoxifen treatment reduced treatment failure at 21 months compared with control (14.2% vs 20.5%, respectively) ⁽⁴⁸⁾. Since then, the efficacy of tamoxifen in the adjuvant treatment of primary breast cancer has been demonstrated repeatedly.

Since tamoxifen became available over 35 years ago, a large number of trials investigated its efficacy and tolerability in the treatment of primary breast cancer. Although some individual trials are too small to justify firm conclusions, a meta-analysis has increased confidence in the effectiveness of tamoxifen in improving DFS and OS. Additionally, large cooperative group (NSABP B-14) and international randomized trials (Stockholm and Scottish trials) of tamoxifen versus placebo have demonstrated a clear benefit in DFS and OS ⁽⁴⁹⁻⁵¹⁾.

An overview of 55 trials studying adjuvant tamoxifen for 1, 2, or 5 years versus no treatment in patients with primary breast cancer showed that tamoxifen treatment produced highly significant benefits in terms of both recurrence of first events and mortality in the hormone receptor–positive population. The reductions in recurrence were 21%, 28%, and 50%, and the reductions in death rate were 14%, 18%, and 28% for 1, 2, and 5 years of tamoxifen treatment, respectively ($P < .00001$ for each). Tamoxifen treatment for 1, 2, and 5 years also reduced the incidence of contralateral breast cancer by 13%, 26%, and 47%, respectively ⁽⁵²⁾. The benefits occurred almost exclusively in the hormone receptor–positive population. Tamoxifen improves the 10-year survival of women who have ER-positive or ER-unknown tumors.

Further clarification of the optimal treatment duration of tamoxifen was investigated in two large trials: ATTOM (Adjuvant Tamoxifen Treatment Offers More) and ATLAS (Adjuvant Tamoxifen—Longer Against Shorter).

The ATLAS trial enrolled women with early breast cancer who had completed 5 years of tamoxifen and randomly assigned the women to either continue tamoxifen for 10 years or stop at 5 years ⁽⁵³⁾. The risk of recurrence during years 5 to 14 was 21.4% versus 25.1% for women who continued tamoxifen versus those who did not. Breast cancer mortality during years 5 to 14 for women who continued tamoxifen versus the control group was 12.2% and 15.0%, respectively. Pulmonary embolus and endometrial cancer occurred significantly more frequently in the extended tamoxifen group (Fig. 27-2).

The ATTOM trial had a similar design to ATLAS ⁽⁵⁴⁾. Women randomized to continue tamoxifen, versus those who stopped tamoxifen, had significantly less breast cancer recurrence (580 of 3,468 patients vs 672 of 3,485 patients, $P = .003$) and significantly decreased breast cancer mortality (392 of 3,468 patients vs 443 of 3,485 patients, $P = .050$). Combining the two trials strengthens the statistical significance of recurrence ($P < .0001$), breast cancer mortality ($P = .002$), and OS ($P = .005$).

With Chemotherapy

The addition of chemotherapy in intermediate- or high-risk groups is recommended ⁽⁵⁵⁾. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overviews in 1990 showed that chemotherapy in combination with tamoxifen had a beneficial effect in premenopausal women. The 1998 EBCTCG overview ⁽⁵²⁾ showed that the benefits of chemotherapy combined with tamoxifen in patients with ER-positive disease occurred irrespective of age or menopausal status. The benefits of chemotherapy in terms of contralateral breast cancer and improved survival also occurred irrespective of age or menopausal status.

It was not until recently that the appropriate sequence of chemotherapy and hormonal therapy was definitively documented. One difficulty was that evidence had existed in experimental systems that tamoxifen could antagonize the cytotoxic effects of particular chemotherapeutic agents.

One particular study was designed to address the specific timing of tamoxifen therapy ⁽⁵⁶⁾. Patients were divided among three groups: tamoxifen alone, FAC chemotherapy followed by tamoxifen, and concomitant FAC and tamoxifen. Patients were followed up for a median of 8.5 years. The estimated DFS was 67% in the sequential treatment group compared with 62% in the concurrent treatment group.

FIGURE 27-2 ATLAS trial studying 5 years versus 10 years of tamoxifen with respect to recurrence (left) and breast cancer mortality (right). RR, relative risk. (Reproduced with permission from Davies C, Pan H, Godwin J, et al. Long-term effects of continuing adjuvant tamoxifen to 10 years versus stopping at 5 years after diagnosis of oestrogen receptor-positive breast cancer: ATLAS, a randomised trial. *Lancet*. 2013 Mar 9;381(9869):805-816.)

Aromatase Inhibitors

First Line

Although tamoxifen has proven efficacy for the treatment of hormone receptor–positive breast cancer both alone and in combination with chemotherapy, its usefulness is in part curtailed by its partial estrogen agonist activity. The documented negative secondary effects of tamoxifen include an increased incidence of endometrial cancer, uterine sarcoma, and thromboembolic disease. Thus, there is great interest in exploring other endocrine therapies.

In women whose ovarian function has ceased, the primary remaining estrogen source is the conversion of adrenal androgens to estrogens in peripheral tissues by the cytochrome P450 enzyme aromatase. Aromatase inhibitors (AIs) reduce the availability of estrogen by inhibiting the aromatase enzyme and are indicated for the treatment of breast cancer in postmenopausal women whose ovarian function has ceased (⁵⁷). The first-generation AI aminoglutethimide became available 25 years ago but was limited by excessive toxicity. Newer generation selective AIs, including anastrozole, letrozole, fadrozole, and exemestane, are now available for the treatment of metastatic breast cancer and in the adjuvant setting. Common side effects of all AIs include hot flashes, osteoporosis, arthritis, and joint and muscle pains.

Based on the antitumor activity of the third-generation AIs in the setting of metastatic disease, these drugs were evaluated in the adjuvant setting. The ATAC (Arimidex [anastrozole], Tamoxifen, Alone

or in Combination) trial was a double-blind, multicenter study of postmenopausal women with invasive operable breast cancer who had completed primary therapy and were eligible for adjuvant treatment. They were randomized to tamoxifen, anastrozole, or a combination of the two (⁵⁸). Time to recurrence was significantly longer with anastrozole versus tamoxifen in the overall population, with a larger benefit seen in the hormone receptor–positive population. A reduction in the incidence of contralateral breast cancers favored anastrozole, with statistical significance in the hormone receptor–positive population. The DFS estimates at 4 years were 86.9% and 84.5% for anastrozole and tamoxifen, respectively (⁵⁹).

Anastrozole was associated with significantly fewer withdrawals from treatment than tamoxifen (21.9% vs 26.0%, $P = .0002$) and significantly fewer withdrawals due to adverse events (7.8% vs 11.1%, $P < .0001$). Anastrozole also resulted in a lower incidence of hot flashes, vaginal discharge, and vaginal bleeding ($P < .0001$ for each), of ischemic cerebrovascular events and thromboembolic events ($P = .0006$ for each), including deep venous thrombosis ($P = .02$), and of endometrial cancer ($P = .02$). Tamoxifen resulted in a lower incidence of musculoskeletal disorders (including myalgias and arthralgias) and fractures ($P < .0001$ for both). The tolerability results in the updated analysis showed no major difference from those seen in the first analysis (⁶⁰).

A meta-analysis published in 2010 reviewed the use of AIs versus tamoxifen in postmenopausal women with ER-positive tumors. This review compared AIs

as initial monotherapy to tamoxifen monotherapy or as a hormone switch after 2 to 3 years of tamoxifen for a total of 5 years. The conclusion was that AI therapy was associated with a lower rate of recurrence when used as an initial monotherapy or after 2 to 3 years of tamoxifen when compared to tamoxifen monotherapy ⁽⁶¹⁾.

Following Tamoxifen

It is postulated that tamoxifen might stop being effective because breast cancer cells develop resistance to tamoxifen, dependence on tamoxifen, or great sensitivity to circulating estrogen. Consequently, the use AIs after tamoxifen was investigated. The MA-17 trial showed that the addition of letrozole after 5 years of tamoxifen resulted in a significant improvement in DFS ⁽⁶²⁾.

The Breast International Group (BIG) 1-98 trial compared letrozole versus tamoxifen in postmenopausal hormone receptor–positive women and was later amended to include two sequential strategies using letrozole either before or after tamoxifen for a total of 5 years. The results showed that upfront AI reduced the risk of recurrence and improved DFS better than upfront tamoxifen and better than either switching strategy ^(63, 64).

Another double-blind randomized trial investigated the use of exemestane to complete the 5 years of adjuvant endocrine treatment after 2 to 3 years of tamoxifen in postmenopausal women with primary breast cancer ⁽⁶⁵⁾. The results showed that exemestane improved the absolute benefit in DFS by 4.7%. Thus, exemestane therapy following 2 to 3 years of tamoxifen significantly improved DFS.

The above data for therapy beyond 5 years of tamoxifen is becoming more convincing, and AIs should be considered as extended therapy for high-risk postmenopausal patients. In general, outcomes with antiestrogen therapies are hindered by noncompliance, with 20% to 50% nonadherence rates. This is the same difficulty faced in other disease states, and a cancer diagnosis does not necessarily command optimal compliance with oral therapy. Many barriers influence compliance including medication cost, access to

mail-order pharmacies, and a lack of understanding of the benefits of such medicine. A population-based study performed in British Columbia noted that adherence was still difficult even when these oral agents were given free of charge in a country with a national formulary system. Patients who are on oral medication should be followed regularly, and compliance should be reinforced as highly important, as shown in multiple studies, even when drug cost is not a barrier ⁽⁶⁶⁾.

Ovarian Ablation and Suppression

The use of oophorectomy or ovarian irradiation to cause ovarian ablation is an efficacious method for treating early-stage disease in premenopausal patients. The 1996 meta-analysis by the EBCTCG demonstrated that for women below age 50 there was a distinct advantage in OS and DFS when they were treated with ovarian ablation versus no adjuvant therapy. In addition, the outcomes for these patients were similar to those who received the CMF regimen. The ZEBRA trial displayed similar results in hormone receptor–positive patients when comparing a luteinizing hormone–releasing hormone (LH-RH) analog, goserelin, to CMF ⁽⁶⁷⁾.

The TEXT and SOFT trials were designed to determine the value of the addition of adjuvant ovarian suppression to tamoxifen or exemestane in premenopausal hormone receptor–positive breast cancer patients. The patients were randomized to receive tamoxifen, tamoxifen plus ovarian suppression, or exemestane plus ovarian suppression for 5 years. In the total population, the addition of ovarian suppression to tamoxifen did not produce a significant benefit. However, in the high-risk cohort who received chemotherapy, ovarian suppression plus tamoxifen improved outcomes when compared to tamoxifen alone. The combined analysis also showed that 5-year DFS with adjuvant endocrine therapy with exemestane was significantly more effective than tamoxifen when ovarian suppression was added. Longer follow-up is needed to evaluate survival data ^(68, 69).

Table 27-3 Five-Year Rates of Recurrence of Patients in SOFT and TEXT Stratified by Chemotherapy Use

5-Year Rate, %	No Chemotherapy			Previous Chemotherapy		
	E + OS	T + OS	T	E + OS	T + OS	T
	(n = 470)	(n = 473)	(n = 476)	(n = 544)	(n = 542)	(n = 542)
FBC	97.1	95.1	95.8	85.7	82.5	78
FDR	99.3	98.7	98.6	87.8	84.8	83.6

E, exemestane; FBC, freedom from breast cancer; FDR free from distant recurrence; OS, ovarian suppression; T, tamoxifen. Data from Francis PA, Regan MM, Fleming G, et al. Adjuvant ovarian suppression in premenopausal breast cancer. *N Engl J Med*. 2015;372(5):436-446.

Ovarian suppression does come at significant costs because the adverse effects are not trivial. In these trials, women receiving ovarian suppression developed significant hot flashes, vaginal dryness, depression, and possible long-term health implications like hypertension, diabetes, and osteoporosis.

HER2 Targeted Therapy

Trastuzumab is a high-affinity humanized monoclonal antibody that recognizes the *HER2/neu* receptor and is a targeted therapeutic for tumors that overexpress this growth factor receptor. Trastuzumab has been evaluated extensively in the *HER2/neu*-overexpressing metastatic setting and has been shown to be effective as a single agent both before ⁽⁷⁰⁾ and after chemotherapy, ⁽⁷¹⁾ and in combination with multiple agents ⁽⁷²⁾. One notable side effect has been a high rate of cardiotoxicity, particularly when trastuzumab is combined with anthracycline-based chemotherapy. This is due in part to overlapping toxicities and the long half-life of trastuzumab (up to 32 days). The toxicity rarely occurs in patients without a history of cardiac disease and not previously or simultaneously exposed to chemotherapy, especially anthracyclines ⁽⁷³⁾.

Therefore trastuzumab was an accepted and standard therapy for metastatic breast cancer that overexpresses *HER2/neu*. The safety and efficacy of trastuzumab-based therapy were then established for earlier stage breast cancer with the NSABP B-31 and North Central Cancer Treatment Group (NCCTG) N9831 trials, where patients received AC plus paclitaxel with the addition of trastuzumab versus placebo.

The joint analysis of these trials showed an absolute difference in DFS of 12% at 3 years and a 33% reduction in the risk of death ($P = .015$) ⁽⁷⁴⁾. An updated analysis with a mean time of 8.4 years on study showed a 37% relative improvement in OS (95% confidence interval [CI], 0.54-0.73; $P < .001$) and an increase in 10-year OS from 75.2% to 84% ⁽⁷⁵⁾.

The BCIRG 006 trial was designed to evaluate the efficacy and safety of docetaxel and carboplatin plus 52 weeks of trastuzumab (TCH) ⁽³²⁾. Patients were randomly assigned to standard doses of doxorubicin and cyclophosphamide followed by docetaxel (100 mg/m²) every 3 weeks (AC-T), the same regimen plus 52 weeks of trastuzumab (AC-TH), or docetaxel (75 mg/m²) and carboplatin (area under the curve [AUC] 6 mg/mL/min) plus 52 weeks of trastuzumab (TCH). At a median follow-up of 65 months, the 5-year estimated DFS was 75% for patients receiving AC-T, 84% with AC-TH, and 81% with TCH. Estimated rates of OS were 87%, 92%, and 91%, respectively. All trastuzumab regimens were statistically superior for DFS and OS to nontrastuzumab regimens. There were significant difference in both DFS and OS

between AC-TH and TCH. Rates of cardiac dysfunction were significantly higher with AC-TH compared with TCH ($P = .001$).

The PHARE trial attempted to answer the appropriate duration for trastuzumab by comparing 6 versus 12 months of adjuvant therapy. After a median follow-up of 42.5 months, the 2-year DFS rate was 93.8% for the 12-month group versus 91.1% for the 6-month group, with a hazard ratio of 1.28 (95% CI, 1.05-1.56). These results support continuing with the standard of care of 1 year of trastuzumab ⁽⁷⁶⁾.

The HERA trial was also designed to answer the question regarding the optimal duration of trastuzumab. Patients were assigned to observation or 1 or 2 years of trastuzumab. Patients were allowed a variety of standard neoadjuvant or adjuvant chemotherapies and had node-positive or high-risk node-negative disease. A recent update includes mature data from patients receiving trastuzumab for 2 years. Comparing 1 year of trastuzumab versus observation revealed a hazard ratio of 0.76 (95% CI, 0.67-0.86; $P < .0001$) for DFS and 0.76 (95% CI, 0.65-0.88; $P = .0005$) for OS despite significant (52%) crossover. No significant differences in DFS or OS were noted between the 1- and 2-year groups ⁽³¹⁾.

NEOADJUVANT THERAPY

Chemotherapy

The concept of giving chemotherapy in the preoperative setting was first evaluated more than 30 years ago for the treatment of locally advanced and inoperable breast cancer. There are multiple possible benefits. One is the ability to downstage a tumor, which would result in making an unresectable tumor operable or enable breast-conserving surgery or segmental mastectomies to be offered to a greater number of patients with operable breast cancer. In addition, there are biological advantages, such as the ability to assess response or resistance to chemotherapy early, delivering the chemotherapy prior to surgical alterations to the vasculature, and using molecular profiling in conjunction with pathologic response to predict outcomes for patients.

In 1978, a study was published that addressed whether there was a benefit for patients with inoperable breast cancer treated with neoadjuvant chemotherapy. A total of 110 patients were enrolled and were treated with doxorubicin and vincristine. Complete response was seen in 16% of patients, and partial response was seen in 55% of patients. All patients also received standard radiation therapy. The 36-month survival rates were 53% for the study group and 41% for the historical controls. The positive results of this study led to other trials ⁽⁷⁷⁾.

The NSABP B-18 trial was the largest to date to investigate neoadjuvant chemotherapy. A total of 1,523 patients with T1 to T3 and N0 to N1 disease were randomized to receive preoperative versus postoperative AC for four cycles (⁷⁸). Results showed a significant increase in lumpectomies in the neoadjuvant group. Final comparison of the two groups showed no difference in DFS or OS at 5 years. This was true for all groups including tumors larger than 5 cm.

Another trial investigated downstaging of axillary nodal metastases after primary chemotherapy (⁷⁹). From Cox regression analysis, it was shown that one of the parameters associated with poor distant disease-free survival was persistent nodal involvement after neoadjuvant therapy. Thus, it was concluded that the response of the axillary nodes to neoadjuvant chemotherapy was a better predictor than the response of the primary tumor.

In general, neoadjuvant therapy with either anthracycline- or taxane-containing regimens has been shown in multiple trials to result in an increase in the number of women able to undergo breast-conserving surgery. Studies have also shown that the use of neoadjuvant therapy, especially with taxanes, can lead to pathologic complete responses (pCRs) as well as clinical responses (⁸⁰). These responses have been well correlated to DFS and OS, making response to preoperative chemotherapy a novel prognostic factor in the treatment of early and locally advanced breast cancer. At this time, the majority of neoadjuvant studies have not yet shown an increase in OS for patients treated with this approach. Preoperative chemotherapy is especially clinically warranted for patients with tumors greater than 3 cm and for axillary node disease.

Endocrine Therapy

Most studies have investigated the potential of using this approach for patients with locally advanced disease rather than early-stage disease. It is a treatment option for women with tumors expressing ER, PR, or both and for patients with low histologic grade tumors.

At this time, neoadjuvant hormonal therapy based on trial results seems to be best suited to women who have locally advanced breast cancer who are otherwise thought to be not suitable for neoadjuvant chemotherapy or whose tumors are noted to be low-grade with expression of ER or PR (^{81, 82}). However, the standard neoadjuvant approach for node-positive or locally advanced breast cancer remains chemotherapy.

HER2 Targeted Therapy

The addition of trastuzumab to standard chemotherapy when given neoadjuvantly has been shown to have improved pathologic responses (⁸³). Additionally,

neoadjuvant therapy has helped accelerate approval of promising drugs because clinical and pathologic responses can be quickly obtained.

Dual blockade of the HER2 signaling is currently under investigation. Lapatinib, a tyrosine kinase inhibitor that blocks both HER2 and *EGFR*, improved progression-free survival when given with capecitabine in the metastatic setting (⁸⁴). In the NeoALTTO trial, trastuzumab and lapatinib (1,000 mg PO daily) were investigated in the neoadjuvant setting. The pCR was significantly higher with both medications (51.3%) versus trastuzumab alone (29.5%; difference 21.1%, 9.1-34.2%, $P = .0001$) (⁸⁵).

The interest in lapatinib was blunted by the first results from the ALTTO trial presented at the American Society of Clinical Oncology (ASCO) annual conference in Chicago in 2014 (⁸⁶). The four-arm trial compared 1 year of lapatinib alone, trastuzumab alone, or both agents in sequence or in combination. After 4.5 years of follow up, DFS was not significantly different between the patients receiving trastuzumab alone versus the patients receiving the combination. This was surprising given the doubling of the pCR rate seen in NeoALTTO. Additional follow-up is necessary for both trials.

Pertuzumab is a monoclonal antibody that inhibits dimerization with other HER receptors, notably HER3, and binds to an independent domain from trastuzumab. With impressive results in the metastatic setting (⁸⁷), pertuzumab was studied in the neoadjuvant setting.

The NeoSphere trial was designed to evaluate the safety and efficacy of pertuzumab along with trastuzumab in locally advanced, inflammatory, and early HER2-positive breast cancer (⁸⁸). The phase II study randomly assigned patients to four treatment groups: trastuzumab plus docetaxel (75 mg/m², escalating if tolerated to 100 mg/m², every 3 weeks); pertuzumab (loading dose of 840 mg, followed by 420 mg every 3 weeks) and trastuzumab plus docetaxel; pertuzumab plus trastuzumab; or pertuzumab plus docetaxel. After completing this regimen, all patients underwent surgery and then received 5-fluorouracil (600 mg/m²), epirubicin (90 mg/m²) and cyclophosphamide 600 mg/m² (FEC) every 3 weeks. The results were that 45.8% (95% CI, 36.1%-55.7%) of patients receiving dual HER2-targeted therapy with docetaxel achieved a pCR compared with 29.0% (95% CI, 20.6%-38.5%) of patients receiving trastuzumab and docetaxel alone (Fig. 27-3).

The TRYPHAENA trial was a phase II that explored the tolerability and efficiency of pertuzumab and trastuzumab given with three different chemotherapy regimens (⁸⁹). All patients had HER2-positive node-positive or node-negative disease but at least a total of T2. Two hundred twenty-five patients were randomized to receive one of the following regimens FEC (doses of 500 mg/m², 100 mg/m², 600 mg/m² respectively) with trastuzumab and pertuzumab followed by docetaxel

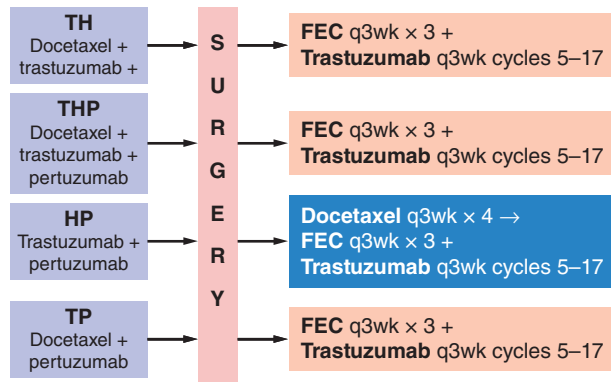

FIGURE 27-3 NeoSphere study design. FEC, 5-fluorouracil, epirubicin, and cyclophosphamide. (Data from Gianni L, Pienkowski T, Im YH, et al. Efficacy and safety of neoadjuvant pertuzumab and trastuzumab in women with locally advanced, inflammatory, or early HER2-positive breast cancer (NeoSphere): a randomised multicentre, open-label, phase 2 trial. *Lancet Oncol.* 2012;13:25-32.)

(FEC+H+P \times 3 \rightarrow T+H+P \times 3; arm A); FEC followed by docetaxel plus pertuzumab and trastuzumab all at same dose and schedule as (FEC \rightarrow T+H+P \times 3; arm B); or carboplatin (AUC6) and docetaxel plus pertuzumab and trastuzumab (TCHP \times 6; arm CC). Upon completion of chemotherapy, all patients underwent surgery and then received adjuvant trastuzumab to complete 1 full year. The majority of patients achieved pCR in the breast (61.6% in arm A, 57.3% in arm B, and 66.2% in arm C), with pCR including lymph nodes in 50.7% (arm A), 45.3% (arm B), and 51.9% of patients (arm C). Eleven patients had declines in left ventricular ejection fraction to less than 50%, and diarrhea was the most common adverse event (Fig. 27-4).

Given the results of these phase II trials, the US Food and Drug Administration granted accelerated approval

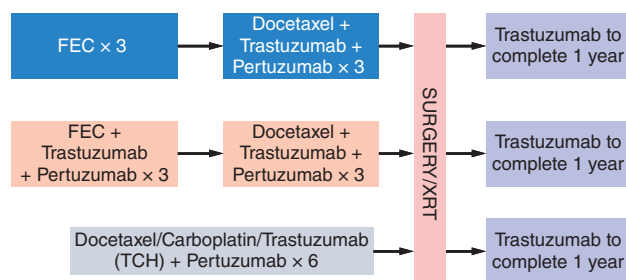

FIGURE 27-4 TRYPHAENA study design. FEC, 5-fluorouracil, epirubicin, and cyclophosphamide; XRT, radiotherapy. (Data from Schneeweiss A, Chia S, Hickish T, et al. Pertuzumab plus trastuzumab in combination with standard neoadjuvant anthracycline-containing and anthracycline-free chemotherapy regimens in patients with HER2-positive early breast cancer: a randomized phase II cardiac safety study (TRYPHAENA). *Ann Oncol.* 2013;24:2278-2284.)

of pertuzumab in combination with docetaxel for neoadjuvant therapy for node-positive or greater than T2 HER2-positive breast cancer.

OTHER SYSTEMIC THERAPY TOPICS

Dose Density

One approach to increase response rate to chemotherapy is dose density. This term refers to the administration of chemotherapeutic agents with a shortened interval between treatments, based on the knowledge that a given dose always kills a particular fraction of cancer cells. More frequent administration of cytotoxic therapy may thus be more efficacious than dose escalation to reduce tumor burden. Several recently published trials have explored dose-density regimens.

The CALGB 9741 trial explored the possible superiority of dose-dense over conventional scheduling of adjuvant chemotherapy for node-positive breast cancer⁽⁹⁰⁾. Patients were randomly assigned to receive doxorubicin, cyclophosphamide, and paclitaxel (175 mg/m²) either in 2-week or 3-week schedules, with growth factor support provided to the dose-dense schedule. At a median follow-up of 36 months, dose-dense treatment improved DFS to 82% (every 2 weeks) versus 75% (every 3 weeks) ($P = .01$). OS was also improved (92% with every 2 weeks vs 90% with every 3 weeks; $P = .013$). There was no difference between OS or DFS between the sequential and concurrent schedules.

As noted in the “Taxanes” section, E1199 demonstrated a significant improvement of weekly paclitaxel over paclitaxel every 3 weeks⁽⁴⁵⁾. It is not clear whether the benefit demonstrated in CALGB 9741 is from the dose-dense nature of the anthracycline or the schedule of the taxane. Additionally, NSABP B-38 found no significant difference in outcomes between TAC for 6 cycles and dose-dense AC with weekly paclitaxel⁽⁹¹⁾.

Lastly, the Southwest Oncology Group (SWOG) SO0221 trial compared weekly paclitaxel (80 mg/m²) versus dose-dense paclitaxel (175 mg/m²) in node-positive breast cancer patients who had already received AC⁽⁹²⁾. The results showed equivalent 5-year PFS between the weekly (82%) and biweekly regimens (81%). The weekly schedule was less toxic and did not require growth factor supplementation.

Oncotype DX

Recent efforts have identified multigene assays that can help quantify a patient’s risk of breast cancer recurrence⁽³⁵⁾. Oncotype DX is a commercially

available, validated laboratory test performed on a tumor specimen that analyzes 21 genes associated with receptor expression, proliferation, invasion, and other factors. Calculations based on the expression of these 21 genes result in a recurrence score that relays the likelihood of breast cancer recurrence in the first 10 years after diagnosis⁽⁹³⁾. These studies found that patients with a low recurrence score derive little benefit from chemotherapy, whereas those with a high recurrence score are likely to benefit from chemotherapy. For women with an intermediate recurrence score, the benefit of chemotherapy was uncertain. To elucidate the benefit of systemic cytotoxic therapy for this middle group, ECOG has designed a trial known as TAILORx, the Trial Assigning Individualized Options for Treatment⁽⁹⁴⁾. This study randomly assigned node-negative, HER2/neu-negative, hormone receptor-positive women with early breast cancer with a mid-range recurrence score to treatment with either hormonal therapy or chemotherapy followed by hormonal therapy. Disease-free survival, recurrence-free interval, and OS will be compared in these large cohorts.

Data are emerging that perhaps analysis of 21 genes is not better than immunohistochemical analysis of receptor status and Ki-67 percentage. A prognostic score based on staining of ER, PR, HER2/neu, and Ki-67, known collectively as IHC4, correlated with the prognostic information provided by the *Oncotype DX* score⁽⁹⁵⁾. This may scale back the elaborate, costly, and time-consuming testing that currently accompanies the evaluation of early-stage breast cancer. The observation regarding IHC4 is based on a single-institution report and requires validation.

The use of a genomic-derived recurrence score helps predict recurrences in patients with node-negative, hormone receptor-positive early breast cancer. However, the details regarding which assay will emerge as most useful, innovative, and cost-effective remain to be seen. The important question is how to manage intermediate-risk patients in terms of adjuvant therapy. Today, intermediate-risk patients should be counseled regarding the uncertainty of their benefit with chemotherapy and encouraged to enroll on clinical trials.

MD ANDERSON CANCER CENTER MANAGEMENT STRATEGIES

Early-Stage Breast Cancer (Stages I and II)

At MDACC, every effort is made to integrate clinical information with imaging, pathologic staging, and molecular characteristics to optimize treatment

efficacy and, whenever possible, perform breast-conserving surgery. A multidisciplinary approach is of upmost importance, especially with regard to planning and combined-modality therapy. Stage I breast cancer includes primary malignancies ≤ 2 cm in greatest dimension that do not involve the lymph nodes and microinvasive tumors that are ≤ 0.1 cm in greatest dimension. Stage II breast cancer encompasses primary tumors of 2 to 5 cm that can involve ipsilateral axillary lymph nodes and tumors >5 cm without lymph node involvement. All patients at MDACC (including those with DCIS) undergo receptor testing for hormone receptor status for ER and PR. In addition, patients are tested for *HER2/neu* status by IHC, and 2+ results are confirmed by FISH.

Stage I

Breast-Conserving Therapy

Breast-conserving surgery (BCS), or segmental resection, has revolutionized patient care for breast cancer over the last two decades. Women are able to preserve their breasts without a negative effect on survival. Breast-conserving therapy involves the surgical removal of tumor followed by radiation therapy to the breast. Multiple studies have shown that patients with stage I breast cancer treated with BCS have DFS and OS rates similar to patients treated with modified radical mastectomies⁽⁹⁶⁾.

There are only a few true absolute contraindications to BCS, including persistently positive resection margins, multicentric disease, diffuse malignant-appearing microcalcifications, a history of prior radiation to the breast or mantle region (for Hodgkin disease), and pregnancy, although it might be possible to perform BCS in the third trimester. Relative contraindications include a history of connective tissue disease suggesting that radiation would be poorly tolerated, centrally located tumors involving the nipple-areolar complex, and a large tumor in a small breast that might lead to a poor cosmetic result. Although the final decision about whether to offer BCS is left to the discretion of surgical colleagues, most patients who do not meet one of the absolute or relative contraindications are offered this surgical approach.

Risk Factors for Ipsilateral Recurrence With Breast-Conserving Surgery

The risk of ipsilateral tumor recurrence ranges from 0.5% to 2.0% per year. Risk factors include age <35 years, an extensive intraductal component, major lymphocytic stromal reaction, peritumoral invasion, positive margins of resection, and presence of tumor necrosis.

Axillary Lymph Node Dissection

Sentinel lymph node biopsy is the standard of care for patients with clinically negative axilla. In accordance with the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial, patients undergoing BCS with T1 or T2 tumors with less than three positive sentinel nodes can forgo complete axillary dissection if they are treated with whole-breast irradiation. Otherwise, if a positive sentinel node is identified, complete axillary node dissection should be performed⁽⁹⁷⁾.

Radiation Therapy After Breast-Conserving Surgery

Patients with node-negative disease are treated to achieve a total dose of 50 Gy with an approximate dose of 2 Gy/d on a schedule of 5 days per week for a total of 5 weeks. A boost of radiation to the tumor bed is standard. Regional nodal irradiation is no longer used for negative axillary lymph nodes. Radiation is usually begun after chemotherapy is completed, but it can be given concomitantly with hormone-based therapy.

Adjuvant Therapy

HER2-Negative Tumors

Based on data detailed in the earlier section on adjuvant therapy, both pre- and postmenopausal women are offered chemotherapy. We do not routinely give chemotherapy to patients with node-negative breast tumors that are ER positive and/or PR positive and HER2/neu negative. For these patients, we are incorporating the use of the *Oncotype DX* test for an estimation of the risk of recurrence (see the “Other Systemic Therapy Topics” section). Patients with a low recurrence score are recommended for adjuvant endocrine therapy. Patients with a high recurrence score are counseled for chemotherapy followed by endocrine therapy. Patients with a mid-range recurrence score are offered a choice of either therapy. Our current standard chemotherapy is either dose-dense AC for four cycles followed by weekly paclitaxel for 12 weeks or FAC for 4 weeks preceded by weekly paclitaxel for 12 weeks.

Chemotherapy is usually initiated 2 to 4 weeks after surgery. Studies have shown that delaying chemotherapy for up to 8 to 10 weeks does not have a negative effect on the development of metastasis or survival.

Chemotherapy is administered if the absolute neutrophil count is $\geq 1,000/\mu\text{L}$ and platelets are $\geq 100,000/\mu\text{L}$. A complete blood count with differential is checked prior to each chemotherapy cycle and weekly after the first cycle. Growth factor support is always given for

dose-dense AC plus paclitaxel and TAC but otherwise is not routinely used. If both chemotherapy and endocrine therapy are used, we give chemotherapy first followed by endocrine therapy. If indicated, radiotherapy follows chemotherapy.

Endocrine Therapy

Estrogen Receptor– and/or Progesterone Receptor–Positive Tumors

Our standard approach, based on previously described information, is to treat receptor-positive stage I disease using a hormonal treatment regimen. Based on the ATAC trial data discussed previously, tamoxifen is given to premenopausal women and AI to postmenopausal women. The ATLAS and ATTOM trials suggest extending tamoxifen to 10 years, which is now recommended. Postmenopausal patients are recommended to receive 5 years of an AI. Endocrine therapies are begun after completion of chemotherapy but can be given concomitantly with radiation therapy (Table 27-4). Given the results of the TEXT and SOFT trials, ovarian suppression therapy is now discussed with premenopausal patients, particularly the younger higher risk patients who received chemotherapy.

HER2-Positive Tumors

Patients with HER2-positive tumors benefit significantly from trastuzumab addition to chemotherapy. For node-negative patients with tumors less than 2.0 cm, the standard of care is AC for four cycles followed by trastuzumab and paclitaxel for 12 weeks or paclitaxel, carboplatin, and trastuzumab for six cycles. Trastuzumab is then given alone to complete 1 full year. If the tumor is hormone receptor–positive, patients are recommended

Table 27-4 Adjuvant Endocrine Treatment Regimens Commonly Used at the MD Anderson Cancer Center^a

Premenopausal	Postmenopausal
Tamoxifen 20 mg PO daily for 10 years	Anastrozole 1 mg PO daily for 5 years
or	or
Goserelin 3.6 mg SC every 4 weeks + anastrozole 1 mg PO daily for 5 years (high-risk patients)	Tamoxifen 20 mg PO daily for 10 years

^aBased on ATAC, ATLAS, TEXT, and SOFT data in women PO, oral; SC, subcutaneous.

to initiate their antiestrogen therapy once chemotherapy has been completed.

Stage II

Surgery

As with stage I disease, multiple studies of stage II patients treated with either BCS or modified radical mastectomy have documented similar long-term outcomes. Patients with tumors >4 to 5 cm are often not considered to be ideal candidates for BCS because of the potential for residual tumor and poor cosmetic result. These patients are usually treated with neoadjuvant systemic therapy. Patients with strongly ER-positive, PR-positive, HER2-negative, low-grade or low Ki-67 tumors would either have a mastectomy or be offered neoadjuvant endocrine therapy.

Radiation Therapy

After Breast-Conserving Surgery

Radiation of the breast after this form of surgery is similar in terms of area treated and dose given to the treatment of stage I. Regional nodal irradiation to negative axillary lymph nodes is not routinely given. Some groups recommend irradiation of the supraclavicular fossa or internal mammary chain for those with positive lymph nodes.

After Mastectomy

Postmastectomy irradiation should be considered for patients with positive postmastectomy margins, primary tumors >5 cm, or four or more positive lymph nodes. The ASCO clinical care guidelines recommend the routine use of postmastectomy radiation for women with stage III or T3 disease or those with four or more positive lymph nodes (%).

According to current recommendations, the dose to be delivered ranges from 45 to 50 Gy. Electron boosts to doses of 60 Gy can be considered if there is gross residual disease or positive margins. Treatment of the axilla in the absence of gross residual disease, even for patients with multiple positive lymph nodes, is not routinely recommended.

Neoadjuvant Therapy

Neoadjuvant therapy is typically given to patients with positive axillary nodal involvement. These institutional guidelines are based on information previously discussed under the sections "Neoadjuvant Therapy" and "Dose Density." Neoadjuvant therapy for HER2-negative patients uses the same regimens discussed in the adjuvant section. Patients with HER2-positive, node-positive disease or T2 tumors are strongly advised to

receive neoadjuvant therapy in order to receive pertuzumab. The regimens offered are those used in the NeoSphere or TRYPHAENA (see Figs. 27-5 and 27-6) clinical trials, while substituting epirubicin for doxorubicin. Following surgery, patients complete a full year of trastuzumab.

Clinical response is documented by serial imaging examinations, usually ultrasound or magnetic resonance imaging. If there is evidence of a level of response that could possibly lead to a tumor pCR, a marker is placed in the breast to identify the primary tumor site. This is done to guide resection, so that if a pCR has occurred, the "scar" tissue from the prior tumor can be resected.

Adjuvant Therapy

Chemotherapy

Patients who do not meet the criteria for neoadjuvant therapy or those who prefer upfront surgery are treated with adjuvant chemotherapy in a fashion similar to those with stage I breast cancer. Data are lacking for pertuzumab in the adjuvant setting. Consequently, patients with HER2-positive breast cancer receive adjuvant chemotherapy regimens with trastuzumab alone.

Endocrine Therapy

Whether patients are treated with neoadjuvant or adjuvant therapy, those with hormone receptor-positive tumors are treated with hormone-based therapy in a similar fashion to those with stage I breast cancer.

Locally Advanced Breast Cancer (Stage III)

About 10% of new patients present with locally advanced breast cancer. These patients usually have easily palpable tumors with large breast masses and/or axillary nodal disease. Inflammatory breast cancer is also included in locally advanced disease and represents 1% to 3% of diagnosed breast cancers. Patients with this very aggressive form of breast cancer can present without a discrete mass and only erythema and edema.

One challenging issue about this group of patients is the heterogeneous nature of their disease, with multiple different subgroups including tumors >5 cm, those with extensive regional lymph node involvement, direct involvement of the skin or chest wall, tumors that have no metastases but are still inoperable, and inflammatory breast cancer. The majority of patients with locally advanced breast cancers will have involved lymph nodes at diagnosis; 50% will have four or more lymph nodes involved. The DFS rates are variable. The most common cause of treatment failure is distant metastases, usually occurring within 2 years

of diagnosis. Both locally advanced breast cancer and inflammatory breast cancer can be divided into the same molecular subtypes as operable breast cancer: luminal A and B, HER2, basal-like, etc. Systemic therapy is selected on that basis.

The importance of a multimodality approach cannot be stressed enough. Previously, women with locally advanced disease were classified as being inoperable. Patients who were treated with a single modality of therapy with surgery or radiation had 5-year survival rates of less than 20%. Chemotherapy was first introduced into the treatment algorithm for this subset of breast cancer in the 1970s ⁽⁹⁹⁾. The EBCTCG review noted a modest benefit in survival for patients treated with postoperative chemotherapy ⁽³⁸⁾. The high risk of developing metastatic disease faced by these patients led to the use of neoadjuvant therapy as part of a multimodality approach.

Neoadjuvant-Based Therapy

Neoadjuvant-based therapy offers many important benefits, including direct in vivo measurement of sensitivity of tumor cells to chemotherapy, which allows for early discontinuation of ineffective therapy. Also, treatment prior to surgical intervention allows the delivery of the chemotherapy through an intact vasculature and thus possibly decreases the probability of developing resistant tumor cells.

Patients with locally advanced disease receive the same chemotherapy as stage II patients. Clinical response is documented by serial physical examinations, mammograms, and ultrasounds of the breast and nodal regions. If there is evidence of response that could possibly lead to a tumor pCR, a radiopaque marker is placed in the breast. Overall, the response to neoadjuvant therapy regimens depends on the patient's tumors characteristics and the treatment. The tumor effect on the axillary lymph nodes, rather than the response of the primary tumor itself, may be more important in predicting long-term outcome ⁽¹⁰⁰⁾.

Surgery

The historical surgical procedure for locally advanced disease is mastectomy. Clinical trials using neoadjuvant chemotherapy have noted that 50% or more of women with locally advanced breast cancer can be treated with BCS after neoadjuvant therapy ⁽¹⁰¹⁾. One concern is that women who need to be downstaged with preoperative chemotherapy to be eligible for segmental mastectomy have a higher local failure rate ⁽¹⁰²⁾. This can be improved through accurate localization of the tumor using a radiopaque clip, so that the appropriate area of tumor involvement can be resected, even

if a complete or near-complete response is achieved with neoadjuvant therapy.

Radiation Therapy

Radiation treatment guidelines recommend that patients with a pathologic response in the primary tumor and axillary lymph nodes, whether they undergo lumpectomy or mastectomy, should receive radiation to the breast and/or chest wall and/or internal mammary lymph nodes to a total dose of 50 to 60 Gy. Patients who achieve a partial response in the primary tumor and have residual nodal disease should have radiation in a comprehensive fashion, including the axillary field.

Adjuvant Therapy

Endocrine Therapy

As in stage I and stage II disease, our standard approach is to treat receptor-positive stage I disease using a hormonal treatment regimen. Based on the ATAC trial data discussed previously, tamoxifen is given to premenopausal women; postmenopausal women receive an AI. The ATLAS and ATTOM trials suggest extending tamoxifen to 10 years. An AI along with ovarian suppression should be considered for this population. Postmenopausal patients are recommended to receive 5 years of an AI. Endocrine therapies are started after completion of chemotherapy but can be given concomitantly with radiation therapy.

Prognosis

Clinical end points have been shown to improve with neoadjuvant therapy involving a combined-modality approach. Patients who are treated with a multimodality treatment approach can achieve long-term survival of 50%. Those who do not respond to neoadjuvant therapy have poorer outcomes. Women who fail to respond to neoadjuvant anthracycline-based therapy remain free of distant disease in only 30% of cases ⁽¹⁰³⁾.

CONCLUSION

Treatment of breast cancer has evolved from single-agent therapies to more contemporary combinations. Combined-modality approaches with refinement in local therapies (surgery, irradiation) have resulted in progressive improvement in survival in this disease. This is reflected in a single-center series of breast cancer patients treated from diagnosis at our institution from the 1940s to the present (Fig. 27-5).

Over the past six decades, there have been significant advances in the care of early-stage, locally advanced breast cancer. Between 1991 and 2005, the rate of death from breast cancer decreased by 37% in the United States ⁽¹⁾.

FIGURE 27-5 Survival of breast cancer patients treated at MD Anderson Cancer Center by decades.

The use of optimal stage- and hormone receptor-specific therapy is of utmost importance, and can significantly affect the risk of recurrence and death from breast cancer. Outcomes have improved with the addition of neoadjuvant therapy, taxanes, hormonal therapy, and HER2-targeted therapy.

Metastatic Breast Cancer

Meghan Karuturi

Vicente Valero

Mariana Chavez-MacGregor

Breast cancer is a significant cause of morbidity and mortality among women. In the United States, it is the most common malignancy among women. It is estimated that approximately 231,840 new cases of invasive breast cancer will have occurred in the United States in 2015 (^{1, 2}). Although lung cancer has surpassed breast cancer as the leading cause of cancer death among women, nearly 39,620 deaths were estimated to occur from breast cancer alone in 2013 (¹).

Since the 1970s, advances in combined-modality therapies have substantially improved the outcomes of patients with breast cancer. Still, approximately 10% to 60% of patients with initial localized breast cancer will suffer a systemic relapse. Metastatic disease is diagnosed at the time of presentation in 3% to 12% of patients depending on the series (^{1, 3}). Bone is the most common site of first distant relapse; other common sites of metastases include lymph nodes, lung, liver, and, less frequently, brain. The 5-year survival rate for localized breast cancer is 99%; for metastatic disease, this rate is only 17% to 28% (¹⁻³). As is true with cancers in general, the clinical course for patients with metastatic breast cancer (MBC) varies, but as a group, patients with MBC have a median survival of 2 years (⁴). Patients with bone-only disease tend to live longer than patients with visceral involvement. Untreated patients with MBC have a median overall survival time of 9 to 12 months. With systemic therapy, the mean survival time is 21 months for patients with visceral disease and as long as 60 months for patients

with bone-only disease. Survival and response to therapy are affected by several factors, including estrogen receptor (ER), progesterone receptor (PR), and *HER2*/neu receptor status; performance status; site of disease; number of disease sites; and duration of disease-free interval (DFI).

The therapeutic objectives and approach to patients with advanced breast cancer is distinct from that of patients with early-stage disease. Treatment for MBC is triaged to endocrine therapy, biological therapy, or chemotherapy, depending on the hormonal and *HER2*/neu receptor status of the tumor, the severity of symptoms, and the site and extent of disease. Generally, breast cancer can be classified as three molecularly and clinically different syndromes: hormone-receptor positive/*HER2*/neu negative, *Her-2*/neu positive (hormone-receptor negative or positive) and triple negative breast cancer. They have different clinical courses, prognoses, metastatic patterns, and responsiveness to available therapies. Systemic treatment prolongs survival, provides palliation of symptoms, and enhances quality of life but, in general, is not considered curative. Therefore, a discussion regarding goals of care is imperative between the patient and treating oncologist. Cure in MBC is rare; less than 2% of patients with MBC may remain disease free after anthracycline-containing therapy. The overall survival of patients has improved in the last few decades due to more effective therapies. This chapter reviews standard care for patients with MBC and discusses some unique approaches used at the University of Texas MD Anderson Cancer Center (MDACC).

DIAGNOSTIC WORKUP

Once metastatic disease is suspected, careful evaluation of the primary disease history, current symptoms, and existing comorbid diseases is essential. The history of the primary disease should include a review of the initial presentation, stage of disease, histology, hormone receptor and *HER2/neu* status, nuclear grade, and treatment modalities employed. Knowledge of the initial tumor type may yield clues about the sites of disease as well as its biology. For instance, infiltrating ductal carcinoma most commonly involve the lungs, pleura, liver, and brain. Infiltrating lobular carcinoma may metastasize to unusual sites such as the bone marrow, meninges, peritoneum, and retroperitoneal structures, such as the ureters⁽⁵⁾.

If possible, a biopsy of the metastatic or recurrence site is required to confirm the histologic type, as well as ER, PR, and *HER2/neu* status, because there is some evidence of significant discordance in the receptor status between the time of diagnosis of the primary tumor and the time of diagnosis of metastasis^(6,7). Changes in ER status occur in 14.5% to 40% of cases, whereas changes in *HER2* expression/amplification range from 0% to 37%⁽⁸⁾. Pathologic confirmation is also essential in patients suspected of having metastases if the clinical presentation or course is not typical. Such relapse scenarios include single-lesion metastasis, unusual metastatic sites, and long DFI. Solitary lesions should always be biopsied because of the possibility that the lesion may not be not malignant or may be caused by a second different primary malignancy. This occurs in up to 10% of patients with solitary lesions and would have a direct impact on the treatment selection.

In addition to a comprehensive physical examination, basic laboratory evaluation should include a complete blood count with differential, liver and renal function tests, and serum calcium determination. In addition, CA 15-3 and CA 27-29 are potentially helpful in monitoring response to therapy. The CA 15-3 test is a combination of two monoclonal antibodies bearing two reactive determinants directed against DF3 and MAM-6 antigens expressed on mammary epithelial cells^(9,10). CA 15-3 and CA 27-29, which are more sensitive than CEA, are elevated in approximately 70% of patients with MBC, but they lack sensitivity and specificity for breast cancer progression. Therefore, their prognostic significance remains indeterminate⁽⁹⁾. Carcinoembryonic antigen (CEA) is elevated in 40% to 50% of patients with metastatic disease^(10,11). Current recommendations from the American Society of Clinical Oncology are that tumor markers can be used in conjunction with diagnostic imaging, history, and physical examination to monitor patients with metastatic disease during active therapy; however, data are insufficient to recommend their use alone to monitor response to treatment⁽¹²⁾. Caution should be used when

interpreting tumor marker levels during the first 4 to 12 weeks of a new therapy, because spurious early rises may occur^(9,12). Furthermore, the absolute value of a tumor marker measurement does not represent the extent of disease, and no therapeutic decision should be based on a single tumor marker measurement. However, trends over time are helpful to monitor clinical course. In monitoring treatment, the physician should be aware of the coefficient of variation of the assays used for CA 15-3 and CA 27-29: changes <10% fall within the accepted intra-assay variability and do not represent real change. The measurement of circulating tumor cells (CTCs) has been studied in patients with MBC. Several studies showed that high levels of CTCs (>5 cells/75 mL of blood) are correlated with poor survival in MBC and with decreased response to treatment^(13,14). However, based on current recommendations, the measurement of CTCs should not be used to make the diagnosis of breast cancer or to influence any treatment decisions. Similarly, the use of the US Food and Drug Administration (FDA)-cleared test for CTCs (CellSearch Assay) in patients with MBC cannot be recommended for routine use until further validation confirms its clinical value. An intergroup trial is under way to determine the implication of changing treatment based on the CTC level⁽¹²⁾.

In most cases, we perform a baseline evaluation that also includes a computed tomography (CT) of the chest and abdomen (ultrasonography is less accurate for the chest and abdomen and would be indicated only in patients who cannot have CT or magnetic resonance imaging [MRI]), but occasionally, MRI of the abdomen may be indicated⁽¹⁵⁾. The presence of bone metastases should be evaluated, and in general, we recommend a bone scan to determine the presence and extent of bone metastasis. Only 30% to 60% of patients with true-positive bone scans have increased levels of alkaline phosphatase^(16,17). Conversely, only 20% of patients with elevated levels of alkaline phosphatase are disease free⁽¹⁷⁾. Impending fractures in the weight-bearing bones, such as the femur, and an unstable spine must be ruled out. The preferred test for spinal evaluation for metastases is MRI. Monitoring of bone metastases is best done with serial MRI or CT scans. Radiographic evaluations of the brain, leptomeninges, and spinal cord have low yield unless the patient is symptomatic or has abnormal neurologic findings⁽¹⁵⁾. Current guidelines discourage the use of positron emission tomography (PET)/CT except in situations where other staging studies are equivocal or suspicious⁽¹⁵⁾.

TREATMENT

General Considerations

The decision whether to use chemotherapy or biological or hormonal therapy for the initial treatment of MBC should be guided by several factors including

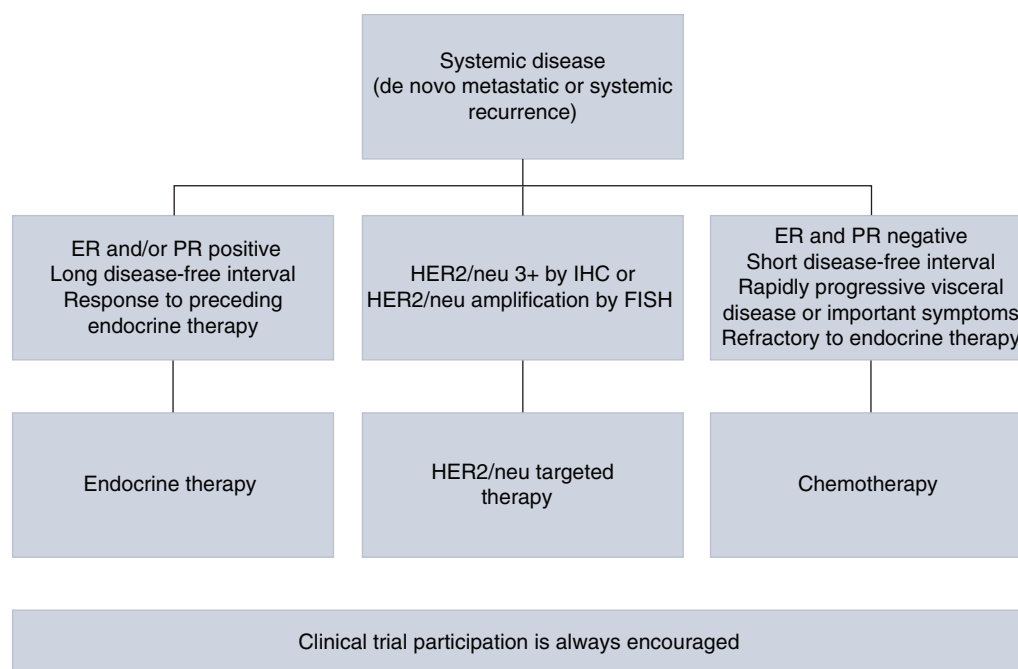

FIGURE 28-1 Principles of treatment selection in patients with metastatic breast cancer. ER, estrogen receptor; FISH, fluorescence in situ hybridization; IHC, immunohistochemistry; PR, progesterone receptor.

hormone receptor and *HER2/neu* status and the presence of symptomatic visceral disease or life-threatening disease (Fig. 28-1). Patients with moderately symptomatic visceral disease or life-threatening disease should be considered for treatment with systemic chemotherapy regardless of hormone receptor status because systemic therapy offers faster palliation of symptoms. Among women who do not have life-threatening or symptomatic visceral disease, those whose tumors are negative for ER and PR should be also considered for systemic chemotherapy. Those whose tumors are positive for ER or PR should be treated with hormonal therapy. Since the discovery of the importance of *HER2* gene amplification in breast cancer and the development of anti-*HER2* therapies, patients with tumors positive for *HER2/neu* overexpression or gene amplification should be treated with anti-*HER2* therapy in combination with chemotherapy because this provides a significant survival advantage.

Multiple agents are active against hormone-responsive tumors. Endocrine therapy tends to be associated with fewer side effects and helps maintain quality of life for many patients. If the tumor does not respond to endocrine therapy or becomes unresponsive to hormonal therapy, systemic chemotherapy should be initiated. For patients with hormone receptor-positive breast cancer, endocrine therapy is at least as effective as chemotherapy.

Currently, the primary goals of chemotherapy for MBC should be palliation of symptoms attributable to cancer and prolongation of life. It is the physician's

duty to balance the benefits of therapy with possible toxic effects and to fully discuss therapeutic options with patients. The patient's multiple previous therapies, decline in performance status, comorbid conditions, and organ function should be taken into consideration in the treatment decision. The MDACC treatment algorithm of patients with MBC is illustrated in Fig. 28-2.

Patients presenting with solitary metastases or oligometastases represent a unique subset of patients who are potentially curable and should be approached with combined-modality therapy, including surgical resection of the metastases (or radiotherapy at curative doses), combination chemotherapy before or after local treatment, anti-*HER2* agents for *HER2*-positive MBC, and endocrine therapy for hormone receptor-positive MBC. Such patients have a 20% to 25% probability of long-term cure after such treatment.

ENDOCRINE THERAPY

Endocrine therapy has dramatically improved outcomes in patients with hormone receptor-positive breast cancer. It can result in significant palliation of symptoms and improvement in quality of life in patients with hormone receptor-positive MBC. Manipulation of the endocrine system as a treatment for MBC was introduced in 1896, when Beatson demonstrated objective regression of breast cancer after oophorectomy. Today, a number of endocrine therapies are used

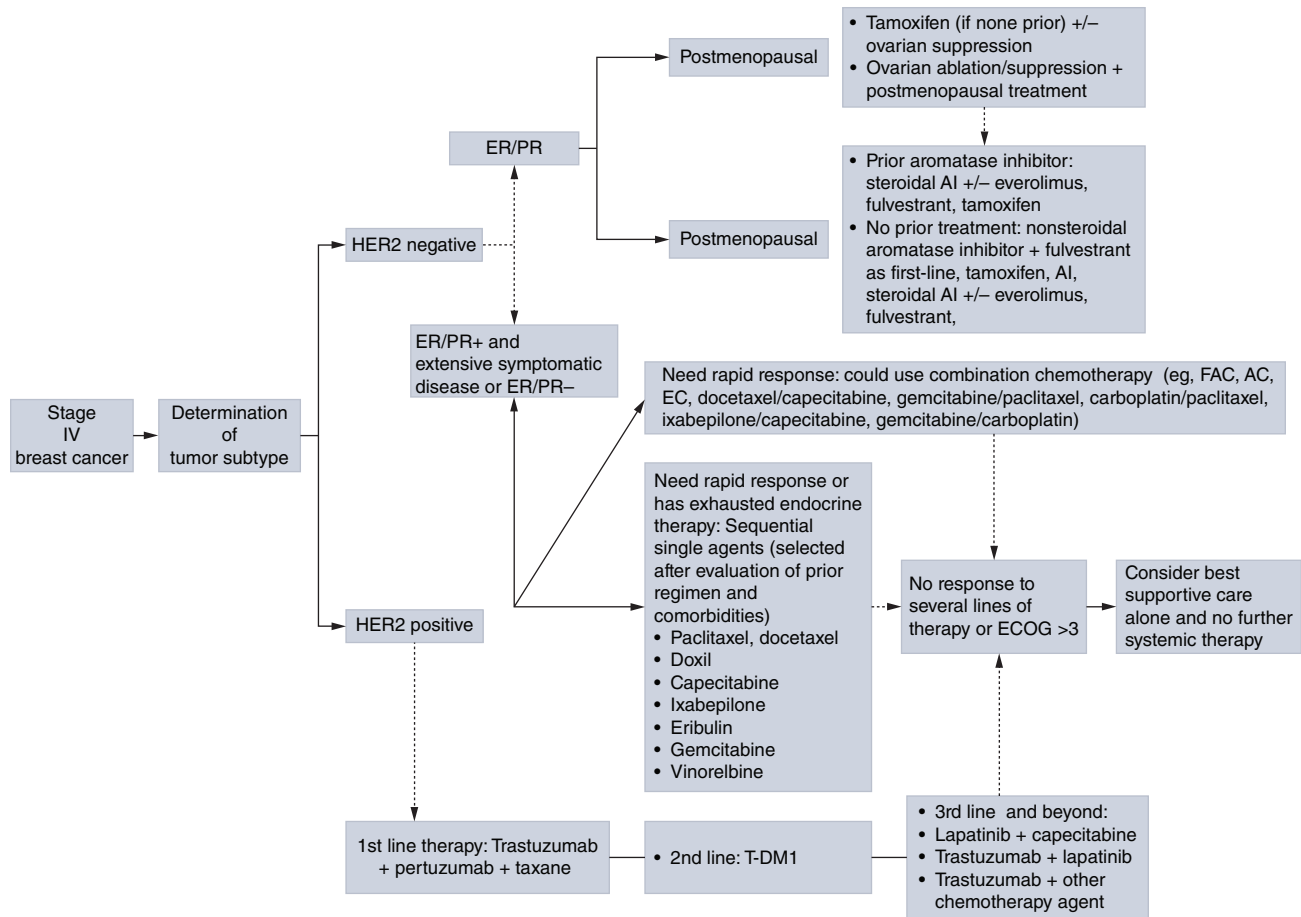

FIGURE 28-2 Algorithm for the treatment of metastatic breast cancer. AC, doxorubicin and cyclophosphamide; AI, aromatase inhibitor; EC, epirubicin and cyclophosphamide; ECOG, Eastern Cooperative Oncology Group performance status; ER, estrogen receptor; FAC, 5-fluorouracil, doxorubicin, and cyclophosphamide; PR, progesterone receptor.

in patients with hormone-sensitive MBC; most therapies are directed at reducing the synthesis of estrogen or blocking ERs in hormone-dependent tumors.

Tumors that are positive for ER and/or PR expression do not respond to endocrine therapy, and these patients should be offered endocrine therapy^{18, 19}. Patients who have tumors that are both ER and PR positive have a 50% to 70% probability of receiving clinical benefit from endocrine therapy. Patients with either ER-positive or PR-positive tumors have a 30% probability of receiving clinical benefit from endocrine therapy. Of patients with a prior history of hormonal response in the metastatic setting, 30% to 50% will have a response or clinical benefit from another hormonal regimen. Patients with low-volume disease and better performance status generally have higher response rates. The duration of first response is usually 9 to 12 months, similar to that with chemotherapy. The selection of endocrine therapy depends on the menopausal status of the patient: tamoxifen and/or ovarian suppression/ablation for premenopausal women and aromatase inhibitors or selective ER downregulators (SERDs) for postmenopausal women.

The side effect profile also aids in the determination of which hormonal therapy to use, because the efficacy of all agents is nearly equal²⁰. A substantial minority of patients with hormone receptor-positive MBC will benefit from sequential single-agent endocrine therapy. Some patients might benefit from three or four lines of endocrine therapy, and a few will continue to respond to multiple lines and for many years. Additionally, for patients whose tumors are unusually sensitive to hormonal manipulation, repeated treatment with a previously effective agent may again be effective if a long interval has elapsed since it was discontinued.

The clinical criteria used to determine eligibility for endocrine therapy are longer DFI, no involvement of vital organs, no major dysfunction of the organs involved by the disease, minimal or moderate visceral involvement, and metastases confined to the soft tissue or bone.

Several types of endocrine therapy are available in managing MBC (Table 28-1). They include ovarian ablation (oophorectomy, ovarian radiation), functional suppression (luteinizing hormone-releasing hormone [LHRH] agonists), selective ER modulators (SERMs),

Table 28-1 Types of Endocrine Therapy for Metastatic Breast Cancer

Type of Therapy	Examples
Ovarian ablation	Surgery, radiation therapy, pharmacologic interventions
LHRH agonists	Goserelin acetate
Selective estrogen receptor modulators	Tamoxifen
	Toremifene
	Raloxifene
	Arzoxifene hydrochloride
Selective estrogen receptor downregulators	Fulvestrant
Selective aromatase inhibitors	Anastrozole
	Letrozole
	Exemestane
	Fadrozole
	Formestane
Nonselective aromatase inhibitors	Testolactone
	Aminoglutethimide
Estrogens	Diethylstilbestrol Estradiol Megestrol acetate
Progestins	Medroxyprogesterone acetate
Androgens	Fluoxymesterone Danazol

LHRH, luteinizing hormone–releasing hormone.

ER downregulators, progestins, androgens, estrogens, and nonsteroidal and steroidal selective aromatase inhibitors (AIs). Medical ovarian castration obviates surgery as a first choice. There is no current indication for adrenalectomy or hypophysectomy. There are no conclusive data to support combined hormonal therapies in postmenopausal breast cancer, aside from the use of fulvestrant with AIs in the first-line setting based on a recent trial noting clinical benefit. In most trials of combinations, some minimal increases in response rates were seen, but without a significant improvement in survival. Additional toxicities are usually observed^(21, 22). As the understanding of the mechanisms of resistance to endocrine-based therapies has improved, the addition of therapies targeting these pathways has resulted in improved clinical outcomes. SERMs (tamoxifen and toremifene) are effective in pre- and postmenopausal patients with breast cancer. The LHRH agonists are effective in premenopausal women only⁽²³⁾, and the combination of tamoxifen and ovarian ablation is superior to ovarian ablation alone^(20, 23). Estrogen biosynthesis is reduced by inhibiting the aromatase enzyme, which catalyzes the final step in estrogen production in humans. This does not completely block ovarian estrogen production in premenopausal women, and there is concern that the use of an AI as a single agent in this patient population

may cause a reflex increase in gonadotropin levels and result in ovarian hyperstimulation. Thus, AIs must be used only in postmenopausal women; they are not effective in premenopausal women^(15, 24-26). The AIs can broadly be categorized as selective and nonselective. The nonselective AIs block not only aromatase but also other enzymes in the cytochrome P450 family. Thus, they alter other steroid hormone levels and are associated with more side effects. Therefore, they are not frequently used.

Endocrine therapy is better tolerated than cytotoxic chemotherapy. However, several unique complications of endocrine therapy should be anticipated. One such complication, flare, is defined clinically by an abrupt, diffuse onset of musculoskeletal pain, increased size of skin lesions, or erythema surrounding the skin lesion within the first month of endocrine therapy. Flare may also be characterized as the worsening of bone lesions on bone scan, the reason for which bone scans may make assessing response to endocrine therapy difficult. The most serious manifestation of flare is hypercalcemia, which can be seen with several hormonal therapies except AIs and surgical castration. Hypercalcemia usually occurs in patients with bone metastases and manifests itself within the first 2 weeks after treatment. The underlying mechanism is the predominant early agonist effect of hormonal agents. Low doses

of prednisone (10-30 mg/d) may abrogate the initial flare of bone pain.

Side effects of endocrine therapy, such as hot flashes and mood disturbances, are related to estrogen deprivation and are common with tamoxifen and AIs, reflecting the mechanism of action of these drugs. Tamoxifen has estrogenic effects that are beneficial in some tissues; it lowers serum cholesterol levels and protects against bone loss and cardiovascular disease but is also associated with potentially life-threatening side effects, such as endometrial cancer and thromboembolic events. AIs are associated with musculoskeletal side effects, such as arthralgias, myalgias, and bone loss. Weight gain is clearly associated with estrogens, androgens, corticosteroids, and progestins. Randomized trials of tamoxifen do not support an association with weight gain because patients on placebo experienced the same degree of weight gain as those on tamoxifen. This side effect is most common with progestins, which can cause both a true increase in weight from their anabolic effect and fluid retention secondary to their glucocorticoid effect. Progestins are the drugs most likely to cause thromboembolism; tamoxifen is the next most likely drug to cause this complication.

The preferred agent for endocrine therapy depends on the menopausal status of the patient. In premenopausal women, tamoxifen is recommended as the initial therapy, although ovarian suppression with an LHRH agonist alone or with tamoxifen can also be used. In patients who are within 1 year of antiestrogen exposure, the preferred second-line therapy is surgical oophorectomy or an LHRH agonist with endocrine therapy⁽¹⁵⁾. In postmenopausal women who are antiestrogen naïve or who are more than 1 year from previous antiestrogen therapy, an AI is recommended as initial first-line therapy, but tamoxifen or the combination of fulvestrant with an anastrozole can be considered. Aromatase inhibitors appear to have superior outcome compared with tamoxifen, but differences are modest^(27, 28). The use of anastrozole or letrozole as initial therapy in postmenopausal women with ER-positive tumors results in increased response rates and longer disease control⁽²⁹⁾. Patients who respond to initial therapy have a higher probability of response to second- and third-line endocrine therapies. There is a partial lack of cross-resistance between steroidal and nonsteroidal AIs. These agents may provide palliation of disease if used sequentially in patients with hormone receptor-positive tumors. There is evidence that a steroidal AI (exemestane) is effective in patients who have disease progression after a nonsteroidal AI. Most patients with hormone-responsive breast cancer benefit from the sequential use of endocrine therapies at the time of disease progression. Patients who respond to endocrine therapy with tumor shrinkage or long-term disease stabilization should receive

additional endocrine therapy at the time of disease progression⁽¹⁵⁾.

Fulvestrant is an ER antagonist that downregulates ER and has no agonist effects. It was compared with tamoxifen in a large randomized trial involving 587 postmenopausal women with advanced breast cancer or MBC who had not previously been treated with endocrine therapy. Patients were given either fulvestrant 250 mg intramuscularly monthly or tamoxifen 20 mg orally (PO) daily. At a median follow-up of 14.5 months, there was no significant difference between fulvestrant and tamoxifen in time to progression (TTP; median, 6.8 vs 8.3 months, respectively)⁽³⁰⁾. Fulvestrant also appears to be as effective as anastrozole in patients whose disease progressed on tamoxifen^(31, 32). The clinical benefit rates of exemestane and fulvestrant observed in a phase III trial of postmenopausal women with hormone receptor-positive breast cancer who experienced disease progression on prior nonsteroidal AIs were comparable (32.2% vs 31.5%)⁽³³⁾. The CONFIRM trial (n = 736) compared fulvestrant at different doses (250 and 500 mg) in postmenopausal women with advanced disease recurring or progressing after prior endocrine therapy. Response rates were similar in both groups (13.8% vs 14.6%), but TTP and overall survival (OS) were significantly longer for the patients who received 500 mg (hazard ratio [HR], 0.80; 95% confidence interval [CI], 0.68-0.94)^(33, 34).

Based on preclinical studies suggesting that the combination of fulvestrant and an AI was superior compared with either agent alone, three prospective clinical trials evaluated this approach in postmenopausal women with hormone receptor-positive MBC. In the Southwest Oncology Group SO226 trial, postmenopausal women (n = 707) with previously untreated metastatic disease were randomized to anastrozole versus anastrozole and fulvestrant, with crossover to fulvestrant encouraged⁽³⁵⁾. Median progression-free survival (PFS) and OS were significantly improved with the combination (median OS, 41.3 months with anastrozole vs 47.7 months with the combination; HR, 0.81; 95% CI, 0.65-1), despite the fact that 41% of patients receiving anastrozole crossed over to fulvestrant. Subgroup analysis revealed that those deriving the greatest benefit were patients who received no prior tamoxifen. The other two studies showed equivalent outcomes in patients receiving the combination. In a randomized phase III trial, Johnston et al reported that patients with hormone receptor-positive MBC who relapsed or progressed while receiving a nonsteroidal AI had similar PFS when treated with fulvestrant plus anastrozole, fulvestrant plus anastrozole-matched placebo, or exemestane⁽³⁶⁾. Another phase III trial showed no advantages in clinical efficacy for the combination of anastrozole and fulvestrant compared to treatment with anastrozole alone

as first-line treatment in postmenopausal women with hormone receptor–positive MBC⁽³⁷⁾. One possible reason for the difference in outcomes of the three studies is a potential imbalance in the prognostic subgroups in the SWOG study⁽³⁸⁾. Given the positive phase III findings and especially the significant prolongation in OS, the combination can still be considered, especially in patients who have never received tamoxifen.

De novo and acquired resistance is a known phenomenon. Options in this setting include changing the class of AI or using a drug with a different mechanism of action, such as fulvestrant or tamoxifen. Another approach is the addition of a mammalian target of rapamycin (mTOR) inhibitor, such as everolimus. Activation of the PI3K/Akt/mTOR pathway in breast cancer has been implicated as a mechanism of resistance to endocrine therapy. Preclinical research has evaluated the molecular basis of resistance to endocrine therapy, combatting resistance by incorporating inhibitors of this pathway⁽³⁹⁾. A phase II study demonstrated similar efficacy and safety with the use of everolimus in combination with tamoxifen in the treatment of 111 patients with hormone receptor–positive, HER2-negative MBC with prior exposure to AI treatment either in the adjuvant and/or metastatic setting⁽⁴⁰⁾. The study fulfilled its primary end point, with a clinical benefit rate at 6 months of 61.1% with everolimus plus tamoxifen versus 42% with tamoxifen alone ($P = .045$). There was a delay in time to disease progression with the combination; the TTP was 8.6 months in patients treated with everolimus plus tamoxifen versus 4.5 months in those treated with tamoxifen alone, resulting in a significant reduction in the risk of disease progression (HR, 0.54; 95% CI, 0.35–0.81; $P = .002$).

The BOLERO-2 study, a randomized, phase III, double-blind, placebo-controlled, multicenter trial⁽⁴¹⁾, randomized 724 patients with hormone receptor–positive advanced breast cancer who had recurrence or progression after receiving previous nonsteroidal AIs to receive either exemestane or exemestane plus everolimus. The combination arm resulted in an improvement in the primary end point of PFS (10.6 vs 4.1 months; $P < .001$). Adverse effects of everolimus reported to affect 30% or more of patients included stomatitis, infections, rash, fatigue, diarrhea, and reduced appetite. The most common grade 3 to 4 adverse reactions affecting 2% or more of patients included infections, hyperglycemia, fatigue, stomatitis, diarrhea, dyspnea, and pneumonitis. In 2012, everolimus in combination with exemestane was approved by the FDA for the treatment of postmenopausal women with recurrent or progressive hormone receptor–positive, HER2/neu-negative disease after failure of therapy with either letrozole or anastrozole.

Enticing new options in the treatment of hormone receptor–positive, HER2-negative MBC are

cyclin-dependent kinase (CDK) 4/6 inhibitors^(42, 43). Together with cyclin D1, CDK4 and CDK6 are kinases that facilitate the transition of dividing cells from the G₁ phase of the cell cycle to the S phase. Preclinical studies have demonstrated that breast cancer cells rely on both CDK4 and CDK6 for division and cell growth. Inhibition of these pathways leads to cell cycle arrest at the G₁/S phase checkpoint⁽⁴³⁾. Palbociclib, LEE011 (ribociclib), and LY2835219 (abemaciclib) are three selective CDK inhibitors presently under evaluation for the treatment of hormone receptor–positive MBC. In a phase I trial of LY2835219, 132 patients with five different tumor types, including MBC, received 150- to 200-mg doses of oral drug every 12 hours⁽⁴⁴⁾. The overall disease control rate for the 36 patients with hormone receptor–positive breast cancer was 81%, with a median PFS of 9.1 months. Common adverse events included diarrhea, nausea, vomiting, fatigue, and neutropenia. In a phase II trial, the oral CDK4/6 inhibitor, palbociclib, resulted in a near doubling of the primary end point of PFS as compared to control in the first-line treatment of 165 postmenopausal women with hormone receptor–positive MBC⁽⁴⁵⁾. Those receiving the combination of palbociclib in addition to letrozole had an objective response rate of 43% compared to 33%, with a PFS of 20.2 months versus 10.2 months (HR, 0.488; $P = .0004$). Common adverse events included leukopenia, neutropenia, and fatigue. The CDK inhibitors are being studied in phase III trials. The PALOMA-2 trial is testing the combination of palbociclib with letrozole in MBC in the frontline setting, and PALOMA-3 (NCT01740427) is evaluating the combination with fulvestrant in patients who have failed previous endocrine therapy. The MONALEESA-2 study is evaluating the efficacy and safety of the selective CDK inhibitor LEE011 in combination with letrozole in postmenopausal women with hormone receptor–positive MBC who have received no prior treatment for advanced disease (NCT01958021).

After third-line endocrine therapy, little high-level evidence exists to help select the optimal sequence of endocrine therapy. There are other hormonal agents available; progestins, for example, are synthetic derivatives of progesterone that have a progesterone agonist effect. Progestins such as megestrol acetate and medroxyprogesterone acetate are effective in treating MBC. These drugs are thought to have antiestrogenic properties and may result in interruption of the pituitary-ovarian axis. Androgens (eg, fluoxymesterone, danazol) have been evaluated and used in patients with MBC treated with multiple endocrine agents who still have hormone-dependent disease. Prior to the identification of hormone receptors or the development of SERMs, high-dose estrogens were commonly used to treat MBC. Their efficacy is similar to that of tamoxifen, although high-dose estrogens

(eg, diethylstilbestrol, ethinyl estradiol) are associated with more severe side effects. Recent data suggest that the use of estrogens can be beneficial for patients with AI-resistant breast cancer (⁴⁶). In a phase II study, 66 patients with AI-resistant MBC were randomized to receive 6 versus 30 mg of estradiol. The clinical benefit rates were 25% with 30 mg and 29% with 6 mg. The authors concluded that 6 mg of estradiol was as effective as 30 mg with greater safety and that this regimen could be a palliative therapeutic strategy in MBC progressing after other endocrine therapies (⁴⁶). The treatment algorithm for treating patients with MBC at MDACC is illustrated Fig. 28-2.

CHEMOTHERAPY

No predictive test for response to chemotherapy has been sufficiently validated to use in a standard clinical setting. For patients with MBC not previously treated with chemotherapy, the response rates are 30% to 75%. Predictors of response to chemotherapy include DFI, sites of disease, organ function, and performance status, among others. Different biomarkers have been studied; some correlate with treatment response, but none is sufficiently accurate to help make a decision to treat or withhold therapy (⁴⁷).

Selection of Agents/Regimen

In deciding which cytotoxic regimen to use in the setting of negative ER/PR and *HER2* status or in patients who have progressive disease after endocrine therapy, consideration should be given to the previous therapies, organ function, and comorbid conditions. Typically, chemotherapy within the conventional range of doses is associated with higher response rates than “low-dose chemotherapy.” As in the setting of adjuvant therapy, high-dose chemotherapy with peripheral blood/bone marrow stem cell transplantation has not been found to be of clinical benefit in randomized trials (⁴⁸).

The choice between sequential single agents and combination chemotherapy is controversial. The principle of nonoverlapping mechanisms of resistance and toxicities has been the basis of combination chemotherapy. Multiple randomized trials involving single-agent versus multiple-agent regimens in MBC have generally demonstrated that combination chemotherapy has improved response rates and TTP, but OS is not improved. Fossati et al (⁴⁹), in a systematic review that included 31,510 patients, estimated that the proportional reduction in overall mortality for combinations versus single-agent regimens is only 18%, translating to an absolute benefit in survival of 9% at 1 year, 5% at 2 years, and only 3% after 5 years. More toxicity was associated with combination therapy.

In two randomized trials of combination versus single-agent therapy in MBC, formal quality-of-life analyses favored the single-agent arms, even though response rates were slightly lower (^{50,51}).

A Cochrane review (⁵²) including 28 trials and 5,707 patients with MBC randomly assigned to receive single-agent or combination chemotherapy found that combination therapy was associated with a higher response rate (odds ratio, 1.28; 95% CI, 1.15-1.42), longer TTP (HR, 0.78; 95% CI, 0.73-0.83), and longer OS (HR, 0.88; 95% CI, 0.83-0.94) than single-agent therapy. Most trials included in the Cochrane review did not specifically investigate the combination versus the sequential use of the single agents, and few studies reported the rate of “crossover” to an additional therapy following progression in the monotherapy arm. Therefore, the studies included evaluated the value of the use of two agents versus a single agent and do not address whether a simultaneous combination or a sequential monotherapy strategy should be pursued.

In the absence of strong evidence to guide the decision, and in agreement with different oncologic societies (⁵³), we believe that use of single-agent therapy is preferable in the absence of rapid clinical progression, life-threatening visceral metastases, or the need for rapid symptom or disease control. Ultimately the choice of the use of sequential versus combination chemotherapy depends on a careful evaluation of risks and benefits for individual patients. The other major indication for combination therapy, as in the adjuvant setting, is the treatment of oligometastases.

Duration of Chemotherapy

The optimal duration of chemotherapy for MBC is controversial. Several studies have compared continuous (maintenance) chemotherapy with intermittent therapy. Several studies found that continuous therapy was associated with a longer time to relapse (⁵⁴⁻⁵⁸) but with worse side effects (⁵⁷). None of the individual studies comparing continuous and intermittent therapy showed prolongation of life with continuous therapy. However, a recent meta-analysis of these data showed a statistically significant improvement in survival for patients receiving chemotherapy for a longer versus a shorter time (⁵⁸). Some regimens, such as anthracycline-containing treatments, have inherent dose-limiting toxic effects that prohibit prolonged use. Other agents, such as trastuzumab, capecitabine, and, possibly taxanes given weekly, lend themselves to prolonged continued therapy. In an unplanned interim analysis, the recently presented Italian MANTA trial found no PFS or OS benefits for maintenance treatment with paclitaxel (175 mg/m² every 3 weeks for eight cycles) after first-line chemotherapy for MBC with an anthracycline/taxane-containing regimen (six to eight

cycles)⁽⁵⁹⁾. Many trials are designed to treat patients until they have progression of disease or for two to three cycles after maximum benefits. Currently, the optimal treatment duration is unknown. The practice at MDACC is to treat patients with MBC with continuous chemotherapy unless unacceptable toxicity arises, at least until a third-line or fourth-line regimen comes into play and/or Eastern Cooperative Oncology Group (ECOG) performance status is ≥ 3 in patients with MBC.

Single-Agent Chemotherapy

Anthracyclines

The introduction of anthracyclines (doxorubicin and epirubicin) in the 1970s represented a significant advance in the treatment of advanced breast cancer. In patients with MBC, response rates to single-agent doxorubicin (25–75 mg/m² every 3 weeks) ranged from 25% to 60% and were heavily influenced by patient characteristics such as prior chemotherapy exposure, performance status, and extent and sites of disease^(60–64). At MDACC, doxorubicin-containing regimens have historically been the initial treatment of choice for MBC treated previously with non-anthracycline-containing chemotherapy. Patients who received anthracyclines and had a prolonged DFI before the development of metastatic disease occasionally benefit from repeat administration of doxorubicin. However, given the increasing number of active agents available to treat MBC, repeat management with anthracyclines should be reserved for patients in whom other treatments have failed, given the potential risk of heart failure.

Epirubicin is a doxorubicin analog that has been shown to have similar efficacy and somewhat less toxicity than doxorubicin at equimolar doses. Although not designed to perform a head-to-head comparison, results from a randomized trial suggested that epirubicin might be as efficacious as doxorubicin. A formal comparison of two different anthracyclines in combination (5-fluorouracil, doxorubicin, and cyclophosphamide [FAC] vs 5-fluorouracil, epirubicin, and cyclophosphamide [FEC]) at equimolar doses found both regimens to be equally effective in terms of response rate, TTP, and survival. The FEC regimen was associated with less gastrointestinal, hematologic, and cardiac toxicity⁽⁶⁵⁾.

Efforts to improve the safety profile of doxorubicin while preserving efficacy have resulted in liposomal formulations of doxorubicin. Response rates with these products appear comparable to those seen in other multicenter trials using conventional single-agent doxorubicin. In a phase III clinical trial, O'Brien et al compared the efficacy and safety of pegylated liposomal doxorubicin with those of conventional doxorubicin as

first-line therapy in patients with MBC⁽⁶⁶⁾. A total of 509 women received a 1-hour infusion of pegylated liposomal doxorubicin (50 mg/m² once every 4 weeks) or conventional doxorubicin (60 mg/m² once every 3 weeks). The median PFS and OS were similar in both treatment groups (6.9 vs 7.8 months and 20.1 vs 22.0 months, respectively). The rates of alopecia, myelosuppression, nausea, and vomiting were lower with pegylated liposomal doxorubicin than with conventional doxorubicin. Perhaps most notably, pegylated liposomal doxorubicin was associated with a significantly lower incidence of cardiotoxicity, even at higher cumulative doses ($P < .001$)⁽⁶⁶⁾. The most important dose-limiting toxicity of pegylated liposomal doxorubicin is palmar-plantar erythrodysesthesia, which is both dose and duration related. The polyethylene glycol coating results in preferential concentration of the drug in the skin; this explains why small amounts of the drug can leak from capillaries in the palms and soles, resulting in redness, tenderness, and peeling of the skin that can be uncomfortable and even painful. As with all liposomal drug delivery systems, there is a low incidence of hypersensitivity reactions.

Taxanes

Taxanes (paclitaxel, docetaxel, and the nanoparticle albumin-bound [nab]-paclitaxel) are among of the most active classes of cytotoxic drugs available today for the treatment of breast cancer. They rival the anthracyclines in terms of response rates and positive impact on TTP. Taxanes are frequently used as first-line chemotherapy for treatment-naïve MBC and also in MBC treated with anthracyclines or if anthracyclines are contraindicated. Response rates with paclitaxel range from 21% to 62%; in anthracycline-resistant breast cancer, response rates are 40%.

Two trials have directly compared doxorubicin and paclitaxel, using different dosing and administration schedules. In the Intergroup E1193 study⁽⁶⁷⁾, similar response rates and TTP were demonstrated with doxorubicin administered at 60 mg/m² and paclitaxel at 175 mg/m² over 24 hours. Thus, paclitaxel may be as effective as doxorubicin when administered as a single agent. The dose and administration schedule may influence the response to paclitaxel. The use of weekly paclitaxel has recently become very popular due to the improvement in the toxicity profile and the ability to deliver a more dose-intensive regimen. At MDACC, the most popular taxane regimen is weekly paclitaxel 80 mg/m², commonly in a “3 weeks on, 1 week off” or “2 weeks on, 1 week off” schedule.

Docetaxel is a semisynthetic taxane with several preclinical, pharmacokinetic, biological, and clinical differences in comparison to paclitaxel. It has demonstrated a 37% to 57% response rate in patients with

anthracycline-resistant tumors and was initially FDA approved for this indication at a dose of 60 to 100 mg/m² every 3 weeks. At this dose, hematologic toxicity is the greatest and the rates of neutropenia are similar to those seen when paclitaxel is given every 3 weeks. In a large clinical trial, 527 patients were randomized to receive docetaxel 60, 75, or 100 mg/m² every 3 weeks. A relationship between increasing dose of docetaxel and increased tumor response was observed, but toxicities were also related to increasing doses (⁶⁸). Docetaxel every 3 weeks at doses between 75 and 100 mg/m² are appropriate choices as first-line therapy for MBC; in most cases at MDACC, we use 75 mg/m². Compared to every-3-week paclitaxel, docetaxel 100 mg/m² was associated with longer TTP (HR, 1.64; 95% CI, 1.33-2.02) and improved OS (HR, 1.64; 95% CI, 1.33-2.02), but also greater incidence of treatment-related toxicities (⁶⁹). To place these data in context, it is important to remember that paclitaxel has greater activity when given on a weekly schedule, yet it is not clear whether docetaxel or paclitaxel provides superior outcomes when each agent is administered at its optimal dose and schedule. In patients who had received paclitaxel previously, docetaxel administration was associated with response rates of 18% to 21%, demonstrating a lack of cross-resistance between the two agents (⁷⁰).

Moderate nail changes and fatigue are commonly seen with weekly paclitaxel and docetaxel; excessive tearing due to partial or complete canalicular stenosis is seen with weekly docetaxel. Diarrhea, stomatitis, and neutropenia and its complications are uncommon with weekly taxane administration. Fluid retention is seen in patients who receive a docetaxel cumulative dose greater than 300 mg/m². Premedication with steroids greatly reduces the magnitude of fluid retention; the optimal doses and schedules for steroid administration are not well established. At MDACC, we routinely prescribe dexamethasone 4 mg PO twice a day for 3 days beginning the day before chemotherapy administration.

Nab-paclitaxel is a nanoparticle albumin-bound paclitaxel (Abraxane) that has been investigated in the treatment of MBC. In different comparisons, it has proven to be better, or at least as effective, as the other taxanes (^{71,72}), with the advantage that it does not require Cremophor for solubility and therefore is associated with less hypersensitivity reactions. In a phase III study, 454 patients were randomly assigned to 3-week cycles of nab-paclitaxel 260 mg/m² or paclitaxel 175 mg/m². Nab-paclitaxel demonstrated significantly higher response rates compared with paclitaxel (33% vs 19%, *P* = .001) and longer TTP (23.0 vs 16.9 weeks, *P* = .006). Grade 3 sensory neuropathy was more common with nab-paclitaxel, the incidence of grade 4 neutropenia was significantly lower with nab-paclitaxel,

but the rate of febrile neutropenia was similar in both groups. A phase II four-arm study compared nab-paclitaxel (300 mg/m² every 3 weeks, 100 mg/m² weekly, or 150 mg/m² weekly) and docetaxel (100 mg/m² every 3 weeks). The weekly dose of 150 mg/m² of nab-paclitaxel demonstrated longer PFS than docetaxel (12.9 vs 7.5 months, *P* = .006), but no differences in PFS or response rates were seen when comparing docetaxel and the 3-week schedule of nab-paclitaxel. Grade 3 or 4 fatigue, neutropenia, and febrile neutropenia were less frequent in all nab-paclitaxel arms, but the frequency and grade of peripheral neuropathy were similar in all groups (⁷¹). At MDACC, nab-paclitaxel is frequently used as first- or second-line therapy administered in a weekly schedule, and it is preferred to paclitaxel for patients with contraindications to steroid use.

Antimetabolites

Capecitabine

Capecitabine (Xeloda) is an oral fluoropyrimidine approved by the FDA in April 1998 as single-agent therapy for the treatment of MBC resistant to anthracyclines and taxanes. In September 2001, capecitabine was approved for use in combination with docetaxel in MBC previously treated with an anthracycline. The first phase II study of capecitabine in breast cancer involved 162 patients previously treated with paclitaxel for MBC (⁷³). The majority of patients had also received previous anthracycline therapy. Capecitabine was administered at 2,500 mg/m²/d in two divided doses for 14 days, followed by 1 week of rest. Twenty-seven (20%) of 135 women with measurable disease demonstrated complete or partial responses. The median duration of response was 8.1 months, and the median survival was 12.8 months. In a phase II trial, O'Shaughnessy et al randomized patients to receive cyclophosphamide, methotrexate and 5-fluorouracil (CMF) or capecitabine in the frontline setting (⁷⁴). The overall response rate was 30% for capecitabine and 16% for CMF; no differences in TTP were seen. Similar levels of nausea, vomiting, and stomatitis were observed in both groups. More cases of grade 3 or 4 diarrhea (8%), fatigue (5%), and hand-foot syndrome (15%) were noted with capecitabine.

Capecitabine is active in the treatment of MBC, and significant response rates can be achieved in women previously treated with an anthracycline and a taxane. However, patients with triple-negative tumors do not benefit from it. The FDA-approved dose and schedule are 2,500 mg/m²/d given orally in two divided doses for 14 days, followed by 1 week of rest. Retrospective studies suggest that a lower starting dose (2,000 mg/m²/d) is better tolerated, with preserved efficacy. Capecitabine as first-line therapy for MBC results in

response rates of 30% to 58%, and it is a reasonable option for some patients. At MDACC, it is often used as first-line therapy for patients who have been previously treated with anthracyclines and/or taxanes in the adjuvant or neoadjuvant setting.

Gemcitabine

Gemcitabine (Gemzar), a nucleoside analog, was approved by the FDA in April 2004 for the first-line treatment of MBC in the United States. In patients with MBC, single-agent response rates have ranged from 14% to 37%⁽⁷⁵⁻⁷⁷⁾. These were small trials, and the disparate results may be due to dosing differences. Generally, chemotherapy-naïve patients tolerate doses of 1,000 to 1,250 mg/m²/wk on days 1, 8, and 15 every 28 days. Omitting the day 15 dose or reducing the dose in subsequent cycles of chemotherapy may improve the patient's ability to tolerate therapy beyond the initial cycles. Pretreated patients may require dose reductions in order to decrease the risk of thrombocytopenia. Gemcitabine has been investigated in many different doublet and triplet combinations; it is a promising agent for its efficacy as a single drug, but also due to its ability to readily combine with paclitaxel, vinorelbine, docetaxel, or cisplatin/carboplatin as first- or second-line therapy. At present, gemcitabine is appropriate treatment for patients with MBC after treatment failure with standard regimens.

Other Agents

Vinorelbine

Vinorelbine (Navelbine) is a semisynthetic vinca alkaloid that interferes with microtubule assembly and is an important active agent in the treatment of MBC. Phase II trials investigating its efficacy in pretreated MBC have demonstrated response rates ranging from 25% to 47%⁽⁷⁸⁻⁸⁰⁾. The primary side effects are neutropenia, pain with infusion, flu-like symptoms, and gastrointestinal symptoms such as nausea or constipation. Vinorelbine is appropriate third-line (or later) therapy for patients with MBC. At MDACC, it is usually given at a dose of 25 mg/m² on days 1, 8, and 15 of 21-day cycles.

Ixabepilone

Ixabepilone (Ixempra) is an epothilone B analog that binds to microtubules and causes microtubule stabilization and mitotic arrest. It was approved by the FDA in October 2007 (alone or in combination with capecitabine) for the treatment of patients with MBC resistant to treatment with an anthracycline and a taxane or whose cancer is taxane resistant and for whom further anthracycline therapy is contraindicated. As a single agent, it is also indicated for patients with tumors resistant or refractory to capecitabine.

Ixabepilone monotherapy was evaluated in a single-arm trial in 126 patients who had previously received an anthracycline, a taxane, and capecitabine⁽⁸¹⁾. The objective response rate was 11.5%, the median response duration was 5.7 months, and the median OS was 8.6 months. Grade 3 or 4 neutropenia was seen in 54% of patients, and grade 3 or 4 peripheral neuropathy was seen in 14%. When used as first-line therapy in patients with MBC who received anthracycline-based chemotherapy in the adjuvant setting, the response rates was 41.5%, with a median duration of response of 8.2 months and a median survival of 22 months⁽⁸²⁾. At MDACC, we frequently use it in patients who have received anthracyclines, taxanes, and capecitabine. Ixabepilone is given at 40 mg/m², but based on toxicities and tolerance, it is not uncommon to reduce the dose to 32 mg/m².

Eribulin

Eribulin mesylate is a synthetic analog, a novel microtubule modulator that induces a conformational change that suppresses microtubule growth and sequestration of tubulin into nonfunctional aggregates. In the phase III study that led to its approval, 762 heavily pretreated women with locally or recurrent MBC were randomized to receive eribulin or physicians' treatment of choice. Patients treated with eribulin had an improvement in OS (13.1 vs 10.6 months; HR, 0.81; 95% CI, 0.66-0.99)⁽⁸³⁾. Asthenia, fatigue, and neutropenia were the most common side effects associated with eribulin. Peripheral neuropathy led to discontinuation of treatment in 5% of patients. Recently, a phase II study evaluated the efficacy and safety of eribulin in the treatment of HER2-negative MBC in the first-line setting⁽⁸⁴⁾. Fifty-six patients were treated, with the majority having received anthracycline- and/or taxane-containing chemotherapy in the adjuvant setting. The objective response rate was 29% (95% CI, 17.3%-42.2%), the clinical benefit rate was 52%, the median response duration was 5.8 months, and the median PFS was 6.8 months.

Combination Chemotherapy

Anthracycline-Based Combination Regimens

Doxorubicin-containing combinations result in overall response rates ranging from 50% to 80%, with response durations of 8 to 15 months. The median survival with doxorubicin-alkylating agent combinations was 17 to 25 months. Although doxorubicin-containing regimens are more efficacious in the metastatic setting than are non-doxorubicin-containing combinations, anthracycline-based combinations are not commonly used because of the associated side effects.

As was discussed previously, the issue of whether combination chemotherapy is superior to single-agent

chemotherapy in the treatment for MBC continues to be debated. For patients with rapidly progressing disease, treatment regimens most likely to produce an objective tumor response are highly desirable; therefore, there is still an important role for the use of combination chemotherapy. For many years, FAC (500/50/500 mg/m²) was the standard regimen for patients with MBC treated at MDACC. Several randomized clinical trials have compared different anthracycline-based chemotherapy regimens in patients with MBC. Nabholz et al^(85, 86) compared the use of docetaxel/doxorubicin/cyclophosphamide (TAC; 75/50/500 mg/m²) with FAC as first-line therapy for MBC (n = 484). The objective response rate was 55% with TAC and 44% with FAC ($P = .02$; HR, 1.5; 95% CI, 1.1-2.2). There was no significant difference in TTP or OS between treatment arms. Febrile neutropenia occurred more frequently with TAC than FAC (29% vs 5%), but similar rates of infection were seen. Carmichael et al reported the results of a trial comparing epirubicin and cyclophosphamide (EC) with epirubicin and paclitaxel (EP) in patients with MBC⁽⁸⁷⁾. A total of 705 patients received up to six cycles of therapy. The objective response rate was higher with EP (67%) than with EC (56%). However, the TTP and OS were similar between the treatment arms. Doxorubicin and cyclophosphamide (AC) were compared to doxorubicin and docetaxel (AT) in 429 patients with MBC⁽⁸⁸⁾. The AT regimen significantly improved the TTP (37.9 vs 31.9 weeks, $P = .014$) and overall response rate (59% vs 47%, $P = .008$) compared with AC, but there was no difference in OS. The AT regimen is a valid option for the treatment of MBC.

Platinum-Based Combination Regimens

As single agents, the platinum salts (primarily cisplatin and carboplatin) have had relatively limited use in the treatment of MBC. Platinum compounds have been reserved for third-line therapy or beyond. Objective responses in this setting are less than 10%⁽⁸⁹⁾. In a limited number of trials of cisplatin or carboplatin first-line chemotherapy for MBC, objective responses were up to 50%⁽⁸⁹⁾. The availability of many active chemotherapeutic regimens and the significant toxicities associated with platinum compounds resulted in their being largely used in the salvage setting. With the introduction of newer cytotoxic agents and preclinical data demonstrating their synergy with platinum compounds, there is renewed interest in incorporating the platinum compounds into regimens for MBC. The major reason for the revival of interest in platinum compounds is a greater understanding of the sensitivity of cells with homologous recombination deficiency, especially those with *BRCA* mutations, to platinum. Platinum monotherapy or platinum-based

combinations are being widely tested in primary breast cancer and MBC in *BRCA* mutation carriers. By extrapolation, there is also much interest in testing platinum-based therapies in patients with triple-negative breast cancer and in those with HER+ tumors because in vitro synergy has been shown with anti-HER2 therapy in experimental models.

Phase II trials have been reported with the combination of paclitaxel and cisplatin. As first-line therapy for MBC, overall response rates have ranged from 50% to 90%. Trials evaluating this combination as second- or third-line therapy reported response rates of 30% to 50%⁽⁸⁹⁾. These results suggest that the combination of cisplatin and paclitaxel produces response rates higher than those expected with paclitaxel alone. Perez et al reported on the combination of paclitaxel (200 mg/m²) and carboplatin (area under the curve [AUC] 6 every 3 weeks) as first-line treatment of MBC⁽⁹⁰⁾. In 53 patients, an overall response rate of 62% was observed, including a complete response rate of 16%. The median TTP was 7.3 months, with a 1-year survival rate of 72%. A similar trial combining paclitaxel (175 mg/m²) and carboplatin (AUC 6) administered every 3 weeks⁽⁹¹⁾ reported an objective response rate of 43% (14% complete response rate); the objective response rate was higher among patients who had received prior adjuvant therapy (76% vs 45%). A phase II study examined the combination of a platinum compound and docetaxel⁽⁹²⁾. Among this previously treated group of patients, the overall response rate was 61%, the median duration of response was 8 months, and the median TTP was 10 months.

The activity of the cisplatin/gemcitabine combination in MBC had been explored with promising results. In one trial, patients previously treated with an anthracycline and/or taxane received cisplatin (30 mg/m²) plus gemcitabine (750 or 1,000 mg/m²) on days 1, 8, and 15 of 21-day cycles. The objective response rate was 50%, with 10% of patients attaining a complete response. The most common toxicities were peripheral neuropathy, nausea/vomiting, and hematologic toxicities (neutropenia, thrombocytopenia, and anemia)⁽⁹³⁾. In a trial evaluating cisplatin 25 mg/m² on days 1 through 4 and gemcitabine 1,000 mg/m² on days 2 and 8 of a 21-day cycle, patients (n = 136) were divided in two cohorts according to prior treatments (heavily pretreated and not heavily pretreated). The response rate for both of the cohorts was 26%, and the median durations of response were 5.3 and 5.9 months, respectively⁽⁹⁴⁾.

Platinum agents may prove to have a specific role in the treatment of triple-negative breast cancers, particularly in tumors harboring *BRCA* dysfunction. In preclinical and clinical studies, mutations in *BRCA* have greater sensitivity to DNA-damaging chemotherapeutic agents, such as platinum agents. Several studies are

evaluating the safety and efficacy of platinum-based chemotherapy in combination with novel agents, particularly poly(ADP-ribose)polymerase (PARP) inhibitors. Given the similarities between triple-negative tumors and tumors harboring *BRCA1* mutations, a large phase III study evaluated the combination of gemcitabine and carboplatin versus gemcitabine, carboplatin, and iniparib. The overall response rate for 258 patients treated with gemcitabine plus carboplatin was 33.7%, with a median PFS of 4.1 months and median OS of 11.1 months⁽⁹⁵⁾. Unfortunately, iniparib was not an active PARP inhibitor, and the trial did not meet its primary end point. A recent meta-analysis evaluated four studies of platinum-based combination chemotherapy in the metastatic setting⁽⁹⁶⁾. The overall response rates were comparable, but patients with triple-negative breast cancer treated with platinum agents had longer PFS. At present, we believe there may be a benefit in the use of platinum-based chemotherapy in all patients with triple-negative breast cancer regardless of *BRCA* status. Ongoing clinical trials will help clarify whether the majority of the benefit is derived from the efficacy of the platinum agents among *BRCA* mutation carriers.

Gemcitabine in Combination With Other Agents

Several phase II trials have investigated salvage therapy with docetaxel/gemcitabine combinations in MBC. Drug doses and schedules varied. Among previously treated patients, the objective response rates ranged from 36% to 79%. In a phase III study, the combination of gemcitabine (1,250 mg/m² on days 1 and 8) and paclitaxel (175 mg/m² on day 1) was associated with an improvement in response rate and TTP compared with paclitaxel alone (39.3% vs 25.6% and 5.4 vs 3.5 months, respectively) as first-line therapy for MBC⁽⁹⁷⁾. Median OS was also significantly improved with the combination (18.6 vs 15.8 months; HR, 0.77; 95% CI, 0.62-0.95). There was more frequent grade 4 hematologic toxicity with the combination. Of note, most patients randomized to paclitaxel alone did not receive subsequent gemcitabine.

A phase III European trial found no difference between gemcitabine-docetaxel (1,000 mg/m² on days 1 and 8 and 75 mg/m² on day 1) and capecitabine-docetaxel (1,250 mg/m² twice a day on days 1-14 and 75 mg/m² on day 1)⁽⁹⁸⁾. Similar PFS, OS, and response rates were seen. The toxicity profile for the gemcitabine-docetaxel combination was better.

Vinorelbine-Based Combination Regimens

A trial of single-agent doxorubicin compared to doxorubicin plus vinorelbine failed to demonstrate a superior response rate with the combination⁽⁹⁹⁾.

Vinorelbine has been successfully combined with taxanes. There are no phase III trials to confirm that these combinations are better than either single agent. Phase II studies combining vinorelbine and paclitaxel in MBC have been reported⁽¹⁰⁰⁾. The overall response rates with first-line vinorelbine/paclitaxel are 49% to 60%. The overall response rates for second-line vinorelbine/paclitaxel and vinorelbine/docetaxel are 46% to 56% and 37% to 59%, respectively. Toxicities associated with vinorelbine/taxane combinations were myelosuppression and mild neurotoxicity⁽¹⁰⁰⁾.

Capecitabine Combination Regimens

In September 2001, the FDA approved capecitabine in combination with docetaxel for patients with MBC previously treated with an anthracycline. This was based on the results of a multinational phase III trial that randomized 511 anthracycline-refractory patients to receive docetaxel 100 mg/m² or capecitabine 1,250 mg/m² twice daily for 14 days plus docetaxel 75 mg/m² intravenously every 3 weeks⁽¹⁰¹⁾. The response rates for the single-agent and combination regimens were 30% and 42%, respectively ($P = .006$). The TTP was 4.2 and 6.1 months, respectively ($P = .0001$). The OS was significantly superior with the combination (HR, 0.775; 95% CI, 0.63-0.94). This is one of the few randomized trials that reported a survival benefit of one treatment over the other, but the design of the trial does not confirm that the combination is better than the sequential administration of single-agent docetaxel followed by capecitabine, or vice versa. Grade 3 treatment-related adverse events were more common with the combination versus docetaxel alone (71% vs 49%, respectively), but overall, the incidence of treatment-related adverse events was similar between the two groups (98% vs 94%, respectively).

Capecitabine in combination with ixabepilone has been approved for the management of resistant MBC or MBC progressing after anthracyclines and taxanes. The trial that led to the approval of this combination randomized 752 patients to ixabepilone (40 mg/m² intravenously every 3 weeks) plus capecitabine (2,000 mg/m² on days 1-14 of a 21-day cycle) or capecitabine alone (2,500 mg/m² on the same day schedule)⁽¹⁰²⁾. Patients receiving the combination had a 25% reduction in the estimated risk of disease progression (HR, 0.75; 95% CI, 0.64-0.88). Median PFS (5.8 vs 4.2 months) and response rate (35% vs 14%) were also higher with the combination. Grade 3 or 4 treatment-related sensory neuropathy, fatigue, and neutropenia were more frequent with combination therapy, as was the rate of death as a result of toxicity (3% vs 1%). Patients with liver dysfunction were at higher risk of complications and therefore should not be treated with this regimen. Despite its toxicity, this combination

represents a good alternative for patients with resistant disease previously treated with anthracyclines and taxanes and in whom a fast response is needed.

TARGETED THERAPIES

HER2/neu-Targeted Therapies

Since the introduction of anti-HER2 therapies to the treatment armamentarium of breast cancer, the outcome of patients with HER2-positive breast cancers has dramatically changed. The use of these therapies is now an integral part of the standard treatment of this subset of patients. For many years, the use of trastuzumab and a taxane was considered as the optimal first-line therapy among patients with MBC. In the past 2 years, the treatment algorithm of patients with HER2-positive MBC has dramatically changed as a result of the introduction of pertuzumab and T-DM1. In the following sections, we will review the most relevant data associated with the different anti-HER2 therapies. At MDACC, the use of trastuzumab, pertuzumab, and a taxane is considered the best regimen, and we use it as first-line therapy, followed by T-DM1 at the time of progression. For third- or fourth-line treatment, a number of different agents can be used. Commonly, we use trastuzumab and lapatinib, lapatinib and capecitabine, or another single chemotherapeutic agent in combination with trastuzumab.

Trastuzumab

The HER2/neu protein, a receptor tyrosine kinase, is overexpressed in 25% to 30% of human breast cancers and plays an important role in tumor development and progression. Trastuzumab (Herceptin) is a murine-human chimeric monoclonal antibody targeted against the HER protein. Trastuzumab was evaluated in two pivotal trials in women with HER2/neu-overexpressed MBC. In one trial, trastuzumab (4 mg/kg loading dose, then 2 mg/kg weekly) was evaluated as a single agent in 222 heavily pretreated women with MBC (¹⁰³). Nine (4%) of 213 treated patients achieved complete response, and 37 (17%) achieved partial response. The median duration of response was 9.1 months. For all treated patients, the median TTP was 3.1 months, and the median OS was 13 months. The most clinically significant adverse event was cardiac dysfunction, which occurred in 10 patients (4.7%), nine of whom had received prior anthracycline therapy. This trial demonstrated that trastuzumab can induce durable objective responses and is associated with an acceptable toxicity profile. The second pivotal trial evaluated the use of chemotherapy with or without trastuzumab in 469 patients who had not received prior chemotherapy for metastatic disease (¹⁰⁴). Women who had received

an anthracycline in the adjuvant setting received paclitaxel 175 mg/m² every 3 weeks. All of the other patients received doxorubicin 60 mg/m² or epirubicin 75 mg/m² plus cyclophosphamide 600 mg/m² every 3 weeks. Trastuzumab 2 mg/kg (after a 4 mg/kg loading dose) was administered weekly until disease progression. The combination of chemotherapy plus trastuzumab resulted in a significantly higher objective response rate than chemotherapy alone (50% vs 32%). Women in the chemotherapy plus trastuzumab arm also had a significantly longer TTP and OS than those treated with chemotherapy alone. Symptomatic or asymptomatic cardiac dysfunction was seen in 27% of women treated with concurrent anthracycline/cyclophosphamide and trastuzumab. Based on the results of this trial, the FDA approved the combination of paclitaxel and trastuzumab as first-line therapy for HER2-overexpressed MBC.

The combination of trastuzumab and docetaxel has a high level of activity and an acceptable toxicity profile (^{105, 106}). When docetaxel (100 mg/m² every 3 weeks) with or without trastuzumab (4 mg/kg loading dose followed by 2 mg/kg weekly) was evaluated, the combination was significantly superior to docetaxel alone in terms of overall response rate (61% vs 34%; $P = .0002$), OS (31.2 vs 22.7 months; $P = .032$), TTP (11.7 vs 6.1 months; $P = .0001$), and duration of response (11.7 vs 5.7 months; $P = .009$). There was little difference in the number and severity of adverse events between the arms.

Given the success of the trastuzumab and paclitaxel combination, trastuzumab has been combined with other active agents against breast cancer (¹⁰⁷). A multicenter phase III study comparing trastuzumab/vinorelbine to trastuzumab/taxane (TRAVIOTA study) randomized 81 patients to receive trastuzumab with weekly vinorelbine or weekly taxane therapy (paclitaxel or docetaxel at the investigator's choice) (¹⁰⁸). Response rates were 51% and 40% for the vinorelbine/trastuzumab arm and the taxane/trastuzumab arm, respectively. The median times to disease progression were 8.5 and 6.0 months, respectively ($P = .09$). Treatment with either regimen was well tolerated. Trastuzumab has also been safely combined with other agents. The trastuzumab/gemcitabine combination provides response rates of 30% to 44% in heavily pretreated patients. For patients who had disease progression on anthracyclines, taxanes, and vinorelbine, the combination of capecitabine (1,250 mg/m² divided twice a day for 14 days) and trastuzumab was shown to be very effective (^{109, 110}). In different trials, the response rates were between 20% and 45% with clinical benefit rates of 70% to 85%. The safety profile of the combination was favorable and predictable, with a low incidence of grade 3 or 4 adverse events. This supports the use of the combination of capecitabine and

trastuzumab in heavily pretreated MBC patients with tumors that have *HER2* overexpression.

A number of trials evaluated triplet combinations. A phase III clinical trial evaluated the combination of trastuzumab/paclitaxel/carboplatin (TPC; trastuzumab 4 mg/kg loading dose followed by 2 mg/kg weekly, paclitaxel 175 mg/m², and carboplatin AUC 6 every 21 days) versus trastuzumab/paclitaxel. The triple combination arm had statistically significant improved response rates and PFS. Both treatments were well tolerated, but more cases of grade 4 neutropenia were seen in the triple combination arm ⁽¹¹¹⁾.

Pertuzumab

Pertuzumab is a humanized anti-*HER2* monoclonal antibody approved by the FDA in 2012 for the treatment of advanced or late-stage (metastatic) *HER2*-positive breast cancer. Compared with trastuzumab, pertuzumab binds to a different extracellular dimerization subdomain of the *HER2* receptor to inhibit signaling, thereby resulting in the reduction of tumor cell proliferation, invasiveness, and survival. The combination of pertuzumab, trastuzumab, and docetaxel was shown to have efficacy in the first-line treatment of *HER2*-positive MBC in a randomized trial known as the CLEOPATRA study ⁽¹¹²⁾. In this study of 800 patients, the addition of pertuzumab resulted in a PFS benefit of 18.5 months versus 12.4 months for the control group (HR, 0.62; 95% CI, 0.51-0.75; $P < .001$). At a median follow-up of 50 months, the addition of pertuzumab significantly improved median OS by 15.7 months (40.8 vs 56.5 months; HR, 0.68; 95% CI, 0.56-0.84; $P = .0002$), with a benefit consistently seen across all subgroups. The side effects profile was comparable between the two groups, although the rates of febrile neutropenia and diarrhea of grade ≥ 3 were higher in the pertuzumab arm. The combination of pertuzumab and trastuzumab was evaluated in a phase II study of 66 patients with progressive metastatic disease in the setting of prior trastuzumab exposure ⁽¹¹³⁾. The overall response rate was 24.2% and PFS was 5.5 months, with 17 patients experiencing stable disease for greater than 6 months. An ongoing study is evaluating the role of pertuzumab in patients with disease progression on trastuzumab, through a randomized phase II trial of trastuzumab/capecitabine alone or with pertuzumab for *HER2*-positive MBC progressing during or after trastuzumab-based first-line therapy ⁽¹¹⁴⁾. A nonrandomized phase II study is evaluating the efficacy of pertuzumab in combination with paclitaxel and trastuzumab in patients treated with up to one prior regimen for MBC, allowing for prior trastuzumab either in the metastatic or adjuvant setting (NCT01276041).

T-DM1

Ado-trastuzumab emtansine (T-DM1; Kadcyla) is the first *HER2*-antibody drug conjugate, combining trastuzumab with a linked antimicrotubule drug, maytansine (DM1). The FDA approved it in 2013 for the treatment of patients with metastatic *HER2*-positive breast cancer previously treated with trastuzumab and taxanes. The initial phase I study conducted in heavily pretreated patients with *HER2* overexpression showed clinical activity, leading to a single-arm phase II study in 112 patients who progressed on trastuzumab, lapatinib, or both. A response rate of 25.9%, clinical benefit rate of 34%, and PFS of 4.6 months were observed ⁽¹¹⁵⁾. Hypokalemia (8.9%), thrombocytopenia (8%), and fatigue (4.5%) were the most common grade 3 or 4 toxicities. The EMILIA trial was an open-label, phase III study comparing T-DM1 versus capecitabine/lapatinib in trastuzumab pretreated *HER2*-positive patients with advanced/metastatic breast cancer ($n = 980$) ⁽¹¹⁶⁾. A significant improvement in PFS was observed with T-DM1 (9.6 vs 6.4 months; HR, 0.650; 95% CI, 0.549-0.771; $P < .0001$). The OS at 2 years was 65.4% with T-DM1 compared to 47.5% with capecitabine/lapatinib. An added benefit is the favorable safety profile of T-DM1 and the potential role of T-DM1 in treating brain metastasis. A phase II trial evaluated the role of treatment with T-DM1 in the first-line setting as compared to trastuzumab and docetaxel, resulting in an improvement in PFS ⁽¹¹⁷⁾. At a median follow-up of 14 months, the median PFS was 9.2 months with trastuzumab plus docetaxel and 14.2 months with T-DM1 (HR, 0.59; 95% CI, 0.36-0.97). The overall response rate with T-DM1 was 64.2% (95% CI, 51.8%-74.8%) versus 58% (95% CI, 45.5%-69.2%) with trastuzumab plus docetaxel. In the TH3RESA trial, 602 patients previously treated with two or more *HER2*-directed therapies were randomized to receive T-DM1 or treatment of physician's choice ⁽¹¹⁸⁾. The PFS was significantly improved with T-DM1 compared with physician's choice (median, 6.2 vs 3.3 months; HR, 0.528; 95% CI, 0.422-0.661; $P < .0001$). An interim OS analysis showed a trend favoring T-DM1. A lower incidence of grade 3 or worse adverse events was reported with T-DM1 than with physician's choice treatment.

The MARIANNE trial is a phase III randomized trial evaluating the efficacy of T-DM1 with or without pertuzumab compared with trastuzumab plus taxane for first-line treatment of *HER2*-positive MBC (NCT01120184). A second phase III trial is seeking to compare T-DM1 to physician's choice of treatment in patients with *HER2*-positive unresectable locally advanced or metastatic breast cancer treated with at least two prior anti-*HER2* regimens (NCT01419197). Finally, a phase IB/II trial is evaluating the role of T-DM1 in combination with pertuzumab in patients

with HER2-positive advanced breast cancer previously treated with trastuzumab ⁽¹¹⁹⁾.

Lapatinib

Lapatinib (Tykerb) is a selective, reversible dual EGFR-HER2 inhibitor. Phase II trials of single-agent lapatinib have shown modest clinical benefit in patients with HER2-positive breast cancer. Lapatinib in combination with capecitabine was approved by the FDA in 2007 for the treatment of advanced or HER2-overexpressing MBC previously treated with an anthracycline, a taxane, and trastuzumab. The trial that led to the approval showed that patients treated with lapatinib and capecitabine had a significant increase in PFS compared to capecitabine alone ⁽¹²⁰⁾. The study was closed prematurely because the first interim analysis showed that the addition of lapatinib was associated with a 51% reduction in the risk of disease progression. The median TTP for patients treated with lapatinib plus capecitabine compared with capecitabine plus placebo was 8.4 versus 4.4 months (HR, 0.49; 95% CI, 0.34-0.71). In a phase II study of patients with HER2-positive breast cancer and brain metastasis treated with lapatinib, 6% of patients had an objective response, defined as ≥50% volumetric reduction of the brain metastasis ⁽¹²¹⁾, suggesting that lapatinib could be of help in the treatment of patients with central nervous system metastasis.

Preclinical studies have shown a synergistic interaction between trastuzumab and lapatinib in HER2-overexpressing breast cancer cell lines and tumor xenografts. Results of a randomized phase III trial combining lapatinib with trastuzumab compared with lapatinib alone in heavily pretreated HER2-positive MBC (n = 296) demonstrated synergy and improved response rates and PFS in the combination arm. Despite a high crossover rate, there was a significant

improvement in OS with the lapatinib and trastuzumab combination (HR, 0.71; 95% CI, 0.54-0.93) ⁽¹²²⁾.

Lapatinib has also been combined with hormonal agents. In a preclinical model, lapatinib restored tamoxifen sensitivity in tamoxifen-resistant breast cancer ⁽¹²³⁾. The EGF3008 trial, a phase III study combining letrozole plus lapatinib versus letrozole, demonstrated a 29% reduction in risk of disease progression and an improvement in median PFS ⁽¹²⁴⁾. A summary of some of the trials evaluating different anti-HER2 therapies is shown in Table 28-3.

OTHER AGENTS

Vascular Endothelial Growth Factor–Targeted Therapies

Bevacizumab

Bevacizumab (Avastin), a monoclonal antibody against all vascular endothelial growth factor (VEGF)-A isoforms has single-agent response rates of 9% in patients with refractory MBC. In a randomized phase III trial comparing capecitabine with or without bevacizumab in patients previously treated with an anthracycline and a taxane, the addition of bevacizumab produced a significant increase in response rates but no improvement in PFS or OS ⁽¹²⁵⁾.

The ECOG 2108 trial randomized 680 patients with previously untreated locally recurrent breast cancer or MBC to receive weekly paclitaxel (90 mg/m² on days 1, 8, and 15) with or without bevacizumab (10 mg/kg on days 1 and 15) in 4-week cycles until progression ⁽¹²⁵⁾. The overall response rate (29.9% vs 13.8%, *P* = .0001) and the PFS (11.4 vs 6.11 months; HR, 0.51; 95% CI, 0.43-0.62) were significantly better with combination therapy; no OS differences were seen. Based on this trial, the combination of bevacizumab and paclitaxel was approved for first-line therapy of MBC. Several phase III studies using bevacizumab combined with different chemotherapy agents have shown improvements in PFS but failed to demonstrate a survival benefit with the addition of bevacizumab. Based on these studies, the FDA revoked the indication of bevacizumab in breast cancer. At MDACC, we have occasionally continued to use bevacizumab in addition to paclitaxel in very selected patients who need to achieve a rapid response and in whom the benefits associated with bevacizumab use outweigh the risks.

Bone Agents

Bisphosphonates are analogs of pyrophosphates that bind to hydroxyapatite crystals and inhibit bone resorption by osteoclasts. They are widely used to

Table 28-2 Clinical Predictors of Improved Response to Chemotherapy for Metastatic Breast Cancer

- Low tumor burden
- Normal organ function
- Normal blood count
- Good performance status
- No recent weight loss
- No prior chemotherapy or radiation therapy
- Softtissue metastases
- Premenopausal status
- Prolonged disease-free interval after adjuvant chemotherapy
- Negative estrogen receptor

Table 28-3 Phase II and III Trials of HER2/neu-Targeted Therapies for Treatment of Metastatic Breast Cancer

Trial	No. of Patients	Patient Population	Regimen	Response	Patient Outcome
Trastuzumab					
Slamon ^(125a) et al (H0648g) Phase III	469	HER2+, first-line setting	1. Trastuzumab/ paclitaxel 2. Paclitaxel 3. Trastuzumab/ AC 4. AC	ORR = 50% (chemotherapy + trastuzumab)	Addition of trastuzumab to chemotherapy was associated with a longer time to disease progression (median, 7.4 vs 4.6 mo; $P < .001$), longer duration of response (median, 9.1 vs 6.1 mo; $P < .001$), higher rate of objective response (50% vs 32%; $P < .001$), lower rate of death at 1 yr (22% vs 33%; $P = .008$), longer survival (median, 25.1 vs 20.3 mo; $P = .046$), and 20% reduction in risk of death. Most important adverse event was cardiac dysfunction, occurring in 27% of the group given AC/trastuzumab, 8% of group given AC, 13% of group given paclitaxel/trastuzumab, and 1% of group given paclitaxel alone.
Andersson (HERNATA) Phase III	141	HER2+, first-line setting, included if completed adjuvant/neoadjuvant therapy at least 12 mo prior to diagnosis (accepted if included trastuzumab)	1. Trastuzumab/ vinorelbine 2. Trastuzumab/ docetaxel	PR = 48.3% CR = 11% ORR = 50.3% (trastuzumab/vinorelbine)	The PFS for trastuzumab/docetaxel vs trastuzumab/vinorelbine was 12.4 vs 15.3 mo (HR, 0.94; 95% CI, 0.71-1.25; $P = .67$).
Inoue Phase III	107	HER2+, first-line setting	1. Trastuzumab/ docetaxel 2. Trastuzumab followed by trastuzumab/ docetaxel	PR = 35% CR = 1% ORR = 36% (trastuzumab/docetaxel)	The PFS of trastuzumab followed by trastuzumab/docetaxel vs trastuzumab/docetaxel was 3.7 vs 14.6 mo (HR, 4.24; 95% CI, 2.48-7.24; $P < .01$). OS was significantly longer in the trastuzumab/docetaxel group (HR, 2.72; $P = .04$). Study was terminated early given significant benefit in the trastuzumab/docetaxel group.

(Continued)

Table 28-3 Phase II and III Trials of HER2/neu-Targeted Therapies for Treatment of Metastatic Breast Cancer (Continued)

Trial	No. of Patients	Patient Population	Regimen	Response	Patient Outcome
Kaufman (TAnDEM) Phase III	207	Postmenopausal, HER2+, ER positive and/or progesterone receptor positive, first-line setting, accepted if previously treated with tamoxifen as adjuvant therapy for hormonal therapy (completed >6 mo from diagnosis), with anastrozole initiated up to 4 wk prior to assignment	1. Trastuzumab/anastrozole 2. Anastrozole	PR = 15% CR = 0% ORR = 73% (trastuzumab/vinorelbine)	The PFS for trastuzumab/anastrozole vs anastrozole was 5.6 vs 3.9 mo (HR, 0.62; 95% CI, 3.8-8.3; $P = .006$), with a TTP of 4.8 vs 2.4 mo (HR, 0.63; 95% CI, 0.47-0.84). There was a higher incidence of grade 3 or 4 AEs in the trastuzumab/anastrozole arm (23% vs 5%). However, no specific grade 3 or 4 AEs occurred in more than three patients in the trastuzumab/anastrozole arm. Grade 4 AEs included hypercalcemia, dyspnea, lower respiratory tract infarction, and myocardial ischemia.
Pertuzumab					
Baselga (CLEOPATRA) Phase III	808	HER2+, first-line setting, included if completed adjuvant/neoadjuvant therapy at least 12 mo prior to diagnosis (accepted if included trastuzumab)	1. Pertuzumab/trastuzumab/docetaxel 2. Trastuzumab/docetaxel/placebo	PR = 65.2% CR = 4.2% ORR = 69.3% (pertuzumab/trastuzumab/docetaxel)	The PFS for pertuzumab/trastuzumab/docetaxel vs trastuzumab/docetaxel/placebo was 18.5 vs 12.4 mo (HR, 0.62; 95% CI, 0.51-0.75; $P < .001$), with an improvement in OS of 15.7 mo (56.5 vs 40.8 mo; HR, 0.68; 95% CI, 0.56-0.84; $P = .0002$). The safety profile was generally similar in the two groups with no increase in left ventricular systolic dysfunction. The rates of febrile neutropenia (56% vs 30%) and diarrhea (32% vs 20%) of grade ≥ 3 were higher in the pertuzumab group than in the control group.

T-DM1					
Verma (EMILIA) Phase III	991	HER2+, previous progression on taxane and trastuzumab	1. T-DM1 2. Lapatinib/capecitabine	1. PR = 42.6% 2. CR = 4% 3. ORR = 43.6% (T-DM1)	The PFS for T-DM1 vs lapatinib/capecitabine was 0.4 vs 5.8 mo (HR, 0.66; 95% CI, 0.56-0.77; $P < .001$). The incidence rates of AEs of grade ≥ 3 were higher in the lapatinib/capecitabine group than in the T-DM1 group (57% vs 40.8%). Diarrhea and palmar-plantar erythrodysesthesia were the most commonly reported grade 3 or 4 events in the lapatinib/capecitabine group (20.7% and 16.4%, respectively). The most commonly reported grade 3 or 4 events with T-DM1 were thrombocytopenia (12.9%) and elevated AST/ALT (4.3% and 2.9%, respectively).
Lapatinib					
Johnston Phase III	1,286	HR+/HER2–or HR+/HER2+	1. Lapatinib/letrozole 2. Letrozole/placebo	ORR = 48% (lapatinib/letrozole)	HR+/HER2–: no significant treatment benefit on PFS (HR, 0.90; 95% CI, 0.77–1.05). Subgroup analysis of patients with HER2– and lower expression of ER had significant improvement in median PFS (13.6 vs 6.6 mo; HR, 0.65; 95% CI, 0.47–0.9) when treated with combination therapy. HR+/HER2+: The PFS was 8.2 for the letrozole/lapatinib arm versus 3 months for the letrozole alone arm versus 3 months for the lapatinib arm. Significant improvement in clinical benefit rate for the combination arm.
Blackwell Phase III	296	HER2+, anthracycline, taxane, capecitabine, trastuzumab refractory	1. Lapatinib/trastuzumab 2. Lapatinib	PR = 10.3% ORR = 24.7% (lapatinib/trastuzumab)	PFS in the combination arm versus lapatinib arm was 12.0 vs 8.1 mo (HR, 0.73; 95% CI, 0.57–0.93); OS was also improved (14.0 vs 9.5 mo; HR, 0.74; 95% CI, 0.57–0.97).

AC, doxorubicin and cyclophosphamide; AE, adverse event; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CI, confidence interval; CR, complete response; ER, estrogen receptor; HER2, human epidermal growth factor receptor; HR, hormone receptor; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; PR, partial response; TTP, time to progression.

prevent skeletal complications in patients with bone metastases. Clinical trials have shown that the use of pamidronate or zoledronic acid is associated with fewer skeletal-related events and pathologic fractures and less need for radiation therapy and surgery to treat bone pain, with some suggesting that zoledronic acid is superior ⁽¹²⁶⁾. During bisphosphonate treatment, monitoring of renal function is needed. Physicians should also be aware of the risk of developing osteonecrosis of the jaw, a rare but serious complication of bisphosphonate therapy. Trial results support the use of bisphosphonates for 2 years, but there are limited long-term safety data. The OPTIMIZE-2 trial evaluated the frequency of zoledronic acid administration in 403 women with bone metastasis who previously received at least nine doses of intravenous bisphosphonate. The study showed that giving zoledronic acid 4 mg intravenously every 3 months was as effective as giving it monthly, with a rate of skeletal-related events of 22% in the monthly group versus 23.2% in the every-3-months group. The less frequent dosing corresponded to lower rates of renal failure and osteonecrosis of the jaw ⁽¹²⁷⁾.

Denosumab is a fully human monoclonal antibody that targets RANK ligand, a protein that acts as the primary signal to promote bone removal. Denosumab is being used in the treatment of osteoporosis, treatment-induced bone loss, and bone metastases. A large (n = 2,033), randomized, placebo-controlled trial evaluated denosumab (120 mg subcutaneously) versus zoledronic acid (4 mg intravenously) in patients with MBC and bone metastases ⁽¹²⁸⁾. Denosumab was superior to zoledronic acid in delaying or preventing skeletal-related events and delayed or prevented hypercalcemia, radiation to bone, and bone pain, suggesting that monthly denosumab is a viable option for the management of bone metastases. An advantage of denosumab therapy is that it is given as a subcutaneous injection. At MDACC, all patients with MBC and bone metastasis who do not have a contraindication to receive bone agents are treated with zoledronic acid or denosumab.

INVESTIGATIONAL THERAPY

Despite therapeutic advances, the prognosis for many women with breast cancer is still poor. Investigational therapies for MBC include new molecules and agents with novel mechanisms of action.

In breast cancer, epidermal growth factor receptor (*EGFR*) plays a major role in promoting cell proliferation and malignant growth. Multiple studies evaluating the use of tyrosine kinase (TK) inhibitors in MBC are ongoing. Phase II studies of gefitinib (Iressa) used as a single agent or in combination with chemotherapy or endocrine therapy have been completed. Single-agent

gefitinib showed minimal clinical benefit; no improvement in response rates was seen when it was used in combination. An exploratory analysis of two randomized phase II trials compared anastrozole or tamoxifen plus gefitinib versus single-agent anastrozole or tamoxifen plus placebo ⁽¹²⁹⁾. In both trials, among endocrine-naïve patients, gefitinib was associated with improved PFS when combined with hormonal therapy compared to anastrozole or tamoxifen alone. Erlotinib (Tarceva) is a small molecule that reversibly inhibits the *EGFR* TK and prevents receptor autophosphorylation. Combinations of erlotinib with drugs known to be active in breast cancer have been conducted. In a dose-escalation study of capecitabine, docetaxel, and erlotinib in patients with MBC, the overall response rate was 67% ⁽¹³⁰⁾. The regimen was well tolerated; manageable skin and gastrointestinal problems were the most common treatment-related adverse effects.

Multikinase inhibitors that inhibit VEGF receptors are under investigation. Sunitinib malate (Sutent) is an oral TK inhibitor that targets several receptor TKs, including VEGFR-1, -2, and -3. In a phase II trial in MBC previously treated with anthracyclines and taxanes (n = 64), sunitinib was associated with a clinical benefit rate of 16% ⁽¹³¹⁾. In a phase II randomized study, 46 patients with HER2-negative MBC were randomized to receive paclitaxel (90 mg/m² weekly), bevacizumab (10 mg/kg every 2 weeks), and sunitinib (25 mg daily for 21 days) as first-line chemotherapy. High rates of dose modification and treatment discontinuation due to toxic effects were seen, leading to the study closure. In previously treated MBC patients, sunitinib (37.5 mg PO daily dose) was compared to capecitabine (n = 482); no differences in PFS or OS were seen, and capecitabine was better tolerated.

Sorafenib (Nexavar) has been evaluated in patients with MBC refractory to anthracyclines and taxanes. Results from the SOLTI-0701 trial evaluated the combination of sorafenib (400 mg PO bid) and capecitabine (1,000 mg/m² on days 1-14 of a 21-day cycle) versus capecitabine and placebo in HER2-negative MBC ⁽¹³²⁾. Similar response rates were seen (38.3% vs 30.7%), but improved PFS (6.4 vs 4.1 months, *P* < .001) was observed with sorafenib and capecitabine. The combination treatment was associated with a 45% rate of grade 3 hand-foot syndrome. The Trials to Investigate the Effects of Sorafenib in Breast Cancer program evaluated the combination of sorafenib and paclitaxel versus paclitaxel and placebo in the frontline setting. The TTP and overall response rate, but not PFS, were improved with the combination. There was also an increase in cases of grade 3 toxicities and an imbalance in the number of deaths due to unusual causes in the paclitaxel and sorafenib group. Other VEGF TK inhibitors such as vandetanib (Zactima), valatinib, and axitinib are currently being tested.

Ongoing research is evaluating insulin-like growth factor inhibitors (CP-751, 856, AMG-479, IMC-A12), RAS/MEK/ERK (tipifarnib), and PI3K/AKT/mTOR pathway inhibitors. The PARP inhibitors are agents that have shown promise, particularly in the setting of metastatic triple-negative breast cancer associated with *BRCA* mutations; PARP-1 is a critical enzyme of cell proliferation and DNA repair. In addition, PARP-1 and -2 are fundamental in the repair of single-stranded DNA breaks (¹³³). Olaparib, a PARP inhibitor, has shown single-agent activity in patients with *BRCA1/2* mutations, with little activity in sporadic breast cancer. Single-agent response rate was 41% in the phase I trial, with a median TTP of 5.7 months. Higher doses of 400 mg twice daily correlated with higher response rates. In a phase II randomized study of triple-negative MBC (n = 123), BSI-201 (iniparib) added to gemcitabine plus carboplatin showed significantly higher objective response rates and survival (¹³⁴). However, the phase III trial revealed modest improvement in PFS/OS that was not statistically significant. The phase III study (n = 519) compared chemotherapy alone versus chemotherapy plus iniparib in the treatment of triple-negative MBC (⁹⁵). Several studies of PARP inhibitors in the setting of *BRCA*-associated MBC are under way. At MDACC, we offer such patients clinical trials that include new and promising molecules.

LOCAL THERAPY

Retrospective studies have suggested a potential survival benefit from complete tumor excision in selected patients with MBC. Substantial selection biases exist in all of these reports that likely confound the results. Recently, two trials evaluated the role of locoregional therapies in women with MBC. In a trial by Indian investigators, 350 patients with MBC and intact primary tumor were randomized to mastectomy followed by complete axillary dissection and radiation therapy versus no locoregional treatment (¹³⁵). All patients received anthracyclines with or without taxanes, with stratification by hormone receptor status, metastatic site, and number of metastases. No difference in OS was noted in the surgical versus nonsurgical group at 72 months. Although the local PFS was better in the surgical group, distant PFS was worse. In a second trial conducted by Turkish investigators, no difference in OS at 40 months was noted between patients with MBC randomized to upfront surgery followed by chemotherapy and patients assigned to chemotherapy alone (¹³⁶). A subgroup analysis identified an apparent survival benefit in women with solitary bone metastases. In the United States, ECOG 2108 is a randomized phase III trial presently evaluating early local therapy for the intact primary tumor in patients with MBC

(NCT01242800). According to the most recent guidelines, patients with MBC and an intact primary should be treated systemically. Consideration for surgery for palliation is indicated in women with impending complications that may compromise quality of life such as skin ulceration, bleeding, fungation, and pain. Surgery in such cases should be performed only if complete local tumor resection can be achieved and if other disease sites are not immediately life threatening. Such surgery requires the collaboration between the breast surgeon and the reconstructive surgeon to provide optimal cancer control and wound closure. Alternatively, radiation therapy may be considered.

SUMMARY

Despite great advances in the treatment of MBC, this condition remains largely incurable, with a median survival of 2 to 3 years. The therapeutic concepts in MBC have changed with the realization that breast cancer is a conglomerate of several molecularly defined subtypes, each with a distinct prognosis, clinical course, and sensitivity to existing therapeutics. Treatment for MBC has dramatically evolved, incorporating new hormonal therapies, cytotoxic agents, and monoclonal antibodies. Refinements of chemotherapy with different combinations of newer agents along with modulating agents and growth factor support have allowed further advancement in the treatment of MBC. Despite great enthusiasm for targeted therapies, these agents have exhibited modest activity when used as single agents. A better understanding of the molecular biology of signaling pathways and the discovery of new biomarkers will help select patients who benefit from specific treatments.

Inflammatory Breast Cancer

Tamer M. Fouad
Vincente Valero
Naoto T. Ueno

Inflammatory breast carcinoma (IBC) is a very aggressive disease and accounts for less than 6% of all breast cancers in the United States. It is characterized by a rapidly progressive clinical course and diagnosed on the basis of distinct skin manifestations that are often confused with inflammation, hence its name. These manifestations include erythema, edema, skin nodules, and nipple retraction. A characteristic infiltration of the dermal lymphatics with tumor emboli is often seen by pathology but is not required to establish a diagnosis.

Although clinically more than 50% of patients do not have a detectable breast mass at the time of diagnosis, up to 85% have already metastasized disease that has spread to the regional lymph nodes, while more than 30% present with gross distant metastasis (¹). Not surprisingly, owing to its high metastatic potential, IBC is associated with a 5-year overall survival (OS) rate of no more than 55% (^{2,3}). Multimodality treatment in the form of neoadjuvant chemotherapy, surgery, and radiation aims to prevent metastatic failure as well as achieve local control.

EPIDEMIOLOGIC CHARACTERISTICS

The epidemiology of IBC has been a challenging area to study due to a number of factors. The rarity of the disease combined with its rapid progression and short OS mean that there are few single centers able to recruit an adequate sample of patients for investigation. In addition, confusion about its clinical definition has led to difficulties in comparing the results of different studies. As a result, the primary source of

epidemiologic data comes from large national registries, which are limited by nonuniform data collection, inability to capture comprehensive details on risk factors, and in the case of IBC, varying case definitions.

To address these issues, the Morgan Welch Inflammatory Breast Cancer Research Program and Clinic at the University of Texas, MD Anderson Cancer Center (MDACC) spearheaded the development of an international IBC Registry. The IBC Registry prospectively collects tissue, serum, plasma, whole blood, imaging, clinical, and epidemiological data from patients with IBC, allowing a more comprehensive examination of the underlying mechanisms associated with the development of this lethal disease.

Incidence

The incidence of IBC is reported to range from 1% to 6% of all breast cancers diagnosed in the United States (⁴). Higher proportions have been reported in North Africa, specifically in Tunisia and Egypt, where IBC accounts for 6% and 10% of all breast cancers, respectively (⁵⁻⁷). Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program have demonstrated a rise in the incidence of IBC over time, although this trend seems to be slowing. Between 1973 and 2002, the incidence of IBC is reported to have increased at an annual rate that ranged from 1.23% to 4.35% per year, depending on the specific database analyzed and the case definition used (^{4,8,9}). In comparison, during the same time period, breast cancer as a whole saw a slower rise of 0.42% per year (95% CI, 0.14% to 0.71%) (⁹).

Mortality

Inflammatory breast carcinoma is commonly lethal and associated with a high risk of early recurrence ⁽¹⁰⁾. Women diagnosed with IBC have a statistically significant poorer survival than women with noninflammatory locally advanced breast cancer (LABC) ($P < .001$), with a median OS of 2.9 years and a 5-year survival rate of 30% to 40% ^(4, 11). This was also true for patients presenting with stage IV disease. Patients with stage IV IBC had a shorter median OS than stage IV non-IBC (2.3 vs 3.4 years, $P = .004$) ⁽¹²⁾. Also, although IBC accounted for only 2.5% of all breast cancer cases in the period 1988 to 2000, it led to 7% of all breast cancer-specific deaths ⁽⁴⁾.

Higher mortality rates were reported for African American women, according to data from SEER, with a median survival of 2.0 versus 2.9 years when compared with Caucasians ($P < .001$) ^(4, 13). The early age at diagnosis and poor survival outcomes observed among African American patients with IBC suggests epidemiological differences between different ethnic groups that could involve an interplay of genetic, environmental, and lifestyle risk factors.

Earlier reports suggested a trend for a modest improvement in mortality rates for IBC ⁽⁴⁾. This trend was compared to a similar improvement seen in non-IBC and attributed to improvements in multidisciplinary treatment, the effect of new therapies, and an increasing awareness of IBC. However, more recently, this trend toward improved survival was not supported by retrospective data at our institution ⁽¹¹⁾. The authors looked at the survival of 398 women with IBC treated over a period of 30 years (between January 1974 and April 2005). After adjusting for patient and disease characteristics, Cox proportional hazards models did not show an association between year of diagnosis and the risk of recurrence or death.

RISK FACTORS

While clearly established risk factors have been associated with the development of non-IBC, this is not the case with IBC, which is much rarer and not consistently defined. For example, while family history, menopausal status, and age at menarche are important risk factors for the development of non-IBC, they have not been confirmed as risk factors for IBC. Despite these limitations, several important epidemiologic factors appear to be consistently associated with IBC (Table 29-1).

Age of Diagnosis

According to an analysis of breast cancer cases diagnosed in the SEER 9 Registries between 1988 and

Table 29-1 Risk Factors Associated With the Development of Inflammatory Breast Cancer

Risk Factor	Degree of Association
• Younger age at diagnosis	+++
• African American ethnicity	+++
• Increased body mass index (≥30)	+++
• North Africa	++
• Ever pregnant	+
• Younger age at live first birth	+
• Duration of breast feeding	+

2000 ($n = 180,224$), IBC developed at a younger age (median 57 years) when compared with non-IBC (61.9 years) ⁽⁹⁾. Young age at diagnosis was also seen in earlier population-based studies ^(8, 14, 15). In addition, these studies found that age of onset varied according to ethnicity, with African American women presenting at a younger age than Caucasians ⁽¹⁵⁾. Age at diagnosis also varied between genders, and men usually were diagnosed 10 years later than women (median 66.5 vs 57 years, $P < .001$) ⁽⁹⁾.

Ethnicity

African Americans have at least a 50% higher incidence of IBC than whites in the United States (3.1 vs 2.2 per 100,000 woman-years, $p < .001$) ⁽⁴⁾. The higher incidence of IBC in African Americans has been confirmed in four different population-based studies ^(4, 8, 14, 15). Three of these studies used the SEER dataset to cover different time periods; the fourth used the North American Association of Central Cancer Registries (NAACCR) database.

Moreover, African Americans were diagnosed at a younger age (median 55.2 vs 58.1 years) and had a poorer prognosis when compared with Caucasians. Of note, Hispanic women have the youngest mean age of onset of the disease (median 50.5 years) ⁽¹⁵⁾.

A recent SEER study that examined patients with breast cancer (IBC and non-IBC) diagnosed between 1990 and 2000 suggested that the inferior outcome seen in African American women was independent of stage or inflammatory status ⁽¹³⁾.

Body Mass Index

One of the most consistent risk factors associated with IBC is a high body mass index (BMI). In contrast to non-IBC, for which elevated BMI is a risk factor in postmenopausal patients only, high BMI is associated with IBC in both pre- and postmenopausal patients. In a case-comparison study conducted at

MDACC, patients with IBC weighed more (median weight 77.6 kg) than those with non-IBC (70.0 kg) or those with history of other cancers (68.0 kg) ⁽⁸⁾. After adjusting for other factors, women with the highest BMI (>26 kg/m²) had an increased risk for development of IBC compared to those with non-IBC (odds ratio 2.54). This was irrespective of menopausal status, age at menarche, or family history of breast cancer.

In the largest case-control study to evaluate the association between risk factors for breast cancer and the development of IBC, Schairer et al compared 617 patients with IBC to three reference groups: LABC ($n = 7,600$), noninflammatory breast cancer not involving the chest wall or skin ($n = 1,151$), and healthy controls ($n = 93,654$). They found that high BMI at diagnosis was associated with an increased risk of IBC irrespective of menopausal status or hormone receptor expression ⁽¹⁶⁾.

The impact of obesity and menopausal status on IBC survival was also evaluated in a cohort of 177 women patients with IBC seen at MDACC between 1974 and 1993. After adjusting for axillary lymph node involvement and chemotherapy protocol, premenopausal obese women had significantly worse survival compared to postmenopausal obese women (hazard ratio [HR] 1.51) ⁽¹⁷⁾. After stratifying by menopausal status, postmenopausal obese women had significantly worse survival than those who were not obese (HR 1.86). These findings suggest that factors associated with a higher BMI at diagnosis may contribute to shorter IBC survival among postmenopausal women but not premenopausal women, who were found to have poorer survival regardless of body size.

Finally, the prognostic value of BMI at diagnosis was evaluated in a retrospective study of 602 patients with LABC, which included a subset of patients with IBC (18%). Obese patients were more commonly associated with a diagnosis of IBC compared with overweight and normal or underweight groups ($p = .01$) ⁽¹⁸⁾. Patients with LABC who were obese or overweight had a significantly worse OS and relapse-free survival (RFS) and a higher incidence of visceral recurrence compared with normal/underweight patients.

Overall, these results are of great importance for IBC because obesity is a modifiable risk factor, and preventive strategies aimed at reducing obesity may yield significant rewards.

Geographic Location

The incidence of IBC has been observed to vary according to geographic location. Using the SEER program registries from 1992 to 2002, rates ranged from 2.064 per 100,000 woman-years in San Jose-Monterey (California) up to 3.042 cases per 100,000 in Los Angeles ⁽⁹⁾. Similarly, reports have suggested

that North Africa is associated with the highest rates in the world, with countries such as Tunisia and Egypt reporting proportions of 6% and 10% of all breast cancers, respectively ⁽⁵⁻⁷⁾. These variations are currently under study and may suggest underlying differences in environmental and lifestyle or genetic risk factors. Alternatively, differences in case definitions and the lack of specificity associated with clinical identification of IBC have somewhat limited the value of these comparisons.

Socioeconomic Position

Data suggest that socioeconomic position (SEP) can affect both the incidence and the outcome of IBC. Whereas the incidence of breast cancer overall has been associated with higher SEP, several studies have suggested a higher incidence rate of IBC among patients with lower SEP ^(13,16). Likewise, in a large, nested case-control study of patients identified from the Breast Cancer Surveillance Consortium database (1994-2009), the risk of developing IBC gradually decreased with increasing level of education ⁽¹⁶⁾.

On the other hand, differences in SEP are associated with different exposure patterns to risk factors and with differences in disease awareness and access to health care, leading to diagnostic delays, mismanagement, and potentially worse OS. This may explain why the association between lower SEP and poorer survival was not significant for IBC after adjustment for other prognostic factors ⁽¹⁶⁾.

Reproductive History

Although IBC is diagnosed at a younger age than non-IBC, there does not appear to be a consistent association between IBC and premenopausal status. Of the patients evaluated at MDACC, 49% of patients with IBC were premenopausal compared to 39% of non-IBC patients ⁽⁸⁾. Similarly, while patients with IBC presented with earlier age at menarche than patients with non-IBC (12.2 vs 12.7 years), this difference was not statistically significant. A study conducted in Pakistan did not show a significant difference in menopausal status among the various comparison groups, including IBC ⁽¹⁹⁾. Larger studies are required to establish relationships between IBC and menstrual history.

Early age at first birth has also been associated with the development of IBC. Women with aggressive breast cancer, including IBC, are more likely to have their first child before the age of 20 when compared to patients with nonaggressive breast cancer ⁽⁹⁾. A later age at first birth was associated with a reduced risk of developing IBC that was estrogen receptor (ER) negative compared to locally advanced and early breast cancer ⁽¹⁶⁾.

An association with pregnancy or lactation has been suggested in earlier reports⁽²⁰⁾. In a study by Bonnier et al, IBC accounted for approximately 21% to 26% of breast cancer tumors in patients who developed breast cancer during or after pregnancy⁽²¹⁾. Later studies reported that the risk of pregnancy seen with IBC was not different from the risk seen in non-IBC⁽²²⁾. Results from our group suggest that lack of breast-feeding history maybe associated with the development of specific IBC subtypes (ER+, triple negative). No association between oral contraceptive use and development of IBC has been found⁽⁸⁾.

Family History

Approximately 15% of women with breast cancer have a positive family history of breast cancer in a first-degree relative, while 5% to 10% of breast cancers are directly attributed to heredity. In a study comparing 68 patients with IBC and 143 patients with non-IBC seen at MDACC, 13% of patients with IBC reported a positive family history of breast cancer, compared with 8% of patients with non-IBC; this was not statistically significant⁽²³⁾. However, in a study conducted in Pakistan, 20% of patients with IBC reported a positive family history of breast cancer, compared to 5% in the non-IBC group, which was statistically significant⁽¹⁹⁾.

Using data from the Breast Cancer Surveillance Consortium database (1994-2009), Schairer et al also found that the presence of a first-degree family history of breast cancer was associated with increased risk of developing IBC (HR 1.6; 95% CI, 1.1 to 2.2)⁽¹⁶⁾.

Other Risk Factors

A host of other risk factors have been explored in IBC, including blood type and area of residence. A higher proportion of Tunisian patients with IBC have blood type A. In addition, a larger proportion of patients lived in rural locations⁽²⁰⁾. Smoking and alcohol use were not associated with a risk of developing IBC⁽²³⁾. Other studies have suggested a link between IBC and a variant of mouse mammary tumor virus⁽²⁴⁾. This relationship remains under investigation.

MOLECULAR PATHOGENESIS

Attempts to distinguish between IBC and non-IBC at the molecular level have so far not been successful. Inflammatory breast carcinoma shares some of the molecular characteristics associated with breast cancer in general, as well as some important differences.

Gene expression profiles: There has been no shortage of gene expression studies aimed at distinguishing IBC from non-IBC at the genomic level⁽²⁵⁻²⁷⁾. Although several gene expression studies of IBC tumors

have revealed useful and promising results, none has yielded an IBC-specific signature.

In breast cancer, the success associated with the identification of several gene expression subtypes of prognostic significance has led to their incorporation in the treatment strategy for women with nonmetastatic breast cancer⁽²⁸⁾. These molecular subtypes are classified into luminal (ER-related genes), *HER2* (*HER2*-related genes), and basal subtypes. Despite differences in their relative frequency, the molecular subtypes of IBC are similar to those expressed in non-IBC^(26,29). Likewise, there are no unique differences between triple-negative IBC and non-IBC at the messenger RNA gene expression level⁽³⁰⁾.

RhoC GTPase overexpression/loss of WNT1 Inducible Signaling Pathway Protein 3 (WISP3):

The transforming oncogene *RhoC* GTPase (guanosine triphosphatase) is one of the most upregulated genes in IBC and is found in 91% of IBC tumors compared to 38% in non-IBC tumors in some studies⁽³¹⁾. *RhoC* GTPase overexpression is thought to be involved in tumor invasion and increased expression of cyclin D1, vascular endothelin growth factor (VEGF), fibronectin, and caveolin-2⁽³¹⁾. The overexpression of *RhoC* GTPase, combined with the loss of the tumor suppressor gene *WISP3/WINT-1*, was found to characterize the IBC cell line SUM149 and is believed to be partially responsible for the aggressive phenotype of IBC tumors^(32,33).

E-cadherin overexpression: E-cadherin is a cell adhesion molecule that is lost in malignant progression and is thought to promote tumor cell metastasis. Loss of E-cadherin is considered to be a fundamental event in epithelial-mesenchymal transition (EMT) that is associated with tumor metastasis and stem cell-like phenotypes. Paradoxically, E-cadherin is overexpressed in IBC and appears to be necessary for tumor emboli formation by enhancing tumor cell-cell contact⁽³⁴⁾.

Increased expression of E-cadherin and nonsialylated mucin-1 (MUC1) has been identified in up to 100% of IBC tumors compared to 68% of non-IBC tumors in one study⁽³⁵⁾. In another study using a xenograft model, a 10- to 20-fold increased expression of E-cadherin and MUC1 was noted and thought to contribute to the passive dissemination of tumor emboli in IBC⁽³⁶⁾. Dual overexpression of these two proteins in IBC is thought to play a role in the aggressive, invasive nature of IBC⁽³⁷⁾.

p53 mutation: In breast cancer, studies have linked p53 mutation to worse prognosis⁽³⁸⁾. In a study performed at MDACC, p53 overexpression was noted in up to 58% of IBC tumors and was independent of histologic grade⁽³⁹⁾. Patients with p53 overexpression were younger (median age 45.2 vs 52.2 years; $P = .02$) and had lower 5-year progression-free survival rates (35% vs 55%; $P = .03$) and 5-year OS rates (44% vs 54%; $P = .4$). Patients with tumors overexpressing p53 had an 8.6-fold higher risk of death in multivariate analysis. These results were in line with previous studies⁽⁴⁰⁾.

Angiogenesis: Inflammatory breast carcinoma is a vascular tumor with overexpression of lymphangiogenic factors such as VEGF and Flt-4^(34, 41). A significantly higher intratumoral microvessel density has been reported in IBC tumors compared to non-IBC tumors⁽⁴²⁾. Evidence also suggests that IBC tumors exhibit the phenomenon of vasculogenic mimicry, by which tumors form vessel-like structures in the absence of endothelial cells. These structures act as a supplementary blood supply by which tumor tissue is able to nourish itself. Both the WIBC-9 and the Mary-X xenograft models have demonstrated a role for vasculogenic mimicry in IBC⁽⁴³⁾.

Inflammation: The degree to which inflammation plays a role in inflammatory breast cancer remains largely unknown. Recent evidence comes from the constitutive activation of major inflammatory signaling pathways (nuclear factor kappa B [NF- κ B], cyclooxygenase 2 [COX-2], and JAK/STAT [Janus kinase/signal transducer and activator of transcription]) as well as in vitro, in vivo, and patient studies⁽⁴⁴⁾. Similarly, inflammatory cytokines and chemokines such as interleukin 6, transforming growth factor beta, tumor necrosis factor alpha (TNF- α), and gamma interferon are involved in all steps of tumorigenesis in IBC. These findings have prompted the testing of several compounds for their anti-inflammatory activity, with the aim of developing therapeutic or prevention strategies for IBC⁽⁴⁴⁾.

Cancer stem cells: Some evidence suggests that IBC cells have characteristics similar to cancer stem cells^(45, 46). The IBC tumors as well as the SUM149 IBC cell line and the Mary-X preclinical model of IBC have all been shown to express stem cell surface markers (CD44+/CD24-/low and aldehyde dehydrogenase 1 [ALDH-1] enzyme production) as assessed by the ALDEFLUOR assay^(46, 47). Expression of ALDH-1 in samples from patients diagnosed with IBC was associated with poor prognosis⁽⁴⁷⁾. Using microarray analysis, IBC was found to express genes known to be associated with breast cancer stem cells⁽⁴⁸⁾. A study using a xenograft model of IBC has demonstrated the potential to reverse the EMT process by which epithelial cells are thought to acquire stem cell-like properties⁽⁴⁹⁾.

Other molecular mechanisms: Overexpression of epidermal growth factor receptor (*EGFR*) is observed in more than 30% of patients with IBC. Patients with *EGFR*-positive tumors have an increased risk of recurrence and worse 5-year OS rates⁽⁵⁰⁾. Elevated levels of extracellular signal-regulated kinase (ERK) have been reported in both SUM149 and KPL-4 IBC cell lines⁽⁴⁹⁾. Dual blockade of *EGFR* and ERK1/2 phosphorylation in SUM19 cells was associated with decreased mitogen-activated protein kinase (MAPK) signaling and induced apoptosis⁽⁵¹⁾.

On the other hand, WISP3 was able to modulate insulinlike growth factor (IGF) signaling in SUM149

Table 29-2 Summary of Potential Biological Targets in the Treatment of Inflammatory Breast Cancer

Category	Molecular Marker	Pharmacologic Class
Oncogenes	Her-2/neu	mAbs, TKIs
	RhoC GTPase	FTIs
Tumor suppressor genes	p53	Gene therapy, p53-stabilizing agents
	PTEN	Proteasome inhibitors, PI3K inhibitors
Angiogenesis modulators	Tie-2	Tie-2 kinase inhibitor
	VEGF	TKIs, mAbs
	Flt-1/Flk-1	TKIs, mAbs
	E-cadherin	E-cadherin inhibitors
	MUC1	MUC1 inhibitors, PIAS
	RhoC GTPase	FTIs

FTIs, farnesyltransferase inhibitors; mAbs, monoclonal antibodies; MUC-1, mucin 1; PIAS, protein inhibitor of activated signal transducer and activator of transcription; PI3K, phosphatidylinositol-3-kinase; TKIs, tyrosine kinase inhibitors; VEGF, vascular endothelial growth factor.

cells, which may be an effective therapeutic target for IBC^(32, 52).

The expanded knowledge gained from preclinical studies has resulted in several promising molecular targets for directed therapy (Table 29-2).

CLINICAL PRESENTATION

The clinical identification of IBC is frequently confused with more common benign diseases and requires a high index of suspicion on the part of the diagnosing physician. On suspicion, the physician must obtain pathologic evidence of breast carcinoma to establish the presence of malignancy. Once evidence of breast carcinoma is obtained, the presence of dermal lymphatic invasion helps to confirm the diagnosis but is neither required nor sufficient to make the diagnosis⁽⁵³⁾.

The affected breast typically presents with a rapid onset of erythema, tenderness, edema, and swelling, accompanied by an enlargement of the draining lymph nodes, frequently in the absence of a breast mass. This clinical picture closely mimics common inflammatory conditions of the breast, such as simple bacterial

mastitis⁽⁵⁴⁾. As a result, many patients with IBC unnecessarily undergo repeated courses of antibiotics before a diagnosis is made.

On the other hand, in the presence of a breast mass, these symptoms are often confused with LABC with secondary erythematous skin involvement. The lack of specific pathologic or molecular characteristics for IBC means that the distinction between IBC and non-IBC is based mainly on clinical grounds.

The confusing clinical presentation of IBC often leads to unnecessary delays in diagnosis and treatment. Haagensen reported that the median duration of symptoms before diagnosis was 2.5 months compared to 5 months for non-IBC⁽⁵⁵⁾. However, a recent study examining the impact of delayed diagnosis, defined as more than 60 days from the time of first contact with a physician, found no effect on patient outcome⁽⁵⁶⁾.

Clinical Criteria

Inflammatory breast carcinoma commonly presents unilaterally, although bilateral disease can occur⁽⁵⁷⁾. Haagensen's original description of IBC outlined a list of characteristic symptoms and their corresponding frequencies⁽⁵⁵⁾. The author's criteria included breast

mass (57%), redness of the skin (57%), breast enlargement (48%), pain in breast or nipple (29%), breast tenderness (16%), generalized breast hardness (16%), nipple retraction (13%), edema of the skin (13%), axillary mass (9%), and warmth of the skin (8%).

One of the defining characteristics of IBC is the **rapid onset** of skin changes. Patients with primary IBC exhibit symptoms characterized by rapid onset erythema occurring less than 6 months from the diagnosis of breast cancer⁽⁵⁸⁾. In contrast, those presenting with delayed erythema occurring more than 6 months after breast cancer diagnosis are considered to have neglected breast cancer with secondary erythematous changes.

Skin changes, in the form of erythema and edema, are a distinguishing feature of IBC and should involve at least one-third of the skin overlying the breast to establish the diagnosis. Patients who present with skin changes involving less than one-third of the skin should not be classified as having IBC.

Erythema tends to be one of the earliest manifestations and typically presents with a mottled pink discoloration of the skin in the affected breast, which may be associated with a sensation of heat. Comparison with the contralateral, unaffected breast helps to identify erythema (Figs. 29-1A, 29-1B). During the course

FIGURE 29-1 Clinical appearance of inflammatory breast cancer. A. Erythema and enlargement noted when compared to normal breast. B. Diffuse erythema of the left breast in a woman with prior history of right breast cancer. C. Peau d'orange appearance of the skin of the right breast. D. Photomicrograph of breast biopsy from a woman with inflammatory breast cancer showing normal-appearing epidermis (*bottom of figure*) with tumor cells infiltrating the lymphatic channels of the dermis.

of its evolution, the degree of erythema may change from a flush of pink to red to bronze; it even may briefly fade and give the misleading picture of disease regression⁽⁵⁴⁾. In more severe cases, skin discoloration involves the entire breast and may change to dark red or purple. These manifestations can vary in African American women, for whom skin erythema is not the predominant symptom, leading to more difficulties in diagnosis. In these cases, *peau d'orange* changes may be easier to identify (Fig. 29-1C).

On the other hand, edema of the skin results from blockage of the draining lymphatics. This also leads to swelling of the breast and exaggeration of pits around hair follicles, giving the characteristic **peau d'orange** (orange peel) appearance. This can cause generalized breast induration as well as wheals and ridging⁽⁵⁹⁾.

Rapid **swelling of the breast** results from breast edema and in some cases can increase in size two- to threefold in a period of a few weeks.

At the time of diagnosis, almost all patients present with **lymph node metastasis**, and up to 30% also have distant metastasis at presentation⁽¹⁾. The ipsilateral axillary lymph nodes are the most common areas of spread, followed by ipsilateral supraclavicular lymph nodes. Contralateral and distant lymph node spread are also common, especially in more advanced and neglected cases⁽¹⁾. On physical examination, lymph nodes are usually enlarged, palpable, and fixed and in extreme cases may be accompanied with arm lymphedema.

Other clinical features not considered diagnostic of IBC include **nipple involvement**, itching, and axillary pain. The nipple may be flattened and retracted and appear blistered or associated with an area of crusting⁽¹⁾. Ulceration is not a common feature of IBC and generally suggests neglected LABC.

Secondary IBC

A distinction must be made between primary IBC and secondary IBC, which is the development of inflammatory changes in a breast or chest wall after a history of non-IBC in either the same or opposite breast. The outcomes from these disease entities are likely very different. In a recent review of eight patients with secondary IBC identified from the Inflammatory Breast Cancer Registry database, patients commonly presented with redness at the surgical scar site, *peau d'orange*, a diffuse rash, or chest wall nodules, which, unlike primary IBC, can become ulcerated^(59, 60). An early study at MDACC identified 96 patients with secondary IBC diagnosed between 1954 and 1981 and suggested there were no major differences in clinical course or outcome between primary and secondary IBC⁽⁶¹⁾. This conclusion should be interpreted cautiously. In view of the recent progress achieved in the

treatment of non-IBC, secondary IBC is likely to have a different outcome compared to primary IBC, and the two entities should be clearly distinguished.

Differential Diagnosis

Inflammatory breast carcinoma is often misdiagnosed as an infection of the breast, such as cellulitis, bacterial mastitis, or breast abscess, which are treated with repeated courses of anti-inflammatory or antibiotic treatment⁽⁵⁴⁾. A high degree of suspicion and the absence of fever, pain, leukocytosis, or other symptoms and signs associated with inflammation help distinguish IBC from breast infection. Acute bacterial mastitis commonly occurs during lactation and resolves in several days. Other infectious entities that can mimic IBC include erysipelas, which is usually caused by group A streptococcus.

Inflammatory breast cancer is also commonly confused with locally advanced neglected breast cancer with secondary erythematous changes. This condition presents with delayed erythema occurring more than 6 months after the initial diagnosis of breast cancer⁽⁵⁸⁾.

Paget disease of the nipple can also mimic IBC but generally develops more slowly and is usually associated with destruction of the nipple⁽⁵⁴⁾. Radiation dermatitis, in its acute phase, may also appear to be IBC; however, desquamation of the skin usually occurs with resolution of skin changes in 2 to 3 weeks.

Other less-common conditions that may be confused with IBC include rare breast malignancies such as sarcoma, inflammatory metastatic melanoma, or breast lymphoma; distant breast metastasis from another primary cancer may also produce a similar clinical picture (Table 29-3).

Table 29-3 Differential Diagnosis of Inflammatory Breast Cancer

Infectious conditions:
<ul style="list-style-type: none"> • Lactational mastitis • Breast abscess • Other infections: erysipelas, tuberculosis, syphilis
Benign (noninfectious) conditions:
<ul style="list-style-type: none"> • Dermatitis • Duct ectasia
Malignant conditions:
<ul style="list-style-type: none"> • Locally advanced neglected breast cancer with secondary erythematous changes • Radiation dermatitis • Rare malignancies of the breast: leukemia, breast lymphoma, sarcoma, inflammatory metastatic melanoma, distant breast metastasis from another primary cancer

Natural History of Inflammatory Breast Carcinoma

Inflammatory breast carcinoma is a rapidly progressive disease and is characterized by high rates of locoregional and distant recurrence. In a pooled analysis of 10 clinical trials conducted at MDACC, patterns of recurrence in 240 patients with IBC were compared to 831 patients with stage-matched non-IBC⁽¹⁰⁾. All patients were reported to have received similar multidisciplinary treatment. Patients with IBC had a higher cumulative incidence of recurrence at 5 years compared to individuals with non-IBC (64.8% vs 43.4%; $P < .0001$) and a lower 5-year OS rate (40.5% vs 63.2%; $P < .0001$). Inflammatory breast carcinoma was associated with significantly higher rates of soft tissue recurrence (skin and lymph nodes) both locoregionally and at distant sites. There was no difference between IBC and non-IBC in terms of distant recurrence to the bone or viscera.

Using data from the SEER registries, Schairer et al compared the risk of contralateral breast cancer in 5,631 patients with IBC versus and 174,634 patients with comparably staged non-IBC among women diagnosed with first breast cancer between 1973 and 2006⁽⁶²⁾. Contralateral breast cancer was further divided into recurrent/metastatic (occurring between 2 and 23 months of diagnosis) and independent second primary breast cancer (occurring in the opposite breast 2 or more years after the first diagnosis). Absolute risk of contralateral breast cancer was higher in IBC (4.9% vs 1.1% at 2 years), irrespective of age or hormonal status. The majority of IBC events occurred within 2 to 23 months from the first diagnosis, reflecting a higher risk of recurrence compared to non-IBC. The risk of contralateral breast cancer continued to be higher for those with IBC, up to 15 years from the time of first diagnosis.

PATHOLOGY

Obtaining a core biopsy with evidence of malignancy is considered the cornerstone of diagnosing IBC. Two additional skin punch biopsies are strongly recommended to detect dermal lymphatic tumor emboli and confirm the diagnosis.

It should be emphasized that IBC is not a true inflammatory process and does not demonstrate any of the pathologic hallmarks of inflammation, such as the presence of inflammatory cells or pus formation.

One of the most striking gross features of IBC is that it commonly presents in the absence of a dominant mass. The cancer usually presents as clumps of tumor cells within the lymphovascular spaces of the skin. These microscopic lesions are known as lymphovascular tumor emboli and represent the pathologic

hallmark of the disease as well as explain most of its clinical manifestations. As a result, IBC often presents with multicentric disease, in some cases bilaterally, and has a high propensity to spread to the regional lymph nodes and the distant organs.

Otherwise, the gross pathology of IBC tends to correspond with its clinical characteristics and includes erythema, thickening of the skin, and generalized enlargement of the breast due to edema.

Histologic Examination

In conjunction with the clinical features associated with IBC, several histopathological features have also been identified. Histologically, IBC tumors are characterized as being of higher tumor grade, with small areas of invasive carcinoma and extensive vascular tumor emboli associated with large tumor-free skip areas (Fig. 29-1D).

Histologic type: Inflammatory breast carcinoma may be associated with any of the invasive subtypes of breast cancer. Invasive ductal carcinoma of no special type or not otherwise specified (NST or NOS, respectively) is the most frequently identified histologic subtype associated with IBC. Other subtypes include lobular, medullary, papillary, mucinous, comedo carcinoma, or Paget disease (rare). An in situ component may be present but is usually minimal. There are no known precursor lesions for IBC.

Histologic grade, proliferative rate: Inflammatory breast carcinoma is an aggressive phenotype of breast cancer that is associated with a high histologic grade⁽⁶³⁾. It is also associated with higher proliferative rates, manifested by higher mitotic index and higher Ki-67 values when compared to non-IBC. These values have also been shown to be prognostic.

Pathology of lymphovascular tumor emboli: Tumor emboli are considered a hallmark of IBC and result from the pathologic plugging of dermal lymphatics by clumps of tumor cells. These clumps ultimately lead to lymphatic obstruction and are responsible for most of the clinical manifestations of IBC. Lymphovascular tumor emboli usually appear early in the disease and migrate readily to distant organs.

Despite being a defining signature, the presence of lymphovascular emboli is inconsistent and hence not required for the diagnosis of IBC. Even with adequate skin samples and tissue sections, dermal lymphatic tumor emboli are found in only 75% of patients with IBC. This is not only partly because IBC is characterized by the presence of large areas of tumor-free skip areas but also because of sampling error. Dermal lymphatic tumor emboli are also present in other malignancies, such as non-IBC and breast lymphoma. As a result, they are useful only in confirming the diagnosis of patients with positive clinical criteria for IBC⁽⁶⁴⁾.

Although the metastatic potential of IBC has been attributed to the presence of tumor emboli, the prognostic significance of dermal lymphatic invasion remains an area of controversy.

Molecular subtypes: Breast cancer is classified into distinct molecular subtypes based on gene expression profiling or immunohistochemistry ⁽²⁸⁾. When compared to non-IBC, IBC tumors have a tendency toward more aggressive subtypes. In a retrospective study conducted at MD Anderson, patients with IBC were assigned according to ER and *HER2* status into four subgroups: ER positive (33%), ER positive/*HER2* positive (12%), *HER2* positive (26%), and triple negative (29%) ⁽⁶⁵⁾.

1. *Hormone receptor status:* In contrast to non-IBC, the majority of patients with IBC present with hormone receptor–negative tumors, which are known to be associated with a poorer prognosis than receptor-positive tumors ^(3, 4). Data from several studies have suggested that patients with hormone receptor–positive IBC is less frequently associated with favorable subtypes, such as luminal A tumors, when compared to non-IBC ⁽³⁾.
2. *HER2 overexpression:* On the other hand, IBC tumors are associated with a higher incidence of *HER2* overexpression (36% to 60%) compared to non-IBC. Unlike non-IBC, the prognostic relevance of *HER2* overexpression in IBC is currently unknown, although it plays a predictive role in determining which patients will benefit from *HER2*-directed therapy. A population-based study using data from the California Cancer Registry found a borderline significant difference in breast cancer–specific survival (BCS) favoring patients with *HER2*-positive IBC (HR 0.82; CI, 0.68–0.99) ⁽⁶⁶⁾.
3. *Triple-negative IBC:* Approximately 29% of patients with IBC present with triple-negative tumors, which are associated with the poorest outcome when compared to other subtypes ⁽⁶⁵⁾. The 5-year OS rates for triple-negative disease was 42.7%, compared to 69.7% for ER-positive, 73.5% for ER-positive/*HER2*-positive, and 54% for *HER2*-positive disease ($P < .0001$). Similarly, both the 5-year locoregional relapse rate (38.6%) and the distant relapse rate (56.7%) were significantly worse when compared to other subtypes ($P < .001$).

IMAGING MODALITIES

Imaging modalities play a key role in the diagnosis and staging of IBC. In the absence of a dominant mass, it is often challenging to define with precision the correct area for biopsy without image guidance. In addition, imaging plays a crucial role in disease staging as well as assessment of treatment response.

Mammography

Because IBC commonly presents with lymphovascular tumor emboli and not with a breast mass, early detection strategies, such as breast self-examination, physical exams, and mammographic screening, are of little use.

In a retrospective analysis of various imaging modalities in the diagnosis of IBC, mammography was the least sensitive, detecting a mere 43% of primary breast parenchymal lesions ⁽⁶⁷⁾. Most readings are negative for malignancy, with thickening of the skin as the most common finding suggestive of IBC (Fig. 29-2) ⁽⁶⁸⁾. Other radiological findings include increased breast tissue density, trabecular and stromal thickening, breast swelling, axillary lymphadenopathy, and nipple retraction. These findings are usually subtle and can only be detected by comparison to the contralateral breast ⁽⁶⁷⁾. Focal asymmetry and architectural distortion are not frequent findings in IBC. In addition, calcification is less common than in non-IBC and was detectable in only 41% of patients in one study ⁽⁶⁷⁾.

Ultrasound

As with non-IBC, ultrasound is useful in localizing sites for biopsy in patients with masses. In a series evaluating 142 women with histologically proven IBC, in contrast to mammography, ultrasound was able to detect an additional 24 masses (18%) obscured by edema, when compared to mammogram alone ⁽⁶⁹⁾. The greatest benefit of ultrasound may be its potential to provide comprehensive evaluation of the nodal stations and pectoral muscle invasion. In this same series, ultrasound was able to detect axillary lymphadenopathy in the majority (73%) of patients and pectoral muscle invasion in 10%. These findings have been confirmed in a series at MDACC, in which sonography found a parenchymal breast lesion and skin thickening in 95% of patients and regional axillary nodal disease in 93% of cases (Fig. 29-3) ⁽⁶⁸⁾.

Magnetic Resonance Imaging

Magnetic resonance imaging has superior sensitivity in diagnosing breast cancer without the disadvantages of ionizing radiation. It is able to detect skin thickening in more than 90% of patients with IBC and axillary lymphadenopathy in up to 75% ^(68, 70). A discrete mass could also be seen in 38% of cases ^(71, 72). In a recent study, MRI was shown to detect the primary breast lesion in 98% of patients with IBC compared to 68% with mammography ($P < .0001$) ⁽⁷³⁾. The majority of masses detected (83%) were multiple, small, and confluent. These findings make MRI the imaging modality of choice in the detection of IBC for many clinicians (Fig. 29-4).

FIGURE 29-2 Bilateral mediolateral oblique mammograms in a 54-year-old woman show global skin and trabecular thickening (*short arrows*) of the right breast with associated right axillary adenopathy (*long arrow*). No visible primary breast parenchymal lesion is noted in the right breast. (Reproduced with permission from Yang WT, Le-Petross HT, Macapinlac H, et al. Inflammatory breast cancer: PET/CT, MRI, mammography, and sonography findings. *Breast Cancer Res Treat* 2008;109:417-426.)

FIGURE 29-3 Ultrasound images of the right breast from patient described in Fig. 29-2. **A.** Extended-field-of-view ultrasound of the right breast in the patient of Fig. 29-2 showing marked diffuse skin thickening and subcutaneous edema (*short arrows*) and a focal solid hypoechoic mass (*long arrow*) representing primary breast parenchymal lesion. **B.** Transverse ultrasound with power Doppler imaging of the primary mass in the right breast shows marked internal hypervascularity. **C.** Transverse ultrasound of the right supraclavicular region shows a solid hypoechoic node that showed metastatic carcinoma on biopsy. (Reproduced with permission from Yang WT, Le-Petross HT, Macapinlac H, et al. Inflammatory breast cancer: PET/CT, MRI, mammography, and sonography findings. *Breast Cancer Res Treat* 2008;109:417-426.)

FIGURE 29-4 A. Sagittal T2-weighted fast spin-echo image with fat suppression shows a dominant heterogeneous mass in the superior right breast (*long arrow*), global skin and subcutaneous edema (*medium arrows*), and right axillary adenopathy (*broad arrow*). B. Sagittal fat-suppressed three-dimensional spoiled gradient-recalled-echo sequence with parallel imaging at 2 minutes postcontrast administration demonstrates multiple rim-enhancing tumor masses (*arrows*) in the right breast and malignant-appearing necrotic right axillary lymph nodes (*broad arrow*). C. Delayed axial fat-suppressed, contrast-enhanced three-dimensional fast spoiled gradient-recalled-echo MRI reveals multiple heterogeneously enhancing masses in the central and lateral right breast (*arrows*) and right axillary adenopathy (*broad arrow*). (Reproduced with permission from Yang WT, Le-Petross HT, Macapinlac H, et al. Inflammatory breast cancer: PET/CT, MRI, mammography, and sonography findings. *Breast Cancer Res Treat* 2008;109:417-426.)

Moreover, MRI is useful in differentiating between acute mastitis and IBC (^{72,74}). In a study evaluating 90 patients (48 with IBC and 42 with acute mastitis), MRIs were able to statistically detect more T2-hypodense masses, infiltration of pectoralis major muscle, and pectoralis edema (⁷⁴). In addition, MRI has been useful in follow-up of acute mastitis by evaluating the success of antibiotic treatment and diagnosis of coexisting or confounding inflammatory carcinoma (⁷²).

The utility of breast MRI has also been evaluated in monitoring response to therapy (^{75,76}). In a study by Chen et al, the accuracy of complete clinical response on MRI to predict pathological complete response (pCR) was 69% (11 of 16), with a sensitivity of 58% (7 of 12), specificity of 92% (11 of 12), and a

false-negative rate of 21% (5 of 24) (⁷⁷). These results suggest that treatment decisions based on MRI findings should be done with extreme caution, especially in cases where no discrete mass was identified.

Computerized Tomography

The utility of helical computerized tomography (CT), which provides high-resolution thin cuts, was also investigated in the diagnosis of IBC. Helical CT was able to detect skin thickening in 100% of the patients with IBC (Fig. 29-5). Axillary lymphadenopathy was found in 82% of patients and distant metastases in 64% in a small cohort of 11 patients (⁷⁸).

FIGURE 29-5 A. PET/CT shows multicentric hypermetabolism in the right breast (arrow) associated with hypermetabolic diffuse skin thickening. B. PET/CT shows a solitary focal hypermetabolic focus in the right lobe of the liver (arrows) that showed a maximum SUV of 5.7. Corresponding CT of the liver shows a focal hypoechoic mass with indistinct margins. C. PET/CT shows a solitary focal hypermetabolic focus in the left proximal femur (arrows) that showed a maximum SUV of 7.7. Corresponding CT of the proximal femur shows this area of hypermetabolism to be within the marrow (whole body bone imaging was negative in this patient). (Reproduced with permission from Yang WT, Le-Petross HT, Macapinlac H, et al. Inflammatory breast cancer: PET/CT, MRI, mammography, and sonography findings. *Breast Cancer Res Treat* 2008;109:417-426.)

Helical CT has also been evaluated for its role in monitoring response to therapy for IBC. Compared to clinical examination and mammography, breast helical CT was useful in the quantitative assessment of response to neoadjuvant chemotherapy and preoperative determination of residual tumor volume in patients with round opacities (correlation coefficients of 0.97)⁽⁷⁹⁾. However, it was not as reliable for tumors with diffuse, scattered, or multinodular opacities (correlation coefficient 0.60). As with MRI, these results have led many to advise caution in the interpretation of helical CT in this setting⁽⁸⁰⁾.

Positron Emission Tomography

Data regarding the role of positron emission tomography (PET) in the diagnosis of IBC is limited. In one study that evaluated PET in seven patients with IBC, skin enhancement was noted in 100% of the patients, axillary lymphadenopathy in 85%, and skeletal metastases in 14% (Fig. 29-5)⁽⁶⁸⁾.

On the other hand, its role in staging is clearer, and it is recommended as an option in the staging workup for breast cancer⁽⁸¹⁾. Its role may even be more relevant in the staging of IBC tumors with their penchant for distant spread. Use of PET/CT can also aid in treatment planning for radiotherapy by determining the extent of skin and nodal involvement.

The prognostic impact of using PET/CT scans in the staging of LABC (IBC and non-IBC) was evaluated in a retrospective study of 935 patients diagnosed with stage III breast cancer between 2000 and 2009⁽⁸²⁾. The RFS and OS times were compared

between patients staged with conventional imaging alone and those staged using conventional imaging plus PET/CT. Relapse-free survival was significantly improved in the subgroup of women with IBC who underwent PET/CT compared to those who did not (HR 0.33; $P = .004$). Although there was a trend for better OS in women with IBC who underwent PET/CT, these results were not statistically significant.

The role of PET/CT in assessment of response to neoadjuvant therapy is another promising area under study. A decrease in SUVmax by PET/CT was an independent predictor of survival in patients with IBC undergoing neoadjuvant chemotherapy⁽⁸³⁾. Further studies are needed to determine the cost-benefit utility of this diagnostic modality.

DIAGNOSIS AND STAGING

Inflammatory breast cancer has had its share of numerous and often-conflicting diagnostic criteria ever since Haagensen's original description in 1956. This has severely limited our ability to compare research across different IBC studies⁽⁸⁴⁾.

Tumor-Node-Metastases System

The diagnosis of IBC has been recognized since the first edition of the American Joint Committee on Cancer (AJCC) manual as a separate clinicopathological entity: inflammatory carcinoma" and classified as T4d within the Tumor-Node-Metastasis (TNM) staging system. The diagnosis required the pathological presence of

Table 29-4 TNM Staging System for Breast Cancer

Tumor Classification	Definition
T4	Any size tumor growing into the chest wall or affecting the skin
T4a	Extension of tumor to the chest wall
T4b	Edema (including peau d'orange), ulceration of the skin, or satellite skin nodules confined to the same breast
T4c	Both 4a and 4b
T4d	Inflammatory breast carcinoma

microscopic dermal lymphatic permeation to exclude “inflamed cancers due to inflammation, infection or necrosis.” With the arrival of the third edition in 1989, patients presenting with specific inflammatory criteria, including diffuse erythema and edema involving a third or more of the skin of the breast, were designated T4d status. This meant that patients with IBC will have at least stage IIIB disease.

The current TNM classification (seventh edition) defines IBC as “a clinicopathological entity characterized by diffuse erythema and edema of the breast, often without an underlying palpable mass” (64). The diagnosis is determined clinically, while pathologic evidence of lymphatic emboli is used for confirmation (see Table 29-4).

Other definitions such as the Poussée Évolutive (PEV) system were commonly used in Europe and North Africa and have led to confusion (7). Under the PEV system, PEV3 (inflammatory signs involving more than half the breast) would coincide with IBC as defined by the AJCC system. However, PEV2 (inflammatory signs involving less than half the breast) includes patients who would not be classified as having IBC in the AJCC system (inflammatory signs involving less than a third of the breast).

Diagnostic Criteria

In an effort aimed at standardizing the definition of IBC, an international panel of experts agreed on a minimal set of criteria required for diagnosis. The consensus statement endorsed the criteria established by the AJCC and addressed issues of ambiguity, such as the rapidity of disease onset (56).

Table 29-5 shows a summary of the clinical criteria and workup required to establish the diagnosis of IBC.

Table 29-5 Diagnostic Criteria for Inflammatory Breast Cancer and Imaging Workup

Medical history:
<ul style="list-style-type: none"> • Rapid onset of skin changes in the breast including erythema, edema (peau d'orange), tender/painful and/or warm breast. • Duration of history of no more than 6 months.
Physical examination:
<ul style="list-style-type: none"> • Erythema and edema occupying at least one-third of the breast. • Presence of mass (absent in more than 50% of patients). • Presence of palpable locoregional lymph nodes.
Pathology:
<ul style="list-style-type: none"> • Core biopsy to establish the presence of invasive carcinoma. • At least two skin punch biopsies are strongly recommended to detect dermal lymphatic (used to confirm the diagnosis). • All tumor tissue should be evaluated for ER and <i>HER2</i> status.
Imaging and staging workup:
<ul style="list-style-type: none"> • Diagnostic bilateral mammography with ultrasonography of the regional lymph nodes. • Breast MRI is used when breast parenchymal lesions are not detected by mammography/ultrasound. • Staging with PET/CT is optional. Otherwise, chest, abdomen, and pelvis CT and bone scan.

MULTIDISCIPLINARY TREATMENT

Inflammatory breast carcinoma presents with advanced locoregional disease and extensive skin involvement that precludes certain therapeutic procedures. Treatment with up-front surgery is not an option, and patients without metastasis are treated with a multimodality approach similar to that used in LABC. This includes tumor downstaging with primary systemic chemotherapy followed by definitive surgery and radiation therapy. The use of *HER2*-targeting therapy (trastuzumab) is indicated for *HER2*-positive cancer. This multidisciplinary approach has dramatically altered the survival outcomes for women with IBC over the last 40 years, with improved 5-year OS rates ranging between 30% and 70% (11).

Surgery

Historically, the efficacy of surgery alone in the treatment of IBC was associated with a median survival of 19.8 months, with a 5-year OS less than 5% (85). Up-front surgery for IBC also provided poor local control, with a local recurrence rate around 50%.

The addition of mastectomy to a combination of chemotherapy plus radiotherapy improved local control in patients with IBC as well as distant disease-free

survival (DFS) and OS in patients with a complete or partial response to induction chemotherapy ⁽⁸⁶⁾.

Procedure: For patients with complete resolution of inflammatory skin changes following neoadjuvant chemotherapy, the recommended surgical procedure is a modified radical mastectomy with complete axillary lymph node dissection. Conservative surgery as well as skin-sparing mastectomies are not recommended in IBC due to widespread dermal lymphatic involvement ⁽⁸⁷⁾. Because the majority of patients present with lymphatic spread at diagnosis, sentinel lymph node biopsies are not recommended in the management of women with IBC ^(88, 89).

The goal of surgery is complete resection of the primary tumor and the axillary lymph nodes with negative safety margins and no gross residual disease ⁽⁹⁰⁾. Patients who achieve a complete pathological response after chemotherapy and surgery have an improved outcome ⁽⁹¹⁾.

Breast reconstruction: Despite reports of reasonable success, the international expert panel on IBC recommends against immediate breast reconstruction following surgery ⁽⁵⁸⁾. Breast reconstruction conducted immediately after mastectomy for women with IBC can limit radiation coverage and therefore compromise locoregional disease control in this highly aggressive disease ⁽⁹²⁾. In addition, the radiation given after reconstruction is associated with poor cosmetic outcomes. The optimal timing of reconstruction is not known and should be determined after completion of preoperative chemotherapy by a multidisciplinary team based on the aggressiveness and course of the disease.

Radiotherapy

The standard approach is to provide locoregional control for IBC in the form of a combination of modified radical mastectomy followed by radiation therapy in patients who respond adequately to neoadjuvant chemotherapy. This approach does not have an impact on OS but results in optimal local control ⁽⁹³⁾.

Historically, local control with radiotherapy alone was given to the breast and draining lymphatics but was associated with a high locoregional recurrence rate ^(14, 93, 94).

The dose and fractionation used for postmastectomy radiotherapy at our institution has changed over time ⁽⁹⁰⁾. The standard postmastectomy radiation dose in non-IBC (60 Gy) is composed of 50 Gy given in 2-Gy fractions delivered once a day to the chest wall and draining lymph nodes (axillary, infra- and supraclavicular, as well as internal mammary lymph nodes), followed by an additional boost of 10 Gy to the chest wall and any undissected regional nodes that were involved at diagnosis.

Several retrospective studies have suggested that dose escalation (from 60 to 66 Gy) with accelerated fractionation (1.5 Gy given twice daily) schedules may improve locoregional control in patients with IBC ⁽⁹⁵⁾.

However, this approach was associated with significant delayed skin toxicity (29% vs 15%). As a result, the hyperfractionated regimen is recommended for patients with a high risk of recurrence. This includes women less than 45 years old, those who responded poorly to neoadjuvant chemotherapy, as well as those with positive, close, or unknown surgical margin status ⁽⁹⁰⁾. At MDACC, patients with IBC who do not present with these high risk criteria are offered a once a day dose similar to the standard regimen used in non-IBC (50 Gy), albeit with 16 Gy boost (total 66Gy). This provides dose escalation with a less aggressive regimen. Generous coverage of the chest wall is essential to ensure treatment of dermal lymphatic infiltration.

Complications: Acute radiation complications include radiation skin changes such as moist desquamation. Late complications such as pneumonitis, lymphedema, chest wall fibrosis, rib fractures, and brachial plexopathies are less common ⁽⁹³⁾. Operative complications were found to be higher in women who received preoperative radiotherapy.

Neoadjuvant Systemic Therapy

Preoperative systemic chemotherapy is recommended, with the dual objective of downstaging of the primary tumor as well as reducing the risks of distant metastasis, given the high propensity of IBC for distant recurrence. The rarity and poor prognosis associated with IBC often resulted in these patients being excluded from most clinical trials. As a result, treatment recommendations are based mainly on retrospective IBC studies and extrapolation from the results of large prospective trials that recruited patients with non-IBC.

Neoadjuvant chemotherapy has transformed a disease that was once considered uniformly fatal with a 5-year survival rate of less than 5% after locoregional strategies alone.

Anthracyclines

Anthracycline-based chemotherapy regimens have been the cornerstone of systemic treatment of IBC since 1974 at our institution ⁽⁹⁵⁾. The standard regimen consisted of three to four cycles of 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC). Over the years, additional agents, such as vincristine, methotrexate, and vinblastine, were added but failed to improve the outcome of anthracycline-based regimens, with the exception of taxanes (discussed in the next section).

A pooled analysis of four prospective trials conducted at MD Anderson and covering a 20-year period examined the outcome of induction chemotherapy followed by local radiation with or without mastectomy. Patients who received anthracycline-based regimens had an overall response rate of 71% and 5- and

10-year OS rates of 40% and 33%, respectively ⁽⁹⁶⁾. The combined-modality approach resulted in a long-term DFS of 28% at 15 years.

Similar results were seen in a cohort of 68 patients with IBC who received three courses of neoadjuvant therapy in the form of cyclophosphamide, 5-fluorouracil, and an anthracycline (doxorubicin or epirubicin) followed by surgery, adjuvant therapy, and radiation therapy. The 5- and 10- year OS rates were 44% and 32%, respectively ⁽⁹⁶⁾.

In a prospective trial conducted by the National Cancer Institute, pCR rates of 33% were observed in a subgroup of patients with IBC ($n = 46$) who received neoadjuvant CAFM. The 10-year OS was 26.7% ⁽⁹⁷⁾.

These findings have helped establish combined-modality treatment (anthracycline-based neoadjuvant chemotherapy, then mastectomy, then adjuvant chemotherapy and radiotherapy) as the standard of care for the treatment of IBC.

Taxanes

Taxanes were introduced at MDACC in the treatment of IBC in 1994. Initial small studies examining the addition of paclitaxel showed promising results, with improvements in clinical response rates and OS ⁽⁹⁸⁾. A pooled analysis of patients treated with these protocols stratified patients based on whether they had received paclitaxel as part of either induction or adjuvant chemotherapy. A subset analysis of patients with ER-negative tumors revealed a significantly higher 3-year OS (54 vs 32 months, $P = .03$) and PFS (27 vs 18 months, $P = .04$) in those receiving the paclitaxel regimens compared with anthracycline-based therapy without paclitaxel ⁽⁹⁸⁾. The addition of paclitaxel was also associated with higher pCR rates compared with treatment using FAC alone (25% vs 10%, $P = .012$) ⁽⁹¹⁾.

A large, multicenter, randomized trial (GeparTrio) prospectively examined the benefit of neoadjuvant docetaxel-/anthracycline-containing regimens by comparing the outcome of patients with IBC ($n = 93$) or LABC ($n = 194$) to the outcome of patients with operable breast cancer ($n = 1,777$) ⁽⁹⁹⁾. Patients received four or six cycles of docetaxel/doxorubicin/cyclophosphamide (TAC) or four cycles of TAC and four cycles of vinorelbine/capecitabine, depending on their initial response to two cycles of TAC. Although pathological response rates were higher for patients in the operable breast cancer group, tumor stage (including IBC status) was not an independent predictor for pCR in multivariate analysis (odds ratio 1.51; 95% CI, 0.88 to 2.59; $P = .13$).

Using data from the SEER registry, Dawood et al found that women with stage III IBC continued to have a poorer outcome than those with stage III non-IBC in the era of multidisciplinary management and anthracycline-/taxane-based polychemotherapy ⁽¹⁰⁰⁾.

The authors examined women diagnosed between 2004 and 2007 who had received surgery and radiotherapy under the assumption that the majority of patients would have received the indicated form of treatment. The 2-year BCS was shorter for IBC compared to non-IBC, 84% (95% CI, 80%-87%) and 91% (95% CI, 90%-91%), respectively. Patients with IBC had a 43% increased risk of death from breast cancer compared with patients with stage III non-IBC.

In an analysis of 398 patients with IBC diagnosed at MDACC between 1974 and 2005, patients who received taxanes had an improved median survival of 6.3 years compared to 3.8 years for those who did not ⁽¹¹⁾. A similar improvement was seen in patients who underwent surgery or achieved pCR. Despite the clear advantages of taxanes in this study, the survival trends did not differ over four decade groups. The authors attributed this to changes in diagnostic and treatment criteria, as well as patient and tumor characteristics over time.

Similarly, an analysis of 104 patients with nonmetastatic IBC diagnosed between 2000 and 2009 aimed to examine contemporary outcomes in the era of trastuzumab and taxane-based chemotherapy. The 5-year OS and distant metastasis-free survival were 46% and 44%, respectively, despite excellent locoregional control (83% at 5 years) ⁽¹⁰¹⁾.

Taken together, these results establish the role of anthracyclines and taxanes as the most effective chemotherapeutic agents in the treatment of IBC.

HER2-TARGETED THERAPY

Up to 40% of IBC tumors overexpress *HER2/neu* compared to approximately 25% in non-IBC ⁽¹⁰²⁾. These patients should receive *HER2*-targeted therapy in the form of trastuzumab in combination with preoperative systemic therapy and trastuzumab continued postoperatively for 1 year ⁽⁵⁸⁾.

Early studies have shown that the addition of trastuzumab contributed to higher rates of pCR in patients with *HER2*-positive IBC ⁽⁹²⁾. This was also confirmed in the NOAH trial, which randomized women with LABC (including IBC) to neoadjuvant chemotherapy with trastuzumab followed by 1 year of adjuvant trastuzumab versus neoadjuvant alone. The addition of trastuzumab was associated with improved pCR rates and event-free survival ⁽¹⁰³⁾.

In a retrospective review of 260 patients with newly diagnosed stage III IBC at MDACC, the inclusion of neoadjuvant *HER2*-directed therapy was associated with improved survival in multivariate analysis (HR 0.38; 95% CI, 0.17-0.84; $P = 0.02$) ⁽¹⁰²⁾.

Treatment with preoperative trastuzumab in 16 patients with newly diagnosed *HER2/neu*-positive IBC at MDACC was associated with a complete pathological response in 10 patients (62.5%). Despite the high

pCR rate, three patients developed brain metastasis (of four patients who experienced disease progression). Brain metastasis was associated with a high expression of CXCR4⁽¹⁰⁴⁾.

Recently, the US Food and Drug Administration granted accelerated approval to the combination of pertuzumab, trastuzumab, and docetaxel for the neoadjuvant treatment of patients with *HER2*-positive, locally advanced, inflammatory, or early-stage breast cancer (either greater than 2 cm in diameter or node positive). This combination is designed to overcome trastuzumab resistance due to the formation of *HER2:HER3* heterodimers. The approval was based on the higher pCR rates obtained from two studies (NeoSphere and TRYPHAENA). As a result, patients with *HER2*-positive tumors can now be offered one of two neoadjuvant combinations: (a) pertuzumab, trastuzumab, and docetaxel followed by adjuvant FEC, FAC, or AC or (b) trastuzumab, pertuzumab, docetaxel, and carboplatin for six cycles (see Table 29-6).

Endocrine Therapy

There is little evidence to suggest a role for preoperative endocrine therapy in the treatment of IBC, and this option is not encouraged in light of studies suggesting hormone receptor-positive IBC may be more endocrine resistant. Despite this, adjuvant endocrine therapy should be offered to all women with hormone receptor-positive tumors, with similar duration and indications as in non-IBC. Ongoing breast cancer studies exploring the combination of endocrine therapy plus molecular targeted agents (eg, everolimus, entinostat) provide promising options for overcoming endocrine resistance in IBC.

Underutilization of Multimodality Treatment

A recent study found evidence of continued underutilization of trimodality therapy (neoadjuvant

Table 29-6 Trimodality Therapy for Inflammatory Breast Cancer at MDACC

A. Neoadjuvant Systemic Chemotherapy	
<ul style="list-style-type: none"> Weekly paclitaxel followed by FEC/FAC/AC 	Weekly paclitaxel (80 mg/m ²) for 12 weeks (In TN-IBC*: consider adding carboplatin AUC 5-6 every 3 weeks for 4 cycles) FEC: Fluorouracil (500 mg/m ²), epirubicin (100 mg/m ²), cyclophosphamide (500 mg/m ²) every 3 weeks for 4 cycles FAC: Fluorouracil (500 mg/m ²), doxorubicin (50 mg/m ²), cyclophosphamide (500 mg/m ²) every 3 weeks for 4 cycles AC: Doxorubicin (60 mg/m ²), cyclophosphamide (600 mg/m ²) every 3 weeks for 4 cycles

*TN-IBC, Triple-negative IBC

chemotherapy, surgery, and postoperative radiation) in community practice (²). Using data from National Cancer Database, the researchers identified 10,197 patients with stage III IBC who underwent surgery between 1998 and 2010. The use of trimodality therapy ranged from 58.4% to 73.4% annually. Five- and 10-year survival rates were significantly lower among those who did not receive all three treatment modalities compared to those who did. This may explain in part the poor outcome seen in women with stage III IBC in the SEER study (¹⁰⁰).

MANAGEMENT OF STAGE IV

Up to 30% of patients with IBC present with metastasis at diagnosis, compared to 6% to 10% in non-IBC (^{15,105,106}). The most common sites of distant metastasis at presentation include bone and visceral metastasis, especially to the lung (^{105, 106}). There is no specific treatment for patients with metastatic IBC. Current regimens are based on the most active therapeutic agents discussed in the nonmetastatic setting as well as the molecular subtype of IBC (⁵⁹). Enrollment in clinical trials is highly recommended whenever possible. In patients with IBC who present with de novo metastasis, chemotherapy alone results in a 5-year OS rate of less than 10% (¹⁰⁷).

Using data from SEER, the outcome of 1,085 patients with stage IV IBC was compared to the outcome of 4,441 patients with stage IV non-IBC, diagnosed between 1990 and 2008. The median BCS was significantly lower for stage IV IBC than stage IV non-IBC (1.75 years, range 0–15.7 vs 2.3 years, range 0–18.9, respectively; $P < .0001$) (¹³).

We compared the outcome of 218 patients with stage IV IBC to 1,454 patients with stage IV non-IBC diagnosed at our institution between 1986 and 2012. The median OS was shorter in IBC versus non-IBC (2.3 vs 3.4 years, $p = .004$). The diagnosis of IBC was associated with poorer OS (HR 1.33; 95% CI 1.05–1.69) (¹²).

The success of multimodality therapy in nonmetastatic IBC has encouraged exploring its use in the metastatic setting. In a review of the SEER database, patients with IBC who presented with metastatic disease in the era of multimodality therapy had a 40% 2-year OS (¹⁰⁸). To evaluate the role of multimodality therapy, the outcomes of 172 patients with metastatic IBC were retrospectively reviewed. Response to chemotherapy and treatment with surgery and radiotherapy were independent predictors of better OS and progression-free survival. These results suggest that in select patients with metastatic IBC, multimodality treatment, including surgery, may offer better local control and OS.

The role of definitive locoregional surgery in patients with breast cancer presenting with metastatic

disease remains controversial. Benefit in this situation may reflect a selection bias for patients who present with less-advanced tumors, better performance status, or higher chemosensitivity. A randomized, controlled trial is needed to validate the findings.

INVESTIGATIONAL THERAPY

Despite advances in systemic and locoregional therapy, the prognosis of IBC has not improved since the introduction of multidisciplinary management (¹¹). Therefore, it is important to explore different treatment approaches and new molecular targets in IBC and to investigate the impact of novel agents.

Despite several encouraging studies, the use of **high-dose chemotherapy** (HDCT) with stem cell support remains controversial. Small phase II trials have reported 3- to 4-year OS rates of 52% to 89% and DFS rates of 45% to 65%, which were favorable compared to historical survival data with standard-dose chemotherapy (¹⁰⁹). In the absence of definitive prospective, randomized trials, the use of HDCT remains investigational (¹¹⁰).

Novel *HER2*-targeting agents include **tyrosine kinase inhibitors**, lapatinib and neratinib; the **monoclonal antibody** pertuzumab; as well as ado-trastuzumab emtansine (TDM-1). Lapatinib is a dual-action *HER1* and *HER2* tyrosine kinase inhibitor currently being investigated in the treatment of *HER2*-positive IBC. The combination of neoadjuvant lapatinib and paclitaxel was evaluated in a phase II, open-label, multicenter study and resulted in clinical response rates of 78.6% and pCR rates of 18.2% (95% CI, 5.2% to 40.3%) (¹¹¹). The combination of trastuzumab and lapatinib, with or without concurrent chemotherapy, is considered investigational in the neoadjuvant setting and should not be offered in routine clinical practice.

Angiogenesis inhibitors could potentially target lymphangiogenesis and vasculogenesis, which play an important role in the pathogenesis of IBC. In a study including 21 patients with inflammatory and LABC, bevacizumab reduced angiogenesis in posttreatment tumor biopsies and dynamic contrast-enhanced MRI (¹¹²). Likewise, some clinical activity was observed in a phase I trial of semaxanib (SU5416), a potent tyrosine kinase inhibitor that targets the VEGF pathway (¹¹³).

Farnesyl transferase inhibitors (FTIs) inhibit RhoC proteins, which are overexpressed in IBC. An example is tipifarnib, which has entered phase II trials in combination with neoadjuvant chemotherapy for IBC (¹¹⁴).

Several agents that target the inflammatory pathways have been explored in the preclinical and clinical settings in IBC (⁴⁴). These include chemokine receptor antagonists, prostanoid receptors (EP4) antagonists,

novel selective COX inhibitors (apricoxib, tranilast), as well as others.

Inflammatory breast carcinoma has been an appealing target for **immunotherapy**. Numerous trials have aimed at improving the outcome of IBC by combining immunotherapy with chemotherapy and radiation. Ongoing studies aim to explore the immunogenic effects of standard therapy (eg, taxanes and trastuzumab) with the addition of breast cancer vaccines to multimodality regimens.

Personalized molecular medicine based on the genotypic characteristics of individual patients is promising owing to the heterogeneous and complex biology of IBC. The recent integration of genomic medicine in the clinical practice and management of patients with breast cancer and advances in genotypic testing and next-generation sequencing have prompted the search for specific IBC gene expression signatures ⁽²⁹⁾. Other potential agents in preclinical phase are shown in Table 29-2.

CURRENT MANAGEMENT STRATEGIES AT MD ANDERSON CANCER CENTER

All patients who present at MDACC with IBC are referred to a specialized IBC clinic and simultaneously enrolled in the MDACC IBC Registry. In addition to samples collected for diagnosis, the IBC Registry prospectively collects additional blood or tissue specimens for translational research. The recommended schema for multimodality treatment of IBC at MDACC is presented in Fig. 29-6.

Diagnosis and Staging

The diagnosis of IBC relies heavily on the medical history and physical examination to establish the presence of minimal diagnostic criteria (see Table 29-5). These include the presence of skin changes in the

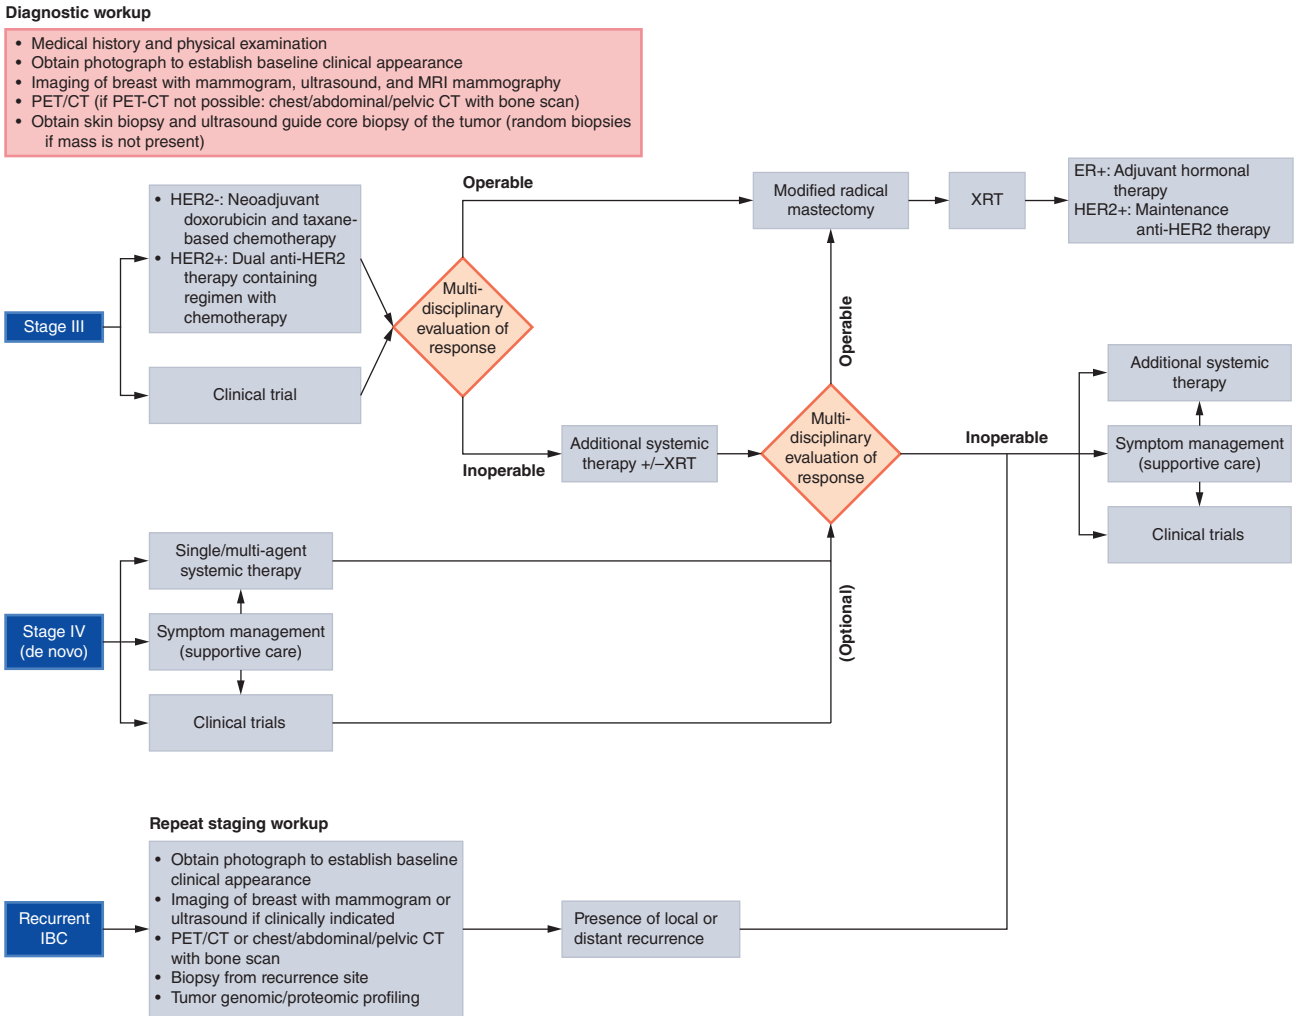

FIGURE 29-6 Diagnostic workup. XRT, x-ray therapy.

form of erythema, edema, or peau d'orange occupying at least one-third of the skin overlying the affected breast. The duration of these symptoms should not be longer than 6 months⁽⁵⁸⁾. Baseline medical photography is extremely important for assessment of response to treatment and for monitoring the reduction in erythema and edema⁽¹⁾.

Patients who present with a clinical picture suggestive of IBC should undergo baseline bilateral mammography with ultrasonography of the regional lymph nodes. Breast MRI is recommended when breast parenchymal lesions are not detected by mammography/ultrasound. All women should undergo staging with CT and bone scan. Use of PET or PET/CT is optional⁽⁵³⁾.

Patients should also undergo a core biopsy to establish the presence of invasive carcinoma. At least two skin punch biopsies are highly recommended to detect dermal lymphatic invasion and confirm the diagnosis of IBC. All tumor tissue is evaluated for ER and *HER2* status. If the workup, including core biopsies, is negative, a trial of antibiotics is initiated. If after 2 weeks there is no evidence of resolution, the workup is repeated.

Multimodality Management

At MDACC, the multidisciplinary treatment of IBC was first evaluated in 1974 and has since become the standard of care⁽⁹⁵⁾. Patients receive neoadjuvant systemic chemotherapy followed by definitive surgery and radiation therapy. The *HER2*-targeting therapy (trastuzumab) is indicated for *HER2*-positive cancer (see Table 29-6).

Neoadjuvant Systemic Chemotherapy

Patients receiving chemotherapy should have an Eastern Cooperative Oncology Group performance status equal to 0 or 1 and adequate cardiac function. Pretreatment blood tests include routine blood counts and renal and hepatic function tests.

Anthracyclines (epirubicin or doxorubicin) and taxanes (paclitaxel or docetaxel) are the most effective cytotoxic agents. The most commonly used regimens at MDACC are listed in Table 29-6 and consist of paclitaxel 80 mg/m² weekly (12 weeks) followed by four cycles of either (a) FEC-100, (b) FAC or (c) AC. Patients with triple-negative IBC may benefit from the addition of carboplatin to paclitaxel. Patients with *HER2*-positive tumors should preferably receive neoadjuvant chemotherapy plus dual-target therapy in the form of pertuzumab, trastuzumab, and docetaxel with or without carboplatin followed by adjuvant FEC, FAC, or AC.

Assessment of Treatment Toxicity and Response

Toxicity from chemotherapy is monitored after each cycle and graded according to the National Cancer

Institute's Common Terminology Criteria for Adverse Events version 4.0 (NCI-CTCAE v4.0). Cardiac monitoring should be performed at baseline and 3, 6, and 9 months to detect evidence of cardiac toxicity. Depending on the toxicity, dose reduction or treatment modification may be needed.

Response to primary systemic therapy is monitored every 6 to 9 weeks by physical examination and by radiological assessment at the end of therapy to compare with baseline images. Clinical response to chemotherapy is evaluated according to the RECIST response criteria. Comparison with medical photographs taken at baseline can help make a more accurate assessment of response. Patients with adequate response, including complete resolution of inflammatory skin changes, are treated surgically and their pathological response to chemotherapy is evaluated.

Approximately, 20% of patients with IBC fail to respond to neoadjuvant chemotherapy. For these patients, the options include preoperative radiotherapy or radiotherapy alone⁽⁹⁰⁾.

Surgery

The recommended surgical procedure is a modified radical mastectomy with complete axillary lymph node dissection. Conservative surgery and skin-sparing mastectomies as well as sentinel lymph node evaluation of lymph nodes are not recommended in the management of women with IBC⁽⁸⁷⁻⁸⁹⁾.

The goal of surgery is complete resection of the primary tumor and the axillary lymph nodes with negative safety margins and no gross residual⁽⁹⁰⁾. Adequate margins are defined as more than or equal to 2 mm; those with resection margins less than 2 mm are considered positive⁽⁹⁰⁾.

Assessment of Pathological Response

Pathological complete response is defined as no evidence of invasive carcinoma in the breast and the axillary lymph nodes at the time of surgery. Patients who achieve pCR after chemotherapy and surgery have an improved outcome⁽⁹¹⁾.

Reconstruction: Immediate breast reconstruction following surgery is not recommended⁽⁵⁸⁾.

Postoperative Radiation

Postoperative radiation therapy delivered to the chest wall and draining lymph nodes (axillary, infra- and supraclavicular, internal mammary lymph nodes) improves local control.

The standard fractionation schedule is an initial dose of 50 Gy given in fractions of 2 Gy delivered once a day to the locoregional areas followed by a boost to the chest wall and any undissected involved regional nodes (ie N3b or N3c) of 16 Gy (total dose

equals 66 Gy and represents a 10% escalation over the standard dose for non-IBC). The standard fractionation schedule is indicated in patients above the age of 45 years and those who have achieved pathological CR in response to neoadjuvant chemotherapy.

At MDACC, we prescribe an accelerated hyper fractionation schedule for patients at higher risk of recurrence with a total dose of 66 Gy⁽⁹⁰⁾. A dose of 51 Gy is delivered in 34 fractions of 1.5 Gy, given twice daily at least 6 hours apart to the chest wall and undissected draining lymphatics. This is followed by a boost of 15 Gy to the chest wall and any clinically involved undissected regional nodes, administered in twice-daily fractions of 1.5 Gy (5 days).

Preoperative radiation: Those who remain inoperable after neoadjuvant chemotherapy may benefit from preoperative radiotherapy^(58, 106). The schedule and doses for patients who require preoperative radiation and personalized.

Adjuvant therapy

There is currently no evidence of benefit from adding chemotherapy postoperatively for patients who have already completed four to six cycles of neoadjuvant anthracycline- and taxane-based regimens.

Treatment with trastuzumab is resumed postoperatively in patients with *HER2*-positive IBC until completion of 1 year of treatment. Adjuvant endocrine therapy should be offered to all women with hormone receptor-positive IBC, with similar duration and indications as in non-IBC.

Posttherapy Surveillance and Follow-up

Following completion of trimodality therapy, patients should be evaluated by clinical examination every 3 to 6 months for 5 years and thereafter every year. Mammograms to the contralateral breast should be performed on an annual basis. Additional investigation may be requested according to clinical indication.

Enrollment in Clinical Trials

It is strongly recommended to enroll patients with IBC in clinical trials, including phase I trials when possible. This is particularly important for patients who relapse after trimodality therapy or those who have metastatic disease at presentation.

CONCLUSION

Inflammatory breast carcinoma remains one of the most lethal forms of breast cancer. Despite promising advances in the diagnosis and treatment of IBC over the past several decades, patients continue to have a

poor outcome. Survival has not improved since the introduction of multidisciplinary management.

Epidemiological studies suggested several important risk associations but have yet to identify a risk model for IBC. Progress in imaging modalities such as MRI and PET/CT continues to enhance the precision of biopsy site identification as well as improve disease staging and assessment of response to treatment.

Advances in molecular biology have unveiled the heterogeneous nature of IBC, and new technologies, such as next-generation sequencing, could help identify new molecular targets and biomarkers. The approval of new target therapies such as pertuzumab as well as a large number of new drugs currently under development may help improve survival of this lethal disease.

Acknowledgments: We (the current authors) would like to thank and acknowledge the significant contribution of the previous authors of this chapter, Drs. Windy Marie Dean and Massimo Cristofanilli. This edition is a revision and update of the original authors' work.

Zahi Mitri

BREAST CANCER DURING PREGNANCY

Epidemiology

Pregnancy-associated breast cancer (PABC) or gestational breast cancer is defined as breast cancer that is diagnosed during pregnancy and the 12 months following delivery. Breast cancer is one of the most common cancers diagnosed during pregnancy. Given that many women are delaying childbearing (¹), and age is a risk factor for breast cancer, the incidence of PABC appears to be on the rise. A study from the Swedish National Health Registry showed that the incidence of PABC increased from 16 to 37.4 per 100,000 deliveries between 1963 and 2002 (²). Factors associated with a diagnosis of breast cancer included age 35 years or older, women with private insurance, and women who delivered in an urban teaching hospital (³).

Diagnosis

The most common clinical presentation of PABC is a painless mass that is either self-detected or noted on clinical exam. The duration of symptoms was significantly longer in patients with PABC compared to their nonpregnant counterparts in a study from Japan. Physiologic changes in a pregnant woman's breast, especially in women younger than 30 years; physician familiarity with PABC; as well as socioeconomic and cultural factors may contribute to delays in diagnosis (⁴).

Biopsy

Although the majority of breast masses during pregnancy are benign, a breast mass that does not resolve within 2 weeks requires further investigation (²). Any clinically suspicious breast mass should be biopsied for a definitive diagnosis whether a patient is pregnant or not. Even though a number of small studies have shown the accuracy of fine-needle aspiration (FNA) in the diagnosis of PABC, a core or excisional biopsy of the breast lesion is necessary to make a diagnosis of invasion (⁵) (Fig. 30-1).

Two large surgical series of pregnant patients who had general anesthesia for a variety of underlying medical problems failed to demonstrate an increase in the risk of congenital malformations as compared with pregnant women who did not undergo surgery (^{6,7}). Ultimately, the least-invasive and most technically accurate method(s) available should be utilized to determine the nature of a breast mass in a pregnant woman.

Diagnostic Imaging

Mammography and Ultrasound

Mammography can be safely ordered during pregnancy with abdominal shielding. The estimated fetal radiation exposure was 0.4 mrad, well below the 5-rad threshold for fetal malformations (²). Ultrasound imaging is a preferred choice due to lack of radiation exposure and the better sensitivity for detecting breast masses in young patients. Ultrasound is also a valuable tool in evaluating nodal basins prior to treatment,

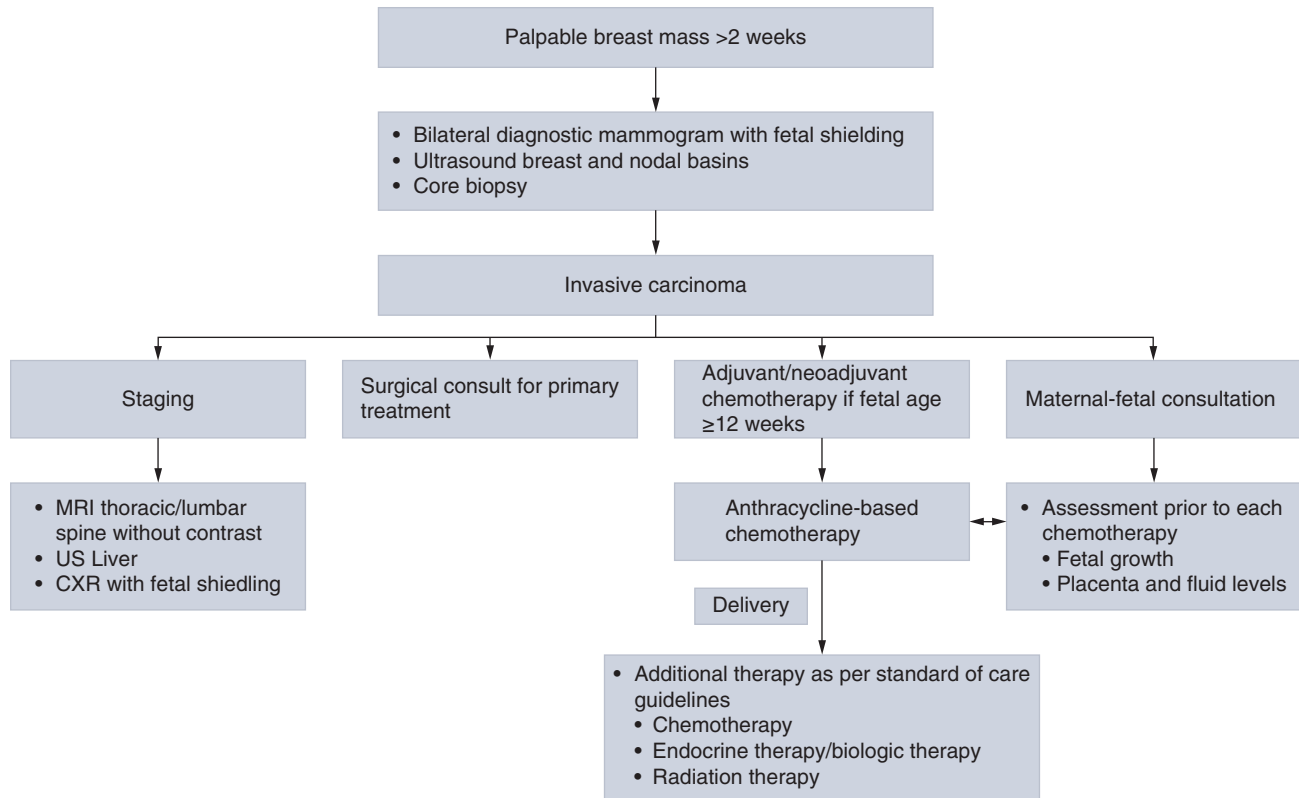

FIGURE 30-1 Algorithm for the evaluation and treatment of a suspicious breast mass during pregnancy. CXR, chest x-ray; US, ultrasound.

as well as monitoring disease response in both in the breast and the nodal basins while on preoperative chemotherapy ⁽⁸⁾.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has not been studied for the diagnosis of breast masses in pregnant or lactating women. Gadolinium has been shown to cross the placenta and cause fetal abnormalities in animal studies. Given these safety concerns, Gadolinium is a Food and Drug Administration class C drug in pregnancy and should not be used routinely in the evaluation of breast masses in pregnancy ⁽²⁾.

Pathologic Features of Breast Cancer During Pregnancy

The most common pathology of PABC is invasive ductal carcinoma. In an MD Anderson Cancer Center (MDACC) case series of patients with breast cancer treated with chemotherapy during pregnancy, PABC was diagnosed at a more advanced stage, with lymph node involvement and poor histologic and prognostic features, including high Ki67 and estrogen receptor (ER) and progesterone receptor (PR) negativity. *HER2*-positive tumors comprised 28% of the specimens.

The most common pathology was infiltrating ductal carcinoma. The authors concluded these features were similar to those reported in young nonpregnant women, and that age rather than pregnancy may be the determinant of tumor biology ⁽⁹⁾.

Staging

The American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) system is used for staging in pregnant patients with breast cancer. Given that stage of diagnosis may have significant psychosocial implications, accurate staging is important.

A complete history and physical examination and laboratory work, including complete blood cell counts and metabolic panel, should be done prior to initiation of treatment. Local imaging should include mammography and ultrasound of the breast and the draining lymphatics. Given that women with PABC often present with advanced-stage disease, the major sites of metastatic disease (lung, liver, and bone) should be evaluated in patients with stage II or higher cancers. Evaluation includes chest radiography with abdominal shielding, ultrasound of the liver, and MRI of the spine without contrast. A transthoracic echocardiogram prior to initiation of anthracycline chemotherapy is recommended ⁽²⁾.

Treatment of Breast Cancer During Pregnancy

The goal of treatment in both pregnant and nonpregnant patients is the same: the control of local and systemic disease. Although the treatment strategies for pregnant and nonpregnant patients are similar, the impact of the treatment on the fetus and the outcome of the pregnancy should be considered in the pregnant patient with breast cancer.

Local Therapy

Surgery and Radiation Therapy

As previously discussed, the use of anesthesia during pregnancy is not associated with an increased risk of fetal malformation ⁽²⁾. Most patients and surgeons elect to wait until the end of the first trimester to operate to minimize the risk of spontaneous abortion. In most reports of pregnant patients with breast cancer, the majority of women underwent modified radical mastectomy with axillary lymph node dissection, possibly reflecting treatment practice during that time period, later stage of diagnosis, or concerns over the need for radiation if breast-conserving surgery is performed. In general, breast radiation is contraindicated during pregnancy because of the risk of radiation exposure to the fetus. With new practices recommending systemic therapy and surgery as initial treatment strategies, radiation therapy can usually be delayed until after delivery ^(2,10).

In a recent series from MDACC, Dominici et al reported on 67 women diagnosed with PABC who received systemic chemotherapy during pregnancy and then proceeded to surgical management. Forty-seven patients underwent mastectomy, and 20 underwent breast-conserving surgery. There were a total of six postoperative complications, with all treated as outpatients; four complications were in the patients with mastectomy, and two were in the patients with breast-conserving surgery. The authors concluded breast-conserving surgery is feasible with no increase in the rate of complications ⁽²⁾.

Cardonick et al reported on 130 patients diagnosed with PABC from the Cancer and Pregnancy Registry. Ninety-five patients underwent surgery, 38 in the first, 48 in the second, and 9 in the third trimester. Fifty-four patients underwent mastectomy, 34 had a lumpectomy, and 15 had an excisional biopsy that did not require further surgery. There was no increase in the miscarriage rate in the first trimester ⁽²⁾.

There are limited data on the use of sentinel lymph node biopsy in pregnant patients with breast cancer. Isosulfane blue dye is not recommended due to reports of anaphylaxis in the patients as well as concerns for the safety of the fetus ⁽²⁾.

Systemic Therapy

The indications for systemic therapy in a pregnant patient with breast cancer are similar to those in the nonpregnant patient. Most of the chemotherapy agents used in pregnancy are rated category D. Limited data are available on pharmacokinetics of antineoplastic agents in the setting of physiologic changes of pregnancy. In a review of 289 pregnant cancer patients treated with chemotherapy for a variety of malignancies, the 14% to 19% incidence of fetal malformations with first-trimester exposure dropped to 1.3% with exposure in the second and third trimesters. Cardonick et al reported a rate of congenital malformations of 3.8% in their series of 104 women who received chemotherapy during pregnancy ⁽²⁾.

Chemotherapy

The only published prospective cohort of pregnant patients with breast cancer treated with systemic chemotherapy during the second and third trimesters of pregnancy did not report any congenital malformations, stillbirths, or spontaneous abortions ⁽¹¹⁾. The 57 women in this prospective series were treated with chemotherapy with FAC (5-fluorouracil 500 mg/m² IV on days 1 and 4; doxorubicin 50 mg/m² IV continuous infusion over 72 hours; and cyclophosphamide 500 mg/m² IV on day 1; every 21 days if blood counts have recovered) for a median of four cycles while pregnant. Chemotherapy was held after 35 weeks to avoid maternal neutropenia at the time of delivery. All women had live births, one child had Down syndrome, and two children had congenital anomalies. One woman died of pulmonary embolism after a cesarean delivery. At MDACC, pregnant women with breast cancer continue to be treated with FAC chemotherapy during their second and third trimesters of pregnancy.

The European registry published a recent report detailing outcomes of 413 women who received systemic chemotherapy during pregnancy. Multiple regimens were used, including taxanes, Cyclophosphamide, Methotrexate, Fluorouracil (CMF), and anthracyclines. There was no difference in obstetric complications between women receiving chemotherapy during pregnancy and those who did not. Despite a similar rate of premature deliveries between the two groups, infants exposed to chemotherapy in utero had a lower birth weight as well as an increased risk of complications compared to infants with no exposure to chemotherapy in utero. The authors concluded that a full-term delivery seemed to be paramount to decrease the risk of infant complications ⁽¹²⁾.

A systematic review of the use of taxanes in pregnancy conducted by Zagouri et al looked at 50 women with breast cancer who received various taxane regimens after the first trimester. They reported that 76% of infants had a normal Apgar score, and at the

16-month follow-up, 90% of the children were completely healthy. One child had recurrent otitis media, one child had immunoglobulin (Ig) A deficiency and constipation, and one child had delayed speech ⁽¹³⁾. Given the scarcity of the evidence and the lack of long-term follow-up for the children, the routine use of taxanes in pregnant patients with breast cancer cannot be recommended. For our node-positive patients, taxanes are given after delivery.

Hormonal Therapy

The routine use of tamoxifen in pregnant patients with breast cancer is not recommended, given animal data suggesting that it could be teratogenic, as well as case reports in humans describing congenital malformations. These include Goldenhar syndrome, ambiguous genitalia, vaginal bleeding, and spontaneous abortions ⁽²⁾.

Biologic Agents

Trastuzumab use in pregnancy is currently not recommended given multiple reports of oligohydramnios and anhydramnios in the literature ⁽²⁾. Lapatinib exposure during pregnancy was described in one patient who received lapatinib until 11 weeks of gestation, then discontinued the drug. The pregnancy was uneventful, and there were no reported maternal or fetal outcomes ⁽²⁾. There are no current reports on the use of pertuzumab or ado-trastuzumab-emtansine during pregnancy.

Prognosis

There are mixed results in describing prognosis of PABC across the literature. In a series of 121 cases of breast cancer diagnosed during pregnancy, Ribeiro et al reported a 5-year survival rate of 39%. A case-control study from Saudi Arabia compared 28 patients with PABC to 84 women without PABCs and showed no difference in relapse-free or overall survival between the two groups. Beadle et al also showed no difference in locoregional recurrence, distant metastasis, and overall survival between the 104 women with PABC and their 564 non-pregnancy-associated counterparts treated at MDACC between 1973 and 2006 ⁽²⁾. Litton et al reported data on 75 patients treated for PABC on a protocol at MDACC with FAC chemotherapy during the second and third trimesters of pregnancy. In this controlled setting, with all patients receiving similar evaluation and treatment, PABC was associated with improved disease-free and overall survival compared to controls ⁽¹⁴⁾. These results show that by using a multidisciplinary approach to the management of PABC, we are able to provide patients with at least as favorable outcomes as their nonpregnant counterparts.

Monitoring the Pregnancy

The pregnant patient with breast cancer should be referred to a high-risk obstetrician skilled in maternal-fetal medicine, who will be charged with monitoring the health of the mother and the fetus while undergoing cancer therapy.

Prior to initiating treatment, ultrasound is used to determine fetal viability and gestational age and expected date of delivery because both will have a significant effect on treatment planning. In our practice, ultrasound is performed before every cycle of chemotherapy to assess fetal growth and development. Amniocentesis may be recommended by the maternal/fetal health team if the fetus is thought to be at higher-than-average risk for karyotype abnormalities or if there are abnormalities detected by ultrasound that should be investigated further. Although not part of the routine evaluation, amniocentesis may be necessary to assess fetal lung maturity, particularly if early induction of labor is being considered.

Timing of delivery should be optimized with relation to the systemic treatment of the breast cancer, occurring no less than 2 weeks after the last dose of anthracycline-based chemotherapy, to minimize the effects of cytopenias ⁽¹¹⁾. Planned inductions of labor and cesarean deliveries are often done to minimize the risk of pregnancy-associated complications ⁽¹⁰⁾.

Breast Feeding

Given that many chemotherapeutic agents are excreted in breast milk, they can carry a risk of complications to the infant. Therefore, breast feeding should be avoided during the administration of chemotherapy, biologic agents, endocrine therapy, and radiation therapy.

Long-Term Implications for the Offspring

Of 57 children born to mothers who underwent chemotherapy for breast cancer in the second or third trimesters, MDACC has reported that the majority of children were healthy and had no developmental delays, with the exception of one child born with Down syndrome ⁽¹¹⁾. A survey was sent to parents and guardians of children who were exposed to chemotherapy in utero to assess the child's health, development, and performance in school. Children's age ranged between 2 and 157 months, and only 2 of 40 evaluated by survey required special attention in school. One child had Down syndrome; the other had attention-deficit disorder. However, longer follow-up of these children will be needed to evaluate possible late side effects, such as impaired cardiac function and fertility. Another study by Aviles et al described similar outcomes for a cohort of 84 children born to mothers

who received chemotherapy for hematologic malignancies while pregnant⁽¹⁵⁾. They also evaluated 81 of these children for cardiac toxicity, using clinical evaluation and echocardiography, every 5 years after birth until 29 years of age. There was no evidence of cardiac dysfunction among the children, ranging in age from 9.3 to 29.5 years (mean 17.1 years)⁽¹⁵⁾.

Pregnancy Termination

A number of case series do not appear to support the previously held belief that pregnancy termination improves the survival of pregnant patients with breast cancer. In contrast, there appears to be a trend toward shorter survival with termination of pregnancy⁽²⁾. A pregnant woman with breast cancer must be fully aware of the evidence, or lack thereof, regarding pregnancy termination and survival. In situations of known or suspected fetal teratogenesis or if maternal health is in jeopardy, pregnancy termination may be an appropriate medical recommendation.

PREGNANCY AFTER A DIAGNOSIS OF BREAST CANCER

Epidemiology

Of the women diagnosed with breast cancer between 2007 and 2011 in the Surveillance Epidemiology and End Results (SEER) database, 1.8% were 20 to 34 years of age, and 9.3% were 35 to 44 years of age.

According to the National Center for Health Statistics, the average age of first-time mothers increased from 21.4 years in 1970 to 25 years in 2006 and to 25.8 years in 2012. From 1970 to 2006, the proportion of first births to women aged 35 years and older increased by almost eight times. In 2006, about 1 of 12 first births was to women aged 35 years and older compared with 1 of 100 in 1970. In the 2012 update, the birth rate for women in their early 20s declined to a record low, but continued to increase in women aged 30 to 44 years old.

Therefore, younger women diagnosed with breast cancer may not have had children at the time of their breast cancer diagnosis and may seek to do so after their breast cancer treatment is completed. Of course, patients with breast cancer who have had children before their diagnosis also may wish to have additional children after treatment.

Chemotherapy-Related Amenorrhea

Chemotherapy-related amenorrhea (CRA) is variably defined as cessation of menstruation for 3 to 12 months in women who have been exposed to chemotherapy⁽¹⁶⁾. The incidence of CRA varies with age, cytotoxic agent

used, and cumulative cytotoxic dose⁽¹⁶⁾. A study by Goodwin et al looked at 183 women who underwent systemic therapy, including chemotherapy and tamoxifen for breast cancer. Multivariate analysis showed that age, chemotherapy, and tamoxifen were all predictors of menopause in patients with breast cancer receiving systemic therapy⁽¹⁷⁾. Taxanes may result in a higher rate of CRA in the first year but have not been shown to cause a longer duration of CRA; this effect is primarily seen in older women, and when age is controlled for, adding a taxane appears to have little-to-no effect on subsequent risk of CRA⁽¹⁸⁾. Lee et al reviewed the risk of permanent amenorrhea by chemotherapy regimen and patient age⁽¹⁹⁾.

The current method recommended by the American Society of Clinical Oncology for fertility preservation is controlled ovarian stimulation followed by oocyte or embryo cryopreservation^(20, 21). The efficacy of ovarian suppression by a gonadotropin-releasing hormone analogue (GnRHa) at reducing the risk of CRA has been evaluated in multiple studies. Gerber et al randomized 60 patients with hormone receptor-negative breast cancer to chemotherapy with or without goserelin. There was no difference in amenorrhea at 6 months between the two groups, and all but one patient had regular menses at 2 years⁽²²⁾. The PROMISE-GIM6 (Prevention of Menopause Induced by Chemotherapy: A Study in Early Breast Cancer Patients-Gruppo Italiano Mammella 6) trial randomized 281 patients with stage I to III breast cancer to chemotherapy with or without triptorelin. There was a significant decrease in the incidence of early menopause in the triptorelin group (26% vs 9%)⁽²³⁾. The POEMS/SWOG (Southwest Oncology Group) 0230 trial enrolled 257 hormone receptor-negative premenopausal patients with stage I to IIIA breast cancer randomized to receive cyclophosphamide-containing chemotherapy with or without goserelin. There was a decrease in the risk of premature ovarian failure (POF) at 2 years in the goserelin group (22% vs 8%), and more successful pregnancies were noted in the goserelin arm. A meta-analysis by Del Mastro et al revealed a significant decrease in the risk of POF, with an odds ratio of 0.43, in patients receiving GnRHa⁽²⁴⁾.

Impact of Pregnancy After Breast Cancer

A number of reviews have concluded that pregnancy after a diagnosis of breast cancer does not worsen survival⁽²⁵⁻²⁷⁾. In a retrospective case-control study by Mueller et al, data from three SEER populations were linked to vital records data to identify women under the age of 45 at diagnosis who had live birth 10 months or longer after diagnosis. When these women were matched to nonpregnant women with a history of breast cancer, women who became pregnant after a diagnosis of breast cancer had a decreased

risk of dying as compared with women who did not become pregnant⁽²⁸⁾. The improved survival noted in this and other studies may reflect a “healthy-mother effect,” whereby women who become pregnant after a diagnosis of breast cancer may have already been at decreased risk of recurrence.

Women who are considering pregnancy after a diagnosis of breast cancer should understand that most data come from retrospective case-control studies in different populations and with different data collection techniques. Women with a history of breast cancer must be aware of their personal risk of recurrence and should weigh this against their desire to have a child. Although it has been suggested that women should wait 2 years after their breast cancer diagnosis before becoming pregnant, there are no data suggesting that a pregnancy in the first 2 years increases the risk of recurrence; rather, data indicate that this is the period of increased recurrence regardless of pregnancy⁽²⁹⁾.

MALE BREAST CANCER

Epidemiology

Male breast cancer is rare, accounting for less than 1% of male cancers. It was estimated that 2,360 new cases of breast cancer would be diagnosed in men in the United States in 2014 and that 430 men would die of the disease⁽³⁰⁾. A large population-based study done by Giordano et al suggested that the incidence of male breast carcinoma is increasing, from 0.86 to 1.08 per 100,000 population between 1973 and 1988, albeit at a slower rate than that of women⁽³¹⁾. Men with *BRCA* mutations are at higher risk of male breast cancer compared to the general population, with a lifetime risk of 4% to 40% for *BRCA 2* mutation carriers and up to 4% for *BRCA 1* mutation carriers⁽³²⁾. Other risk factors for development of male breast cancer include testicular abnormalities, infertility, Klinefelter syndrome, positive family history, benign breast conditions, radiation exposure, increasing age, and Jewish ancestry. Other studies have also identified *PTEN* mutations, *CHEK 2* mutations, obesity, and gynecomastia as potential risk factors for male breast cancer. There is a 2.5-fold increase in risk in men who have female relatives with breast cancer^(32,33).

Diagnosis and Staging

The most common presenting symptom for men with breast cancer is a painless lump. Other symptoms include nipple retraction, local pain, nipple ulceration, nipple bleeding, and nipple discharge⁽³³⁾. The mean age of diagnosis is 67 years, compared to 62 years for women with breast cancer⁽³²⁾. Male breast cancer is more likely to have a delay in diagnosis when

compared to women; this is thought to in part account for the later stage of disease and greater tumor size with lymph node involvement at diagnosis⁽³³⁾.

A biopsy should be performed of any suspicious mass. If breast cancer is diagnosed, the male patient with breast cancer should undergo staging evaluations appropriate for the given tumor stage, based on the AJCC TNM staging system.

Pathologic Features of Male Breast Cancer

As in women with breast cancer, increasing tumor size, lymph node involvement (including increasing numbers of positive lymph nodes), and higher histologic grade are poor prognostic features^(32,33). The majority of cases are infiltrating ductal carcinoma, with a high rate of hormone receptor-positive tumors (ER 80%-90%, PR 73%-81%). *HER2/neu*-positivity reports are inconsistent, initially reported as equivalent to female breast cancer, but more recently noted at 5% to 15% in different studies^(32,33).

Treatment of Male Breast Cancer

The overall prognosis for men with breast cancer is similar to that of women with similar stage disease, with studies showing an equivalent benefit of surgery, chemotherapy, and tamoxifen when compared to women with breast cancer^(34,35). The goals of treatment are the same: to control local and systemic disease (Fig. 30-2).

Surgery

There are no randomized trials that compare surgical interventions for localized male breast cancer. Clinical practice is based on retrospective data as well as extrapolation from female breast cancer. The current recommendation is a modified radical mastectomy, which was found to be equivalent to a radical mastectomy⁽³³⁾. Given the scarce evidence available for breast-conserving surgery, and the potential lack of cosmetic benefit in men, modified radical mastectomy remains the standard of care for surgical management of male breast cancer.

As in women with breast cancer, evaluation of the axilla with a sentinel lymph node biopsy or axillary node dissection as indicated is considered part of standard of care⁽³³⁾.

Radiation Therapy

A study by Yu et al evaluated 81 male patients with breast cancer between 1977 and 2006 treated at London Regional Cancer Program in Ontario, Canada. The local therapy consisted of surgery alone for 26 patients and surgery with postmastectomy radiation therapy

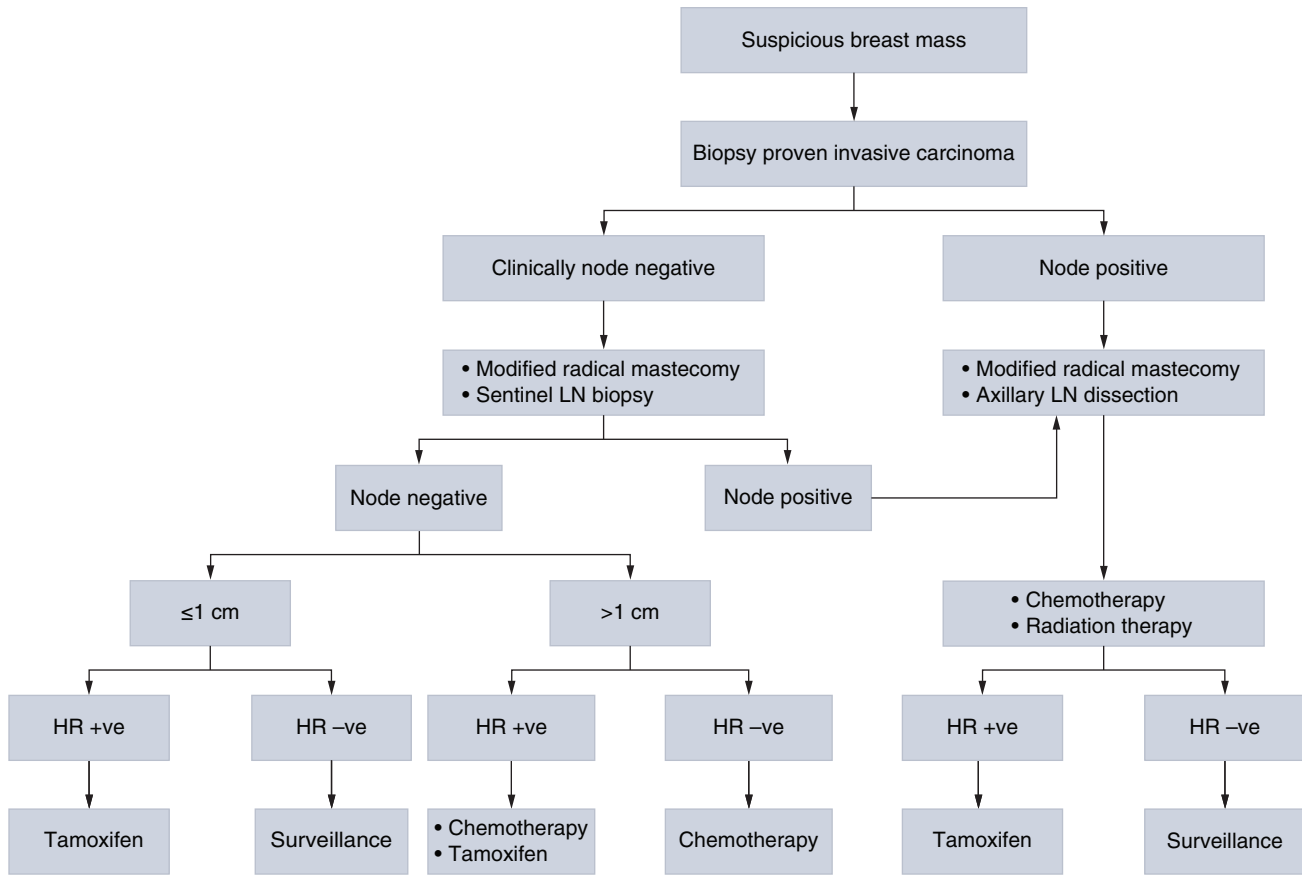

FIGURE 30-2 Algorithm for the treatment of male breast cancer. HR +ve, HR positive; HR -ve, HR negative; LN, lymph node.

(PMRT) for 46 patients. There was no difference in overall survival between the two groups; however, there was a significant decrease in locoregional recurrence in the PMRT group⁽³⁶⁾. A study from MDACC looked at 142 male patients with breast cancer to determine factors associated with a benefit from adjuvant radiation therapy. In this cohort, 18% of patients had locoregional failure. Tumor size, margin status, and lymph node involvement were noted as predictors of locoregional recurrence⁽³⁷⁾.

Adjuvant Systemic Therapy

The MDACC experience was reported by Giordano et al. Between 1944 and 2001, there were 135 male patients with breast cancer evaluated and treated; 51 received adjuvant systemic therapy: 13 received chemotherapy alone, 19 received hormonal therapy alone, and 19 received both. There was a significant increase in time to recurrence (HR 0.49; 95% CI, 0.27-0.9) and survival (HR 0.45, 95% CI, 0.25-0.84) in patients receiving hormonal therapy. In patients with lymph node-positive disease, there was a nonsignificant trend toward improvement in time to recurrence and overall survival with the use of chemotherapy⁽³⁸⁾.

A review from MDACC on 64 men treated with tamoxifen revealed at a median follow-up of 3.9 years that 34/64 (53%) of patients experienced one or more toxicities while on tamoxifen therapy. The most common side effects were weight gain and sexual dysfunction; 13 patients discontinued tamoxifen due to side effects⁽³⁵⁾. A study by Xu et al revealed that adherence to tamoxifen decreased from 65% at year 1 to 18% at year 5 in a cohort of 116 hormone receptor-positive male patients with breast cancer. Five- and ten-year disease-free survivals, as well as overall survival, were significantly lower in the low-adherence group compared to the adherent group⁽³⁹⁾.

The role of aromatase inhibitors in the adjuvant setting of male breast cancer is currently limited. One study from the German Cancer Registry looked retrospectively at 257 male patients with breast cancer who were treated with either tamoxifen ($n = 207$) or an aromatase inhibitor ($n = 50$). The authors found that overall survival was significantly better following tamoxifen adjuvant therapy compared to aromatase inhibitors⁽⁴⁰⁾. Aromatase inhibitors are not currently recommended as adjuvant therapy for male patients with breast cancer.

Therapy for Metastatic Disease

Given the high proportion of hormone-sensitive tumors among men with breast cancer, a variety of hormonal therapies have been used for the treatment of metastatic disease⁽⁴¹⁾. Tamoxifen has been established as first-line hormonal therapy because of its limited toxicity and established efficacy in men⁽³³⁾. The role of aromatase inhibitors in metastatic disease is not yet clear, although some case reports with disease response exist^(42, 43). One study showed an overall response rate of 40% in 15 patients with metastatic breast cancer receiving an aromatase inhibitor⁽⁴⁴⁾. A phase II SWOG trial investigating anastrozole and goserelin for the treatment of male patients with hormone receptor-positive metastatic or recurrent breast cancer closed in 2007 because of lack of enrollment. Aromatase inhibitors may be used as a second-line option in metastatic male breast cancer following progression on tamoxifen, alone or in combination with a luteinizing hormone-releasing hormone analogue.

In men with hormone receptor-negative disease or who fail hormonal therapy, systemic chemotherapy may offer significant palliation for metastatic disease. Jaiyesimi et al reported an overall response rate of 40% for the use of chemotherapeutic agents or regimens such as FAC in men with metastatic breast cancer⁽³³⁾. The use of *HER2*-directed agents has not been formally studied in male breast cancer. Their use remains a consideration in *HER*-amplified male breast cancer, through extrapolation of the data from female breast cancer studies.

THE RISKS AND BENEFITS OF HORMONE REPLACEMENT THERAPY

A great debate occurred over several years regarding the value of hormone replacement therapy (HRT) in women as a cardiovascular protective agent when weighed against the risk of developing breast cancer. The combined estrogen and progesterone arm of the Women's Health Initiative (WHI), a large, randomized clinical trial designed to evaluate the role of HRT in the primary prevention of coronary artery disease, demonstrated an increased risk of breast cancer and ischemic stroke without any decrease in cardiovascular events⁽⁴⁵⁾. Combined HRT failed to improve cognitive function and health-related quality of life, although there was an improvement in vasomotor symptoms and sleep disturbances^(46, 47). There was a nonsignificant increase in the incidence of ovarian cancer in the WHI study, with no difference in incidence of endometrial cancer⁽⁴⁸⁾. Combined HRT was effective at increasing bone mineral density and decreasing

fractures in healthy postmenopausal women⁽⁴⁹⁾. Given the information obtained from the WHI, the decision to recommend combined HRT in a postmenopausal woman for either the vasomotor symptoms of menopause or bone health must be made carefully by weighing the risks and benefits for that individual.

The estrogen-only arm of the WHI closed for a lack of improvement in cardiovascular health among those treated with estrogen⁽⁵⁰⁾. Although there was a non-statistically significant decrease in breast cancer among those women randomized to the estrogen arm, the decision to recommend estrogen alone as HRT for a postmenopausal woman must be made carefully by weighing the risks and benefits for that individual.

A Cochrane review, last updated in 2012, evaluated the effect of long-term HRT by reviewing 19 trials involving 41,904 women⁽⁵¹⁾. The results showed that continuous combined HRT significantly increased the risk of breast cancer, among other conditions. The continuous estrogen-only HRT did not significantly increase the risk of breast cancer. The HRT was only effective at decreasing the incidence of fractures. Given these findings, HRT is not indicated for the routine management of chronic disease at this time, and more evidence is needed regarding its safety.

Hormone Replacement Therapy in Breast Cancer Survivors

The first published, randomized trial evaluating the safety of HRT in breast cancer survivors was the HABITS (Hormone Replacement After Breast Cancer—Is It Safe?) trial⁽⁵²⁾. This study was a randomized, non-placebo-controlled, noninferiority trial that evaluated the risk of a new breast cancer in women with a history of breast cancer if they subsequently received HRT. Of the planned recruitment of 1,300, there 447 women randomized; 221 women received HRT, and 221 women acted as controls. This study was terminated early after the results of the WHI trials became available. With a median of 4 years of follow-up, the hazard ratio (HR) for the development of a new breast cancer in women receiving HRT in the HABITS trial was 2.4 (95% CI, 1.3-4.2). The cumulative incidence of breast cancer at 5 years was significantly increased in the HRT group at 22.2% compared to 8% in the control arm.

Given the results of the HABITS trial and the WHI data, one must carefully consider the use of HRT for postmenopausal breast cancer survivors. Among postmenopausal women without a history of breast cancer in the WHI cohort, combination HRT increased the risk of breast cancer and was most beneficial for the treatment of vasomotor symptoms and the prevention of bone loss and fracture. In women with a history of breast cancer, it may be best to pursue other

pharmacologic therapies for bone health or vasomotor symptoms before prescribing HRT.

DUCTAL CARCINOMA IN SITU

Epidemiology

Ductal carcinoma in situ (DCIS), also called intraductal carcinoma, is a noninvasive breast cancer whose age-adjusted incidence rose from 5.8 per 100,000 to 32.5 per 100,000 women between 1975 and 2004 (^{53,54}). The increase in incidence is likely secondary to screening mammography and better detection of lower-grade lesions. The rates of noncomedo DCIS has increased across all age groups, whereas the rates of comedo DCIS have overall remained stable (⁵⁵). The most common presentation of DCIS is an abnormal mammogram demonstrating clustered microcalcifications (⁵⁶).

Pathologic Features

Traditionally, DCIS has been classified primarily on the basis of architectural pattern (solid, papillary, micropapillary, or cribriform), as well as the presence or absence of comedo necrosis. The comedo subtype is characterized by extensive central zonal necrosis (⁵⁶). Bellamy et al reported that this classification correlates with the extent of disease. Micropapillary DCIS involved more than one quadrant in 71% of cases, compared to 18%, 17%, and 25% in comedo, solid, and cribriform subtypes, respectively. The solid DCIS subtype was the most likely to be excised fully at surgery (⁵⁷). Nuclear grade (low, intermediate, or high) and the presence or absence of comedonecrosis has also been used to classify DCIS (⁵⁸). High-grade DCIS is more frequently ER and PR negative, has a higher proliferation rate and higher expression of *HER2* when compared to low-grade DCIS. Intermediate grade is more heterogeneous and shows variability in its immunoprofile (⁵⁶).

Ductal carcinoma in situ is classified as having microinvasion if the invasive component is 0.1 cm or less in greatest dimension (⁵⁹). If there are multiple foci of microinvasion, the size of the largest area is used to classify the microinvasion.

Although an axillary or sentinel lymph node biopsy is not the standard of care for all women presenting with DCIS, a small proportion have axillary lymph node involvement. A National Cancer Data Base review of almost 11,000 women with DCIS who had a lymph node dissection between 1985 and 1991 found that 3.6% had axillary metastases (⁶⁰). Silverstein et al evaluated 100 patients with DCIS treated with either mastectomy or radiation therapy who underwent axillary lymph node dissection. No patients were found to have positive axillary lymph nodes (⁶¹). Two studies

looking at pure DCIS without evidence of microinvasion reported 1/102 (0.98%) sentinel lymph node positivity in one study (⁶²) and 5/87 (6%) sentinel lymph node positivity in the other (⁶³).

A study looking at high-risk DCIS and DCIS with microinvasion revealed that 9/76 (12%) of patients with high-risk DCIS had positive sentinel lymph nodes (7/9 were micrometastasis), and 3/31 (10%) of patients with DCIS with microinvasion had positive sentinel lymph nodes (⁶⁴).

Currently, routine lymph node evaluation is not recommended for all patients with DCIS. However, nodal evaluation may be considered in patients with high risk of invasive carcinoma, that is, large (> 3 cm) tumors, which frequently have a high nuclear grade and are of the comedo subtype (^{65,66}). In addition, sentinel lymph node biopsy may be discussed as an option for those undergoing a simple mastectomy for DCIS as the opportunity for a sentinel lymph node biopsy is lost if invasive or microinvasive disease is subsequently found as the tumor bed is no longer in place.

Treatment

Local Therapy

The options for the surgical management of DCIS range from excision alone to mastectomy. Retrospective series of mastectomy for DCIS have shown 10-year breast cancer-specific survival rates in excess of 98% (⁵⁶). The risk of local and distant recurrence following mastectomy is low, and recurrences usually present as invasive breast carcinomas (⁶⁷). Mastectomy is a highly effective method for the treatment of DCIS; however, it is a radical procedure for a disease that carries a low probability of malignant transformation.

Multiple studies have evaluated the benefit of adjuvant radiation therapy at decreasing risk of recurrence in patients who undergo breast-conserving surgery for DCIS. A retrospective study by Vargas et al reviewed 405 patients treated at a single institution with lumpectomy alone (n = 54), lumpectomy and radiation therapy (n = 313), or mastectomy (n = 43). At a median follow-up of 7 years, the rates of ipsilateral breast tumor recurrence were 9.3% after lumpectomy alone, 8% after lumpectomy and radiation, and 4.7% after mastectomy. Of the 32 local failures, 20 involved invasive cancers. In this study, there was no difference in the rates of local control, cause-specific survival, and overall survival between the lumpectomy and mastectomy groups. Risk factors associated with local failure included young age (<45 years), close or positive margins (<2 mm), no breast radiation, and lower electron boost energies (⁶⁸).

The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 study compared lumpectomy to

lumpectomy with radiation for women with primarily small-volume DCIS (≤ 2 cm) and negative resection margins. Through 8 years of follow-up, the use of radiation therapy significantly reduced the incidence of noninvasive breast cancer recurrence from 13.4% to 8.2% and that of invasive disease from 13.4% to 3.9% ⁽⁶⁹⁾. Moderate-to-marked and absent-to-slight comedo necrosis was found to be an independent high- and low-risk predictor for ipsilateral breast tumor recurrence, respectively ⁽⁷⁰⁾.

In a European trial, women with DCIS up to 5 cm in size at the time of excision were randomly assigned to no further treatment or radiation therapy ⁽⁷¹⁾. With a median follow-up of 10.5 years, the 10-year local recurrence-free rate was 74% in the group treated with excision alone compared with 85% in the women treated by excision and radiation ($P < .0001$; HR 0.53; 95% CI, 0.4-0.7). The HRs for DCIS and invasive local recurrence were 0.52 (95% CI, 0.34-0.77) and 0.58 (95% CI, 0.39-0.86), respectively. In multivariate analysis, factors significantly associated with an increased local recurrence risk in this study were young age, symptomatic detection of DCIS, intermediate or poorly differentiated DCIS, cribriform or solid growth pattern, involved or close margins, and treatment by local excision alone. The effect of radiation therapy was homogeneous across all assessed risk factors.

The need for radiation therapy in women with low-volume, good-prognosis DCIS was planned in a randomized trial conducted by the Radiation Therapy Oncology Group. Unfortunately, this study, which randomized women with good-prognosis DCIS to radiation with or without tamoxifen or to tamoxifen with or without observation, was closed due to slow accrual. A recent Cochrane review confirmed the benefit of adding radiation therapy to breast-conserving surgery in the treatment of all patients with DCIS ⁽⁷²⁾.

Multiple randomized trials have confirmed the benefit of the addition of radiation therapy to lumpectomy in reducing the risk of ipsilateral breast cancer recurrence. It must be noted that DCIS overall has excellent prognosis, with a breast cancer-specific survival in excess of 95% across all trials in all treatment groups: mastectomy, lumpectomy, and lumpectomy plus radiation ⁽⁵⁶⁾.

Systemic Therapy

The only approved therapy in the United States for the systemic treatment of DCIS is tamoxifen. In the NSABP B-24 study, 1,804 women with small-volume DCIS (most ≤ 2 cm), including some with positive margins, who had undergone a lumpectomy and radiation therapy were randomly assigned to either placebo or tamoxifen 20 mg by mouth daily for 5 years ⁽⁷³⁾. There was a statistically significant

absolute risk reduction of 5.2% in all breast cancer events (invasive and noninvasive combined) in women who received tamoxifen. This risk reduction was mainly the result of a decrease in ipsilateral invasive disease and contralateral noninvasive disease. The risk of the development of breast cancer at regional or distant sites was not significantly reduced among tamoxifen users. The most serious but rare side effects of tamoxifen were deep venous thrombosis (1%), nonfatal pulmonary embolism (0.2%), and uterine cancer (approximately 0.1%).

Subsequent analysis of available tumor tissue from women who participated in NSABP B-24 was performed to determine if response to tamoxifen was influenced by ER status ⁽⁷⁴⁾. Although tamoxifen was beneficial among women with ER-positive DCIS, the number of women with ER-negative DCIS was small in this subanalysis, so the investigators concluded that the benefit of tamoxifen was unclear in this group of women. At MDACC, tamoxifen is recommended for women with ER-positive DCIS but not those with ER-negative DCIS. The benefit of tamoxifen in women with ER-negative but PR-positive DCIS is unclear.

Anastrozole is an aromatase inhibitor currently approved for the treatment of adjuvant and metastatic hormone receptor-positive breast cancer. The IBIS II trial assessed the efficacy and safety of anastrozole in the prevention of breast cancer in high-risk postmenopausal women. At 5-year follow-up, there was a significant benefit of anastrozole at reducing the risk of breast cancer (HR 0.47; 95% CI, 0.32-0.68). In this study, 366 patients had ER-positive DCIS, which was treated by mastectomy within 6 months of enrollment. The authors reported that the benefit of anastrozole was seen across all groups, including the DCIS subgroup, with an HR of 0.44 (95% CI, 0.11-1.15) ⁽⁷⁵⁾. These results should be interpreted with caution as antiestrogen therapy is usually prescribed in patients following lumpectomy aiming at reducing the risk of ipsilateral invasive cancers, whereas all patients with DCIS in IBIS II underwent mastectomy. The NSABP B-24 data do not show any benefit of tamoxifen at reducing the incidence of contralateral invasive disease, and tamoxifen is not routinely prescribed in patients undergoing mastectomy for DCIS ⁽⁷³⁾. Given these findings, the role of aromatase inhibitors in DCIS treatment remains to be elucidated. The NSABP-35 is a trial currently comparing anastrozole to tamoxifen in postmenopausal women with hormone-sensitive DCIS who have undergone lumpectomy and radiation therapy.

The role of trastuzumab for *HER2*-positive DCIS is currently being investigated in the NSABP B-43 trial. Trastuzumab is currently not recommended in the treatment of DCIS.

HIGH-DOSE CHEMOTHERAPY WITH TRANSPLANTATION

In an attempt at reducing the risk of death for women with early-stage, poor-prognosis, or metastatic breast cancer, the effectiveness of more aggressive chemotherapeutic regimens, including high-dose chemotherapy (HDC) with either bone marrow or stem cell support, has been investigated. Despite initial encouraging results, two meta-analyses failed to show a survival benefit in poor-prognosis, early-stage breast cancer or in metastatic breast cancer^(76,77). Given the results of these trials, HDC with stem cell support is not used in the management of breast cancer at MDACC.

RISK REDUCTION STRATEGIES FOR *BRCA 1* AND *BRCA 2* CARRIERS

Although a family history of breast cancer, especially in a first-degree relative, has been identified as a risk factor for the development of breast cancer, most women with breast cancer do not have a significant family history⁽⁷⁸⁻⁸⁰⁾. It is believed that approximately 5% to 10% of breast cancer cases are due to the inheritance of rare, highly penetrant germline mutations, particularly in the *BRCA 1* and *BRCA 2* genes⁽⁸¹⁾. Women with mutations in one of these two genes have a cumulative lifetime risk of invasive breast cancer (up to age 70 years) of 57% and 49%, invasive epithelial ovarian cancer of 40% and 18% for *BRCA 1* and *BRCA 2* mutations, respectively⁽⁸²⁾.

Chemoprevention

The benefit of tamoxifen for risk reduction among women with mutations in either the *BRCA 1* or *BRCA 2* gene is unclear. A subgroup analysis of the 288 patients in the P1 breast cancer prevention trial who developed breast cancer examined the protective effect of tamoxifen in the development of breast cancer among *BRCA 1* or *BRCA 2* mutation carriers. Of the 288 patients, 19 (6.6%) tested positive for deleterious *BRCA 1* or *BRCA 2* mutations. Within the *BRCA 1* mutation carriers ($n = 8$), 5 patients received tamoxifen and 3 received placebo (risk ratio 1.67; 95% CI, 0.32-10.7). Within the *BRCA 2* mutation carriers ($n = 11$), 3 received tamoxifen and 8 received placebo (risk ratio 0.38; 95% CI, 0.06-1.56). In this small subset of patients, tamoxifen did not reduce breast cancer incidence in *BRCA 1* mutation carriers; however, it was effective at reducing breast cancer incidence by 62% in *BRCA 2* carriers, a figure similar to the risk reduction among all women involved in the P1 trial. Of note, 83% of *BRCA 1* carriers had ER-negative tumors, compared to 76% of *BRCA 2* carriers who were ER positive⁽⁸³⁾.

The Hereditary Breast Cancer Clinical Study group reported that tamoxifen protected against the development of contralateral breast cancer in *BRCA 1/BRCA 2* mutation carriers, with an odds ratio of 0.50 for *BRCA 1* carriers and 0.42 for *BRCA 2* carriers. In the small subgroup of patients who had undergone an oophorectomy, no benefit was noted from tamoxifen use. No information on hormone receptor status of the tumors was available in this study⁽⁸⁴⁾. Gronwald et al recently published a matched case-control study in 1,504 women (411 with bilateral breast cancer and 1,093 with unilateral breast cancer) with known *BRCA 1* or *BRCA 2* mutations, looking at the effect of tamoxifen in reducing incidence of contralateral breast cancer. Three hundred and thirty-one women (22%) used tamoxifen during the follow-up period. The use of tamoxifen was associated with a decrease in contralateral breast cancer in both *BRCA 1* (OR 0.58; 95% CI, 0.39-0.85) and *BRCA 2* (OR 0.39; 95% CI, 0.19-0.83) groups. The authors also found there was no additional protective effect with longer durations of tamoxifen use. The strongest protective effect was for women with 1 year or less of tamoxifen use (OR 0.37; 95% CI, 0.20-0.69; $P = 0.001$), followed by women with 1 to 4 years of tamoxifen use (OR 0.53; 95% CI, 0.32-0.87; $P = 0.01$), and nonsignificant in women with 4 or more years of tamoxifen (OR 0.83; 95% CI, 0.44-1.55; $P = 0.55$). The authors concluded that a short-term course of tamoxifen for chemoprevention may be as effective as a conventional 5-year treatment course in *BRCA 1/BRCA 2* carriers⁽⁸⁵⁾.

Given these results, the most effective chemoprevention strategy for women with known *BRCA 1* or *BRCA 2* mutations, the optimal duration of its use, and the age at which to begin have not yet been demonstrated⁽⁸⁶⁾. Patients with a known mutation in the *BRCA 1* or *BRCA 2* gene should be encouraged to participate in clinical trials evaluating the efficacy of chemoprevention agents for breast cancer.

Prophylactic Mastectomies

A woman with a mutation in either *BRCA 1* or *BRCA 2* gene should be counseled regarding the potential role of prophylactic mastectomy in reducing her future risk of developing breast cancer.

Both types of prophylactic mastectomies, subcutaneous or total, are likely to leave behind a small amount of residual breast tissue, making this a risk reduction strategy that is not 100% effective in preventing subsequent breast cancer.

Hartmann et al examined the effectiveness of prophylactic mastectomies among women at increased risk of breast cancer. In the moderate-risk group, 4 breast cancers were diagnosed, compared with 37.4 predicted by the Gail model, an 89.5% risk reduction.

In the high-risk group, 214 women who underwent bilateral prophylactic mastectomies were compared to their sisters who did not undergo prophylactic mastectomies. At a median follow-up of 14 years, the incidence of breast cancer in the women who underwent prophylactic mastectomies as compared to their sisters who had not was 1.4% and 38.7%, respectively⁽⁸⁷⁾. As a follow-up to this study, the investigators then genotyped 176 of the women who had prophylactic mastectomies. Of these, 26 were found to carry germline mutations in *BRCA 1* or *BRCA 2*. None of these 26 women developed breast cancer over a median follow-up of 13 years⁽⁸⁸⁾.

Meijers-Heijboer et al prospectively followed 139 women with germline *BRCA 1* or *BRCA 2* gene mutations. After a mean follow-up of 2.9 years, no breast cancers were observed in the 76 women who underwent prophylactic mastectomy, compared to 8 breast cancers in the 63 women who did not undergo prophylactic mastectomies. The authors concluded that prophylactic bilateral total mastectomy was effective at reducing breast cancer incidence in *BRCA 1* or *BRCA 2* mutation carriers⁽⁸⁹⁾.

In the PROSE study group, Rebbeck et al prospectively followed 483 women with *BRCA 1* or *BRCA 2* gene mutations. Of those, 105 women underwent bilateral prophylactic mastectomy and 378 did not, serving as matched controls. With a mean follow-up of 6.1 years, 2/105 (1.9%) women in the surgery group were diagnosed with breast cancer, compared to 184/378 (48.7%) in the control group, a greater than 90% risk reduction⁽⁹⁰⁾.

Domcheck et al reported a prospective multicenter cohort study to evaluate the relationship between risk-reducing surgeries and cancer outcomes in *BRCA 1/BRCA 2* mutation carriers. Among 247 women who underwent prophylactic mastectomies, no breast cancers were diagnosed, compared to 98 breast cancers in 1,372 women who did not have risk-reducing mastectomy⁽⁹¹⁾.

At MDACC, women with a known deleterious mutation in either the *BRCA 1* or *BRCA 2* gene are evaluated and counseled by our genetic counselors and breast surgeons regarding the potential breast cancer risk reduction of bilateral prophylactic mastectomies or bilateral mastectomies in patients who already carry a diagnosis of breast cancer.

Prophylactic Bilateral Salpingo-Oophorectomies

In addition to decreasing the risk of gynecologic cancer among women with a known mutation in either the *BRCA 1* or *BRCA 2* gene, prophylactic bilateral salpingo-oophorectomy (BSO) may decrease the risk of developing breast cancer^(92,93). A prospective study

by Kauff et al followed 170 women 35 years of age or older with either a *BRCA 1* or *BRCA 2* mutation, of which 98 chose to undergo risk reduction BSO and 72 opted to undergo surveillance. With a median follow-up of 24.2 months, breast cancer and peritoneal cancer were diagnosed in 3 and 1, respectively, of the 98 women who chose prophylactic BSO. Of the 72 women who chose surveillance, breast cancer was diagnosed in 8 women, ovarian cancer in 4, and peritoneal cancer in 1. There was also a significant increase in the time to diagnosis of breast cancer of *BRCA*-related gynecologic malignancy in the BSO group (HR 0.25; 95% CI, 0.08-0.74). The authors concluded that prophylactic BSO was effective at decreasing the risk of breast and *BRCA*-associated gynecologic malignancies; there was still a residual risk of peritoneal cancer⁽⁹³⁾.

In a large, multicenter prospective study, 1,079 women 30 years of age and older with ovaries in situ and a deleterious *BRCA 1* or *BRCA 2* mutation were enrolled at 1 of 11 centers from November 1, 1994, to December 1, 2004⁽⁹²⁾. Women self-selected prophylactic BSO or surveillance. Of 792 patients assessable for gynecologic cancers, 12/283 women in the surveillance group were diagnosed with gynecologic cancers (10 in *BRCA 1* carriers, 2 in *BRCA 2* carriers) compared to 3/509 diagnosed with peritoneal cancer in the BSO group (all in *BRCA 1* carriers). Of 597 patients assessable for breast cancer, 28/294 (19 in *BRCA 1* carriers, 9 in *BRCA 2* carriers) were diagnosed with breast cancer in the surveillance group, compared to 19/303 (15 in *BRCA 1* carriers, 4 in *BRCA 2* carriers) in the BSO group. The BSO was protective against ER-positive breast cancer but not against ER-negative breast cancer. The authors concluded that BSO was most effective at reducing the risk of *BRCA 1*-associated gynecologic malignancies (HR 0.15; 95% CI, 0.04-0.56) and at reducing the risk of *BRCA 2*-associated breast cancer (HR 0.28; 95% CI, 0.08-0.92).

Domcheck et al reported a significantly lower incidence of ovarian cancer in patients undergoing BSO. These results were conserved in patients with or without a prior history of breast cancer. Patients undergoing BSO had a lower risk of first diagnosis of breast cancer in *BRCA 1* and *BRCA 2* mutation carriers. The authors also noted that BSO was associated with a significant reduction in all-cause mortality, breast cancer-specific mortality, as well as ovarian cancer-specific mortality⁽⁹¹⁾.

Results from a meta-analysis of 10 studies in *BRCA 1/BRCA 2* carriers showed that prophylactic BSO was associated with a significant reduction in the risk of *BRCA*-associated gynecologic cancers (HR 0.21; 95% CI, 0.12-0.39). The same meta-analysis reported a statistically significant decrease in the risk of breast cancer in *BRCA 1/BRCA 2* mutation carriers (HR 0.49; 95% CI, 0.37-0.65). Similar risk reduction for breast cancer was observed in the *BRCA 1* and *BRCA 2* subgroups. Data

were insufficient to stratify gynecologic cancer risk reduction by *BRCA 1* and *BRCA 2* mutations⁽⁹⁴⁾.

Our patients with germline mutations in either *BRCA 1* or *BRCA 2* are counseled by qualified professionals on the possible reduction in ovarian cancer as well as breast cancer risk through the use of prophylactic BSO. However, fertility is clearly impaired by this risk reduction strategy. Also, the premenopausal patient with a known mutation in *BRCA 1* or *BRCA 2* who is considering a prophylactic BSO should be counseled regarding the physiologic changes that may be associated with premature menopause, including bone loss and psychosocial changes, such as changes in mood and sexual function.

EPITHELIAL OVARIAN CANCER

Epidemiology

Ovarian cancer is the second most common cancer of the female genital tract, with approximately 21,290 cases expected in the United States in 2015 ⁽¹⁾. Epithelial tumors comprise 90% of ovarian cancers, and the most common histologic subtype is high-grade serous carcinoma, followed by endometrioid, clear cell, and mucinous tumors. Ovarian cancer remains the number one cause of death due to gynecologic cancers in the United States, accounting for 14,180 deaths this year. Among women, ovarian cancer is the fifth most common cancer-related cause of death in the United States ⁽¹⁾. The lifetime risk of a woman in the United States developing ovarian cancer is approximately 1 in 70 (1.37%). Ovarian cancer is also more common among white women compared to African American or Asian American women in the United States, although the differences are narrowing. In most parts of Europe and North America, the incidence of ovarian cancer was constant during the decades prior to the 1990s. However, among white women, ovarian cancer incidence rates are reported to have declined from 2001 to 2010 by 2.2% per year ⁽²⁾.

This cancer is predominantly a cancer of the perimenopausal and the postmenopausal period, with 80% to 90% of cases occurring after the age of 40. The incidence is higher in older women, and the median age at diagnosis is 63 years.

Mortality

Ovarian cancer accounts for 5.5% of the deaths from cancer that occur in women between 60 and 79 years of age ⁽¹⁾. Prognosis among women with ovarian cancer is dependent on the stage of disease at the time of diagnosis. Five-year survival rates among women with localized, regional, and distant disease at the time of diagnosis are 92%, 72%, and 27%, respectively ⁽¹⁾. Relative survival rates for ovarian cancer have improved substantially over the last decade by an average of 2% per year, and modern 5-year survival estimates are between 45% and 50% ⁽³⁾. Survival among white women with ovarian cancer in the United States is reportedly better than survival among black women, and the improvement noted was not observed in black women ^(1,4).

Etiology

The etiology and the tissue of origin of ovarian cancer are not fully understood. Over the past decade, there has been an increased appreciation that epithelial ovarian cancers (EOCs) represent a heterogeneous group of malignancies. Some of this heterogeneity is related to distinct pathophysiology associated with the development of different histologic subtypes. For example, the majority of high-grade serous ovarian cancers are now believed to arise from fallopian tube fimbria rather than ovarian surface epithelium. This fallopian tube hypothesis originated from observations in women undergoing risk-reducing (prophylactic) salpingo-oophorectomy due to hereditary breast-ovarian cancer syndromes.

Approximately 5% to 10% of these women are diagnosed with an occult ovarian cancer⁽⁵⁻⁷⁾. The majority of these early cancers are either located in the fimbrial portion of the fallopian tube or, on close histologic examination, have a coexisting carcinoma in situ component in the fallopian tube fimbria. Subsequent investigations revealed that careful sectioning of fallopian tubes from high-risk women frequently revealed areas of marked cytologic atypia and disorganized growth within the fimbria. These areas have been called serous tubal intraepithelial carcinoma (STIC) or tubal dysplasia and are characterized by cytologic atypia, positive p53 immunostaining (which correlates with mutations in the *TP53* gene), abnormal proliferation (as evident by Ki67 staining), and DNA damage (Fig. 31-1)⁽⁸⁻¹⁰⁾.

Based on their distinct molecular features and clinicopathologic characteristics, other carcinogenesis models have been proposed for endometrioid, clear cell, mucinous, and low-grade serous ovarian cancers. Endometrioid and clear cell tumors have a strong epidemiologic link with endometriosis, and there is accumulating evidence that they may arise from endometriotic cysts or areas of atypical endometriosis. Low-grade serous carcinomas are thought to arise from borderline neoplasms. However, this remains a controversial area, and much research is focused on better understanding the pathophysiology of different subtypes of EOC.

Risk Factors

Numerous studies have attempted to demonstrate possible links between environmental, dietary, reproductive, endocrine, viral, and hereditary factors and

the risk of developing ovarian cancer. These factors are summarized in Table 31-1.

The strongest risk factor for ovarian cancer is a genetic predisposition. Women with *BRCA1* and *BRCA2* mutations have a 39% to 46% and 10% to 27% lifetime risk of developing ovarian cancer, respectively, which is 18 to 36 times higher than that of the background risk. A smaller proportion of cases of familial ovarian cancer are associated with mutations in mismatch repair genes (*MLH1*, *MSH2*, *MHS6*, *PMS2*) related to Lynch syndrome, with a lifetime risk of ovarian cancer ranging from 0% to 24%. Patients with germline mutations in *MLH1* and *MSH2* seem to be at the highest risk for ovarian cancer compared to patients with *MSH6* and *PMS2* mutations. Most recently, germline mutations

Table 31-1 Risk Factors for Developing Ovarian Cancer

Increased	Decreased	Indeterminate
Hereditary Family history of ovarian cancer Personal history of breast cancer <i>BRCA1</i> or <i>BRCA2</i> mutation Lynch syndrome	Reproductive Multiparity Breastfeeding	Fertility drugs Exercise Cigarette smoking Perineal talc exposure
Reproductive Advanced age Nulligravity Infertility	Hormonal Oral contraceptives Progestins

in *BRIP1*, *RAD51D*, and *RAD51C* have been associated with an increased lifetime risk of ovarian cancer, ranging from 10% to 15%.

Other factors associated with an increased risk of ovarian cancer include age, early menarche, late menopause, and obesity⁽¹¹⁻¹³⁾.

Protective factors that have been shown to reduce the risk of ovarian cancer include the use of oral contraceptives, multiparity, breast feeding, hysterectomy, and tubal ligation⁽¹⁴⁾. Other factors, including exercise, perineal talc exposure, infertility treatment, and use of postmenopausal hormone replacement therapy, have not been definitively shown to alter a woman's risk of developing ovarian cancer.

Screening

Stage I ovarian cancer is associated with excellent survival; however, more than two-thirds of patients are diagnosed with stage III or IV disease. These observations have provided a compelling rationale in support of screening for early-stage disease. The most commonly used screening strategies include a combination of serum cancer antigen 125 (CA125) levels and pelvic sonography. While several large trials have demonstrated that screening can detect cancer in asymptomatic women, there are concerns regarding the poor positive predictive value for these strategies and lack of proven survival benefit. The findings of four key trials are summarized in [Table 31-2](#)⁽¹⁵⁻¹⁹⁾. Currently, the US Preventive Services Task Force recommends against screening for ovarian cancer in asymptomatic women of average risk. However, the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) is using the Risk of Ovarian Cancer (ROC) time series algorithm to interpret CA125, which has shown an encouraging sensitivity and specificity, and the mortality data are anticipated in 2015.

The Molecular Landscape of Epithelial Ovarian Cancer

Molecular Biology

Although the different subtypes of EOC possess unique molecular aberrations ([Table 31-3](#)) and transcriptional signatures, their morphologic features resemble the specialized epithelia of the reproductive tract that derive from the Müllerian ducts.

As noted, accumulating evidence points to the distal fallopian tube epithelium as the tissue of origin for most high-grade serous carcinomas. The most common molecular alterations in serous carcinomas are mutations in *TP53*, which are nearly ubiquitous. The Cancer Genome Atlas (TCGA) project has also significantly advanced our understanding of other molecular

and genetic alterations in high-grade serous carcinoma. In addition to the expected *TP53* mutations in 96% of tumors, low prevalence recurrent somatic mutations in *NF1*, *BRCA1*, *BRCA2*, *RB1*, and *CDK12* were also observed. Serous carcinomas are also characterized by a high degree of chromosomal instability (gene copy number amplifications and deletions), and both total and regional instability are associated with tumor grade and altered patient outcomes⁽²⁰⁾. Somatic copy number analysis performed as part of TCGA also confirmed 8 and 22 chromosomal regions of recurrent gain and loss, respectively. Five of the gains and 18 of the losses occurred in more than half of the tumors. Although such aberrant areas of DNA frequently carry multiple genes, it is presently thought that only a limited number of genes are “key drivers” of the process. These key drivers are thought to be the most critical markers and potential treatment targets. Candidate drivers at areas of copy number gain and loss are frequently proposed. For example, it has been suggested that 45% of high serous cancers harbor altered phosphatidylinositol 3-kinase (PI3K)/RAS signaling mediated by multiple copy number alterations, including *PTEN* deletion and *PIK3CA*, *KRAS*, *AKT1*, and *AKT2* amplification. Low-grade serous carcinomas have been found to have alterations in the mitogen-activated protein kinase (MAPK) pathway. Approximately 20% to 40% of tumors have a *KRAS* mutation, while a smaller proportion of tumors demonstrate mutations in *BRAF*, accounting for 5% of low-grade serous carcinomas⁽²¹⁾.

Clear cell and endometrioid cancers are epidemiologically and molecularly linked to endometriosis. Frequent somatic mutations of *PIK3CA* and *ARID1A* (AT-rich interactive domain-containing protein 1A) have been documented in tumors associated with endometriosis^(22, 23). Common genetic abnormalities identified in endometrioid ovarian carcinomas include somatic mutations of *CTNNB1* and *PTEN*⁽²⁴⁾.

Cytokines and Growth Factors

Several cytokines and growth factors have been studied in ovarian carcinogenesis. For instance, levels of interleukin 10 (IL-10) and interleukin 6 (IL-6) are particularly elevated in ovarian cancer ascites. Endogenously produced IL-6 can protect tumor cells from natural killer cell-mediated killing, and IL-6 expression by immunohistochemistry was associated with poor prognosis⁽²⁵⁾. Furthermore, IL-6 has been identified as an etiologic paracrine factor in paraneoplastic thrombocytosis and associated poor prognosis in ovarian cancer⁽²⁶⁾. When compared to high-grade serous tumors, ovarian clear cell carcinomas are associated with higher circulating levels of IL-6⁽²⁷⁾.

A detailed review of growth factor pathways targeted in ovarian cancer is beyond the scope of this chapter.

Table 31-2 Summary of Major Trials in Ovarian Cancer Screening

	Ovarian Cancer Screening Trials in the General Population			
	University of Kentucky Study (¹⁹)	Japanese Shizuoka Cohort Study of Ovarian Cancer Screening (⁸)	Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial (¹⁷)	United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) (^{15,16})
Study design	Single-arm prospective study	RCT with 1 screening strategy in study group	RCT with 1 screening strategy in study group	RCT with 2 screening strategies in the study group
Cohort	25,327	41,688	30,630	98,305
Screening strategy	Ultrasound	Physical exam, ultrasound and CA125	Ultrasound and CA125	Two screening arms (ultrasound, USS) and CA125 followed by ultrasound (multimodal, MMS)
Interpretation of CA125	35-kU/L cutoff	CA125 using a 35-kU/L cutoff	CA125 using a 35-kU/L cutoff	CA125 interpreted using the Risk of Ovarian Cancer (ROC) algorithm
Key screening findings	Encouraging sensitivity (81%) for primary OC/FT cancer; 76.3% for primary invasive OC/FT cancer	Encouraging sensitivity (77.1%) for primary OC/FT cancer	Lower sensitivity (69.5%) for primary OC/FT cancer; 68.2% for primary invasive OC/FT cancer when compared to the other trials (only 28% were stage I/II)	Encouraging sensitivity (89.4% MMS/84.9% USS) for primary OC/FT cancer; 84.9% MMS/75.0% USS for primary invasive OC/FT cancer (47% MMS/50% USS were stage I/II). Superior sensitivity (88.6% vs 65.8%) and PPV (21.7% vs 5.8%) of MMS compared to the USS arm for detection of primary invasive epithelial OC/FT cancers during incidence screening, with 40.3% in the MMS and 51.5% in the USS arm detected at early stage
Key mortality/surrogates of mortality findings	Longer 5-year survival in the screened arm (74.8%) compared to unscreened women from the same institution treated by the same surgical and chemotherapeutic protocols (53.7%) ($P < 0.001$)	Stage shift: more stage I ovarian cancers in the screened group (63%) compared to the control (38%)	No mortality benefit: 118 ovarian cancer deaths in the screened arm, 100 in the control arm	Mortality data awaited in 2014/2015
Current status	Completed	Mortality data to be reported	Completed	Mortality data to be reported in 2015

Table 31-3 Current Concepts Regarding the Origins and Molecular Pathology of Epithelial Ovarian Cancer

Histology	Precursor	Molecular Features
Low-grade serous carcinoma	Cystadenoma–borderline tumor–carcinoma sequence	Mutations in <i>K-RAS</i> and/or <i>b-RAF</i>
High-grade serous carcinoma	“De novo” in epithelial inclusion cysts	<i>p53</i> mutation and <i>BRCA1</i> dysfunction (usually promoter methylation) <i>PIK3CA</i> ^b amplification (25%–40%)
Low-grade endometrioid carcinoma	Endometriosis and endometrial-like hyperplasia ^a	Mutations in <i>CTNNB1</i> (B-catenin gene) and <i>PTEN</i> with microsatellite instability
High-grade endometrioid carcinoma	Epithelial inclusion glands/cysts	<i>p53</i> mutation and <i>BRCA1</i> dysfunction (usually promoter methylation) <i>PIK3CA</i> mutation
Mucinous carcinoma	Cystadenoma–borderline tumor–carcinoma sequence	Mutations in <i>K-RAS</i> ; <i>p53</i> mutation associated with transition from borderline tumor to carcinoma.
Clear cell carcinoma	Endometriosis	<i>PTEN</i> mutation/loss of heterozygosity <i>PIK3CA</i> mutation

^aEndometriosis and adjacent low-grade endometrioid carcinoma share common genetic events, such as loss of heterozygosity at the same loci involving the same allele (eg, *PTEN*). In contrast, high-grade and poorly differentiated endometrioid carcinomas are similar to high-grade serous carcinomas.

^b*PIK3CA* is the gene at chromosome 3q26 that specifically encodes the p110α subunit of the phosphatidylinositol-3-kinase (PI3K) protein.

Instead, we briefly highlight the vascular endothelial growth factor (VEGF) pathway, which has proven to be the most clinically useful target to date. The VEGF signaling cascade is mediated through a partially redundant set of ligands and receptors, which have emerged as promising targets for antiangiogenic cancer therapy. The VEGF ligand family consists of seven ligands: VEGF A-E, placenta growth factor 1 (PlGF1), and PlGF2. The receptor tyrosine kinases involved in this signaling cascade include VEGF receptor type 1 (VEGFR1), VEGFR2, and VEGFR3. Vascular endothelial growth factor ligands are overexpressed in EOC cells, while the receptors are present mainly on the tumor endothelial cells⁽²⁸⁾. Vascular endothelial growth factor is a key mediator of angiogenesis, which is stimulated by hypoxia. Bevacizumab, a monoclonal anti-VEGF-A antibody, is the prototypical member of this class, and as a single agent has been the most promising biological compound for the treatment of recurrent ovarian cancer.

Prognostic Factors

Prognostic factors are tumor-related characteristics that determine the biologic behavior and risk of death from the disease; their predictive value may change during the course of treatment and thereafter.

Factors associated with poor prognosis in advanced ovarian cancer (stage III or IV) fall into two subgroups (as determined by multivariate analysis in clinical trials):

1. *Variables prior to systemic treatment predictive of survival:* age, stage at diagnosis, performance status, residual tumor volume, and tumor histology

2. *Variables at the time of relapse predictive of time to progression:* less than 6 months from last chemotherapy (platinum-resistant disease), poorer performance status, mucinous histology, larger number of sites of disease, best previous response to chemotherapy versus progression, serum CA 125 levels

Stage

Stage is a dominant prognostic factor in ovarian cancer. The main prognostic factors in early-stage ovarian cancer (stages I–IIA) are International Federation of Gynecology and Obstetrics (FIGO) stage, histologic grade, histologic type, and patient's age. Early-stage ovarian cancer is discovered early in fewer than 30% of patients; in such cases, the 5-year survival is good, ranging from 51% to 98%⁽¹⁾.

Cancer Antigen 125

Cancer antigen 125 is a high molecular weight glycoprotein that is elevated in 80% of EOCs⁽²⁹⁾. There is no definitive evidence that pretherapeutic CA125 levels correlate with survival in EOC⁽³⁰⁾. The most aggressive tumors are not necessarily those with the highest CA125 levels. However, there has been evidence that the kinetics of an individual's CA125 level during treatment may be related to best response to treatment as well as survival⁽³¹⁾.

Residual Disease

It is logical to assume that the extent of postoperative residual tumor volume is affected by both the biology

Low-grade serous carcinoma of the ovary is characterized by relative uniformity of the cells and up to 12 mitoses per 10 high-power fields. Courtesy of Anaïs Malpica, MD.

High-grade serous carcinoma of the ovary is characterized by pleomorphism; there is marked nuclear atypia and >12 mitoses per 10 high-power fields. Courtesy of Anaïs Malpica, MD.

FIGURE 31-2 Low-grade and high-grade serous carcinoma. (Used with permission from Anaïs Malpica, MD.)

and the history of the disease, as well as the radicality, emphasis, and effort involved in the tumor reductive surgery. What remains controversial is the relative contribution of these factors to the prognostic significance of residual disease. On one hand, the tumors that are more aggressive and disseminated are more difficult to resect and therefore associated with larger residual disease. Therefore, how advanced the tumor was before debulking may be more important than how much disease was left behind. Other features—such as the type of chemotherapy, the intrinsic chemosensitivity of the tumor, and the presence of other biological variables—may be as important as or even more important than the extent of the surgery. Proponents of the importance of maximal surgical effort point to a wealth of retrospective data and the evolution of “optimal cytoreductive surgery” from less than 2 cm to R0 (no visible residual disease) as evidence for the importance of the surgical result⁽³²⁾. The only prospective randomized trial of the neoadjuvant approach versus up-front tumor reductive surgery in patients with advanced-stage EOC was carried out by the European Organization for Research and Treatment of Cancer (EORTC)–Gynaecological Cancer Group. In this trial, optimal resection (as defined by residual tumor of 1 cm or less) was noted in 41.6% of patients who underwent primary debulking compared to 80.6% of patients who underwent neoadjuvant chemotherapy interval debulking⁽³³⁾.

Histologic Subtypes

Serous Carcinoma

Serous carcinoma is the most common histologic subtype of EOC, and this subtype can further be divided

into high-grade and low-grade serous carcinomas⁽³⁴⁾. Recently, MD Anderson developed a two-tier grading system in serous carcinomas based on nuclear atypia and mitotic rate to distinguish high-grade from low-grade tumors (Fig. 31-2). This has been adopted by the gynecologic oncology community to further define these two diseases.

High-Grade Serous Carcinoma

High-grade serous carcinomas account for 70% to 80% of all ovarian cancers and are the most common type of EOC. High-grade serous carcinomas may present with varying architectural patterns, but the defining characteristic of these tumors is high mitotic activity (>12 mitoses per 10 high-power fields [HPFs]) and the presence of multinucleated cells⁽³⁴⁾.

Low-Grade Serous Carcinoma

Low-grade serous carcinoma accounts for 6% to 10% of serous ovarian cancers and 5% to 8% of all ovarian cancers. These tumors are now thought to arise from borderline tumors have distinct molecular aberrations and clinical behavior when compared to their high-grade counterpart. Low-grade serous tumors have low mitotic activity (<12 mitoses per 10 HPFs) and are distinguished from borderline tumors based on destructive invasion of more than 5 mm⁽³⁵⁾.

Mucinous Carcinoma

In older references, the proportion of mucinous ovarian cancers is as high as 30%. However, there is now increased recognition that many such tumors, on careful evaluation, are thought to represent metastases from the gastrointestinal tract. Contemporary estimates of the prevalence of primary ovarian mucinous

FIGURE 31-3 Operative removal of mucinous ovarian tumor.

carcinoma is approximately 3%. Primary ovarian origin is favored by unilaterality, large size greater than 12 cm, smooth external surface, and association with other ovarian pathology. Conversely, metastases tend to be bilateral, be less than 10 cm in size, exhibit surface involvement, and have colloid and signet ring morphology. True mucinous ovarian tumors are low-grade malignancies that have a low propensity for metastatic spread and are usually diagnosed as unilateral stage IA tumors even though they may reach enormous size (Fig. 31-3) ⁽³⁶⁾. Newer studies have also dispelled the notion that pseudomyxoma peritonei is commonly secondary to an ovarian mucinous carcinoma. It is now recognized that pseudomyxoma peritonei is almost always associated with an appendiceal mucinous lesion ⁽³⁷⁾.

Endometrioid Adenocarcinoma

Overall, 10% of epithelial ovarian tumors are of endometrioid histology and resemble endometrial adenocarcinoma, and both types occur simultaneously as synchronous primary tumors in as many as 25% of cases in patients younger than 45 years of age ⁽³⁸⁾. Identification of multifocal disease is important because patients with disease metastatic from the uterus to the ovaries have a 5-year survival rate of 30% to 40%. Those with synchronous multifocal disease have a 5-year survival rate of 70% to 80%. Concurrent endometriosis is present in 10% of cases. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be seen.

Clear Cell Carcinoma

Clear cell carcinomas comprise 5% to 10% of ovarian cancers and, like endometrioid tumors, may be associated with endometriosis or endometrial cancer. Some

studies indicated that clear cell carcinoma may be resistant to standard carboplatin-paclitaxel-based chemotherapy regimens. However, other investigators have shown that when the pathology was carefully reviewed by a gynecologic pathologist, only suboptimal cytoreduction and spread of disease were associated with a significantly increased risk of platinum resistance ⁽³⁹⁾.

Transitional Cell Carcinoma

Transitional cell carcinomas were previously thought to represent malignant Brenner tumors; however, recent studies have shown that they are molecularly similar to high-grade serous carcinomas. These tumors are now classified as a subtype of high-grade serous carcinomas ⁽⁴⁰⁾.

Undifferentiated Carcinoma

Undifferentiated carcinomas are thought to represent the most poorly differentiated high-grade serous carcinomas rather than a separate entity ⁽⁴¹⁾.

Histologic Grading

Previously, a three-tier grading system was used in the diagnosis of EOC; however, there was no consensus on the definition of this system. More recently, two-tier grading systems (high grade vs low grade) have been shown to have better prognostic and interobserver variability ^(34, 42). Consistent with their distinct pathophysiology and tumor biology, low-grade serous carcinomas are more resistant to chemotherapy and are associated with significantly higher rates of platinum-resistant disease ⁽⁴³⁾.

Staging

Accurate staging is critical to the success of surgery and adjuvant therapy. The staging of ovarian cancer is based on the gross and pathologic findings of the initial surgical evaluation. The FIGO classification uses the sites and extent of the disease, including capsule rupture and ascites, to categorize ovarian cancer into four stages. This is summarized in Table 31-4.

Diagnosis

Symptoms of ovarian cancer are nonspecific and include early satiety, bloating, constipation, and weight loss. It is not uncommon for patients to have been referred for a gastrointestinal evaluation before the correct diagnosis is reached. Objective signs of ovarian carcinoma are also nonspecific and include a pelvic mass, ascites, carcinomatosis, possible pleural effusion(s), and occasionally supraclavicular lymphadenopathy.

Table 31-4 FIGO Staging for Ovarian Cancer

FIGO		TNM
0	Primary tumor cannot be assessed	TX
	No evidence of primary tumor	T0
I	Tumor confined to ovaries	T1
IA	Tumor limited to one ovary, capsule intact	T1a
	No tumor on ovarian surface	
	No malignant cells in the ascites or peritoneal washings	
IB	Tumor limited to both ovaries, capsules intact	T1b
	No tumor on ovarian surface	
	No malignant cells in the ascites or peritoneal washings	
IC	Tumor limited to one or both ovaries	T1c
IC1	Surgical spill	
IC2	Rupture prior to surgery, tumor on ovarian surface, positive malignant cells in the ascites, or	
IC3	positive peritoneal washings	
II	Tumor involves one or both ovaries with pelvic extension	T2
IIA	Extension and/or implants in uterus and/or tubes	T2a
IIB	Extension to other pelvic organ	T2b
III	Tumor involves peritoneal metastasis outside the pelvis and/or regional lymph node metastasis	T3
IIIA1 (i)	Positive retroperitoneal nodes only ≤ 10 mm	T1, T2,
IIIA1 (ii)	Positive retroperitoneal nodes only > 10 mm	T3aN1
IIIA2	Microscopic, extrapelvic (above the brim) peritoneal involvement \pm positive retroperitoneal lymph nodes	T3a/T3aN1
IIIB	Macroscopic, extrapelvic, peritoneal metastasis ≤ 2 cm \pm positive retroperitoneal lymph nodes; includes extension to capsule of liver/spleen	T3b/T3bN1
IIIC	Macroscopic, extrapelvic, peritoneal metastasis > 2 cm \pm positive retroperitoneal lymph nodes; includes extension to capsule of liver/spleen	T3c/T3cN1
IVA	Pleural effusion with positive cytology	M1
IVB	Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside the abdominal cavity)	

Other major recommendations are as follows:

- Histologic type including grading should be designated at staging.
- Primary site (ovary, fallopian tube or peritoneum) should be designated where possible.
- Tumors that may otherwise qualify for stage I but involved with dense adhesions justify upgrading to stage II if tumor cells are histologically proven to be present in the adhesions.

Management

In general, the initial management and staging of EOC is surgical. In early-stage ovarian cancer, comprehensive staging allows for proper triage to adjuvant therapy. When comprehensive staging is performed, a substantial number of patients initially believed to have disease confined to the pelvis will be staged upward⁽⁴⁴⁾.

In advanced EOC, surgery and chemotherapy are both utilized in initial management. However, there remains debate regarding the sequence of these interventions in the treatment of advanced ovarian cancer. Patients have historically been candidates for neoadjuvant chemotherapy if they have multiple medical comorbidities, poor performance status, or extensive disease on imaging that is not felt to be amenable to

up-front surgery. Despite this, there is no current consensus regarding which patients should have up-front cytoreduction or neoadjuvant chemotherapy. The current approach at MD Anderson is for all patients with suspected advanced ovarian cancer (based on computed tomographic [CT] imaging) to undergo a preoperative laparoscopic assessment (Fig. 31-4).

This laparoscopic evaluation provides the following: surgicopathologic diagnosis, assessment of metastatic disease burden and likelihood of complete resection (modified Fagotti score)⁽⁴⁵⁾, and research tissue acquisition. Our laparoscopic triage is accomplished by scoring made by two independent and blinded surgeons. Those patients scored less than 8 undergo primary cytoreduction (with up to a 2-week interval). Those with scores of 8 or more undergo neoadjuvant

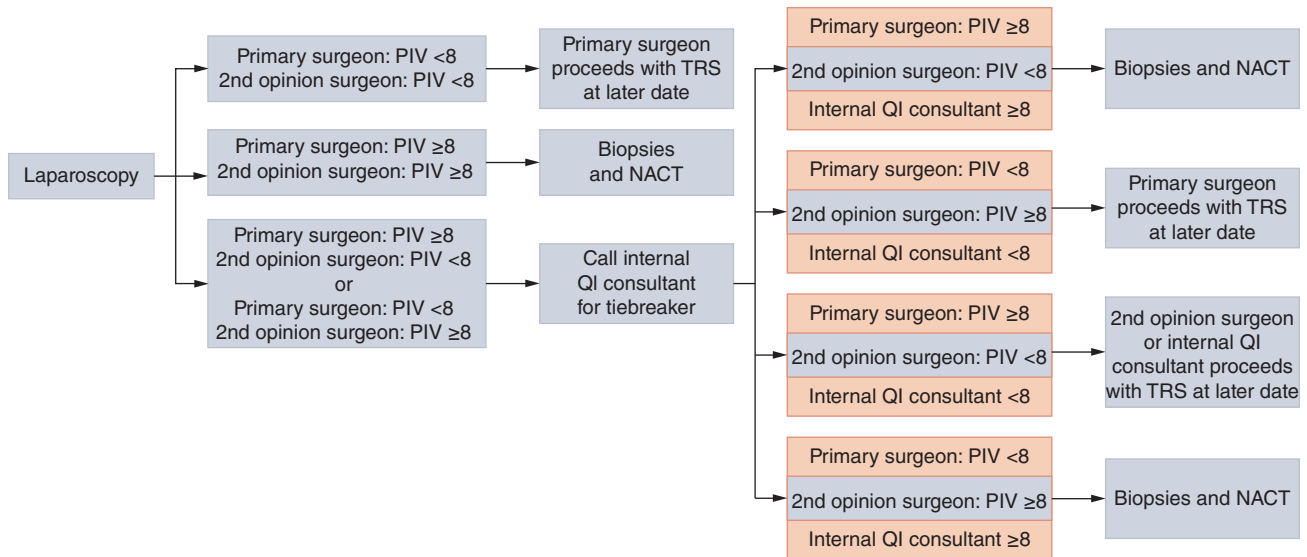

FIGURE 31-4 Laparoscopic scoring system utilized at MD Anderson to determine resectability of disease. (Reproduced with permission from Nick AM, Coleman RL, Ramirez PT, et al: A framework for a personalized surgical approach to ovarian cancer. *Nat Rev Clin Oncol*. 2015;12(4):239-245.)

chemotherapy (consisting of three cycles of carboplatin and paclitaxel), followed by consideration of interval cytoreductive surgery and three additional cycles of chemotherapy (\pm maintenance therapy)⁽⁴⁶⁾. An outline of our treatment algorithm is shown in Fig. 31-5.

In addition to a preoperative evaluation with lab testing, imaging, and office examination, the National Comprehensive Cancer Network (NCCN) now recommends genetic testing for all newly diagnosed high-grade serous ovarian cancers.

Primary Cytoreductive Surgery

A staging laparotomy involves the following steps:

1. Midline vertical incision
2. Evacuation and cytologic analysis of ascites
3. Inspection and palpation of all peritoneal (intraperitoneal and retroperitoneal) surfaces, including the subdiaphragmatic areas
4. Total abdominal hysterectomy and bilateral salpingo-oophorectomy
5. Omentectomy with debulking to no gross residual disease
6. If disease limited to ovaries, bilateral pelvic and para-aortic lymph node sampling; multiple biopsies, including the paracolic gutters, cul-de-sac, lateral pelvic walls, vesicouterine reflection, subdiaphragmatic sites, and intra-abdominal areas
7. Appendectomy if a mucinous tumor is found

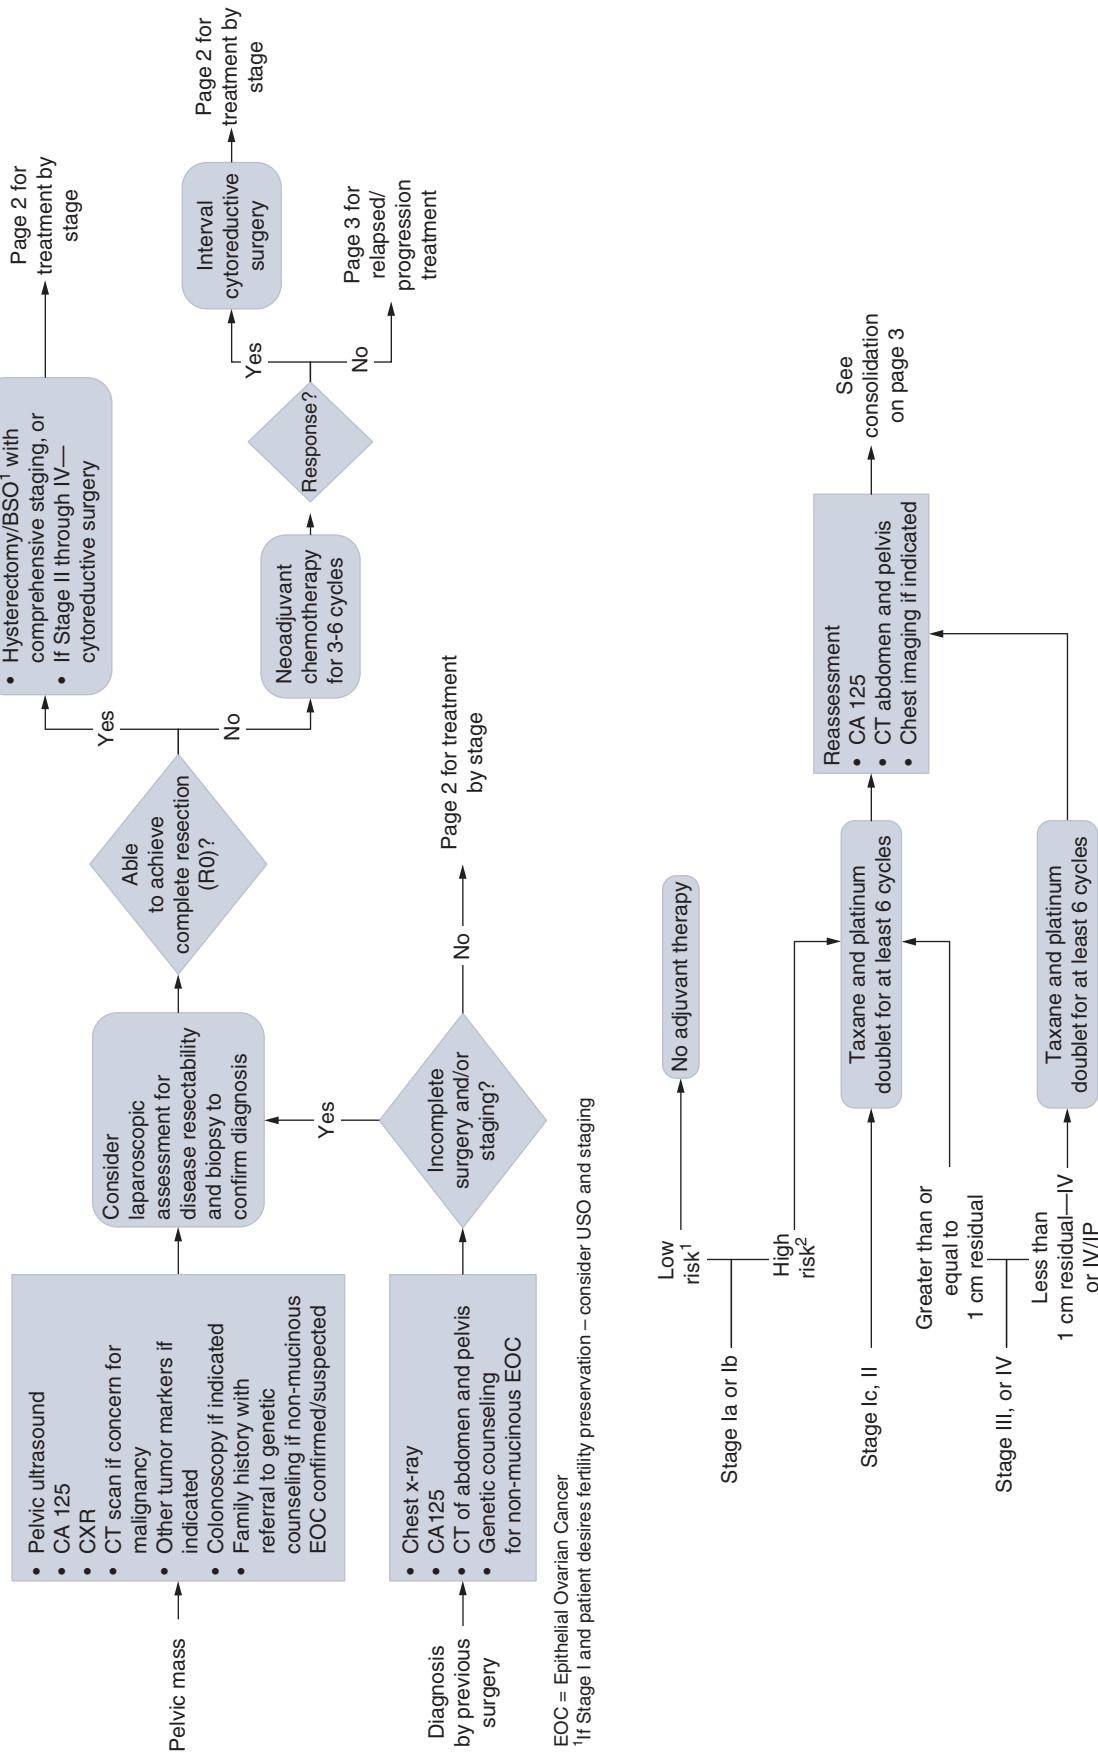

The goal of an initial cytoreductive surgery is to remove all visible tumor because the amount of

residual disease left behind is inversely correlated with patient survival. Currently, an optimal tumor-reductive surgery is defined as no residual nodules greater than 1 cm in size. More recent studies have tried to refine the definition of *optimal* cytoreductive surgery by dividing patients into those with no visible residual disease and others as these patients have improved overall survival (OS), even compared to patients with less than 1 cm of residual disease⁽³²⁾.

The only prospective randomized trial of the neoadjuvant approach versus up-front tumor-reductive surgery in patients with advanced-stage EOC carried out by the EORTC demonstrated the noninferiority of the neoadjuvant approach with respect to progression-free survival (PFS) and OS⁽³³⁾. However, this study has been criticized by the lower rate (41.6%) of optimal cytoreductive surgery in the primary debulking group (which was defined as largest single tumor nodule <1cm in this study) compared to reports from institutions in the United States and elsewhere. Hence, this remains a controversial area in the management of ovarian cancer.

Secondary Cytoreduction for Recurrent Disease

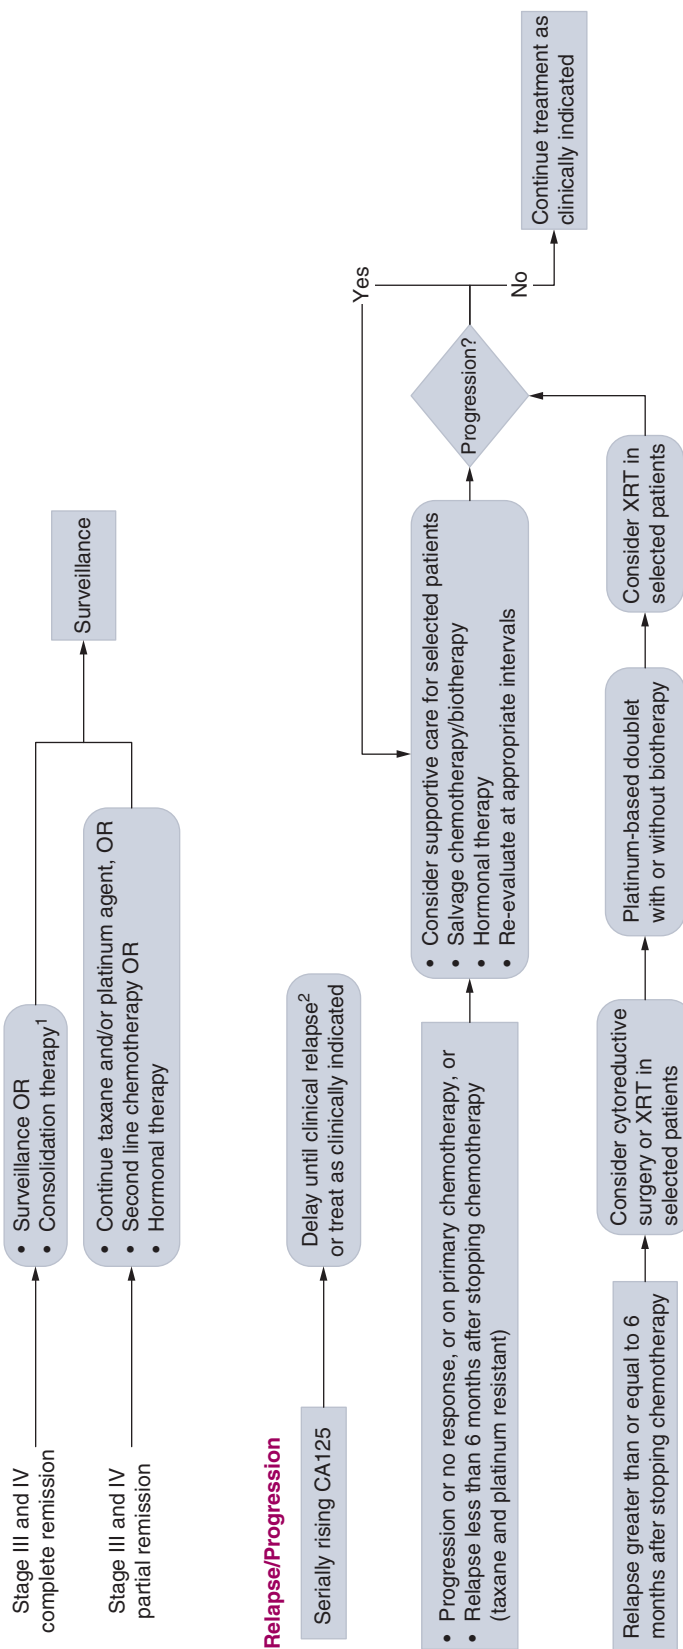

The benefits of secondary cytoreduction for recurrent disease are also unclear, although accumulating data suggest that, in certain circumstances, secondary cytoreduction may lead to a survival benefit. Eisenkop et al published a large series of patients with recurrent ovarian cancer undergoing cytoreduction for recurrent disease⁽⁴⁷⁾. There were 106 patients who had a complete clinical response to initial therapy. These patients had a disease-free interval of at least 6 months prior to

recurrence. Sixty percent underwent reexploration and debulking, and 82% were rendered disease free at that time. The authors evaluated factors that might be predictive of surgical outcome (optimal debulking) as well as those that might be indicative of survival. Predictors of complete cytoreduction included the following:

1. Size of recurrent tumor less than 10 cm
2. The use of chemotherapy before cytoreduction
3. Good Karnofsky performance status

A study from MD Anderson Cancer Center (MDACC) looked at a similar group of patients who also had a disease-free interval of at least 6 months, with similar results. These investigators noted that there was significantly improved survival in women who underwent optimal cytoreduction of tumor to less than 2 cm (19.5 vs 8.3 months). Others have published similar findings, all noting that the duration of prior clinical response is important in terms of survival and chances of optimal cytoreduction.

Adjuvant Therapy

Chemotherapy

Early-Stage Disease

Previous studies have defined a subset of patients with early-stage disease who are at increased risk of relapse. These high-risk features include:

1. Stage IC disease
2. Clear cell histology
3. High-grade tumor

Patients with these features should be considered for adjuvant therapy. Two large meta-analyses have shown that adjuvant chemotherapy improved both recurrence-free survival (RFS) and OS in patients with early-stage disease; however, women who had no gross residual disease following surgery did not benefit from adjuvant treatment⁽⁴⁸⁾. Subgroup analysis showed that women with high-risk features who received chemotherapy did have improved OS compared to women who received no adjuvant therapy⁽⁴⁸⁾. Most recently, the ACTION trial randomized patients with early-stage disease to platinum-based chemotherapy or observation. Overall, adjuvant chemotherapy improved RFS (70% vs 62%); however, there was no improvement in patients who had complete surgical staging (RFS 78% vs 72%)⁽⁴⁹⁾. This trial supports the need for complete surgical staging in early-stage ovarian cancer to appropriately triage patients for adjuvant chemotherapy as well as prognostic counseling for the patient.

There is no consensus on the number of cycles of adjuvant chemotherapy to give in early disease. The

main clinical trial targeting early stage ovarian cancer in the platinum and taxane era was conducted by the Gynecologic Oncology Group (GOG). The goal was to determine whether six cycles of carboplatin and paclitaxel would significantly lower the rate of cancer recurrence, compared to three cycles of the same agents following surgical staging operations on patients with stage IA grade 3, stage IB grade 3, stage IC, and completely resected stage II ovarian epithelial cancer. A secondary objective was to compare the toxicities of the two treatments. Following surgical staging, 321 patients were randomized to either three or six cycles of paclitaxel 175 mg/m² infused over 3 hours followed by carboplatin 7.5 AUC (area under the curve) infused over 30 minutes. Cycles were repeated every 21 days. A total of 70% of these patients had stage I disease. In the standard three-cycle arm, the estimated probability of cancer recurring within 5 years was 27%, compared to 19% in the six-cycle arm. The recurrence rate for six cycles was 24% lower (hazard ratio [HR] 0.761; 95% CI, 0.51–1.13; *P* = .18). It was concluded that the addition of three cycles of carboplatin and paclitaxel over the standard three cycles did not significantly alter the rate of cancer recurrence in patients with early-stage ovarian epithelial carcinoma. In addition, six cycles caused significantly more toxicity than three cycles⁽⁵⁰⁾. However, potential weaknesses of this study include the fact that it was likely underpowered to result in statistically significant differences, and that toxicity outcomes lacked external validity given that the high dose of carboplatin (AUC = 7.5) used in this trial is rarely used in clinical practice. At MD Anderson, we currently administer six cycles of neoadjuvant chemotherapy if utilized in the adjuvant setting for early-stage disease.

Advanced-Stage Disease

Carboplatin and paclitaxel remain the gold standard drugs in primary adjuvant treatment of EOC. The effect of incorporating additional cytotoxic agents (gemcitabine, liposomal doxorubicin, topotecan) in combination with carboplatin and paclitaxel was evaluated in GOG182. This randomized four-arm trial showed equivalent PFS and OS in all the arms and a better toxicity profile in the control carboplatin and paclitaxel alone arm⁽⁵¹⁾. Addition of bevacizumab to carboplatin and paclitaxel in the frontline setting was tested in GOG218 and ICON7^(52,53). Both studies showed that the addition of bevacizumab resulted in a modest improvement in PFS, but without an improvement in OS. Furthermore, the 4-month improvement in PFS observed in GOG218 was only associated with the arm receiving prolonged administration. There was no difference in the PFS of the control and carboplatin paclitaxel plus bevacizumab arms. Incidences of serious bowel toxicity (perforation or fistulas) and hypertension were about 2% and 23%,

respectively⁽⁵²⁾. Given the significant costs of bevacizumab and the lack of OS improvement, cost-effective analysis has shown that the use of bevacizumab as part of frontline therapy in ovarian cancer is not cost-effective⁽⁵⁴⁾.

Intraperitoneal Chemotherapy

The frequent metastasis of EOC within the peritoneal cavity and the ability to achieve a much higher concentration of platinum and taxane drugs following intraperitoneal administration are the principal rationale for the use of intraperitoneal chemotherapy for the treatment of patients with advanced-stage EOC who have undergone optimal resection (largest residual tumor nodule less than 1 cm). Three randomized trials have revealed improved PFS and OS in patients receiving intraperitoneal chemotherapy⁽⁵⁵⁻⁵⁷⁾. While all three trials have been criticized, the publication of GOG172 results, which revealed a 17-month OS benefit in the intraperitoneal arm, led the National Cancer Institute (NCI) to issue a Clinical Announcement recommending that women with stage III ovarian cancer who undergo optimal surgical cytoreduction be considered for intraperitoneal chemotherapy.

However, the better outcomes associated with intraperitoneal chemotherapy are associated with higher toxicity, illustrated by the fact that fewer than half of women randomized to the intraperitoneal arm were able to complete the six prescribed cycles⁽⁵⁵⁾. Furthermore, the regimen used in GOG172 included an inpatient administration of day 1 and 2 (for 24-hour paclitaxel and intraperitoneal cisplatin). While most centers have substituted a better-tolerated and outpatient regimen from the original GOG172, legitimate concerns regarding the equal efficacy of such regimens remain. In hopes of arriving at a better-tolerated and more efficacious intraperitoneal regimen, GOG252 was conducted to compare the GOG172-derived outpatient regimen to intraperitoneal carboplatin and weekly dose-dense paclitaxel and standard intravenous regimen (with bevacizumab included in all three arms). The results of this trial are anticipated in 2015.

Carboplatin and Dose-Dense (Weekly) Paclitaxel

The Japanese GOG protocol 3016 (JGOG3016) compared the administration of carboplatin (AUC = 6) with paclitaxel (180 mg/m²) every 3 weeks or weekly paclitaxel (80 mg/m² on days 1, 8, and 15 of a 21-day cycle). This study showed a significantly better median PFS and OS in the weekly dose regimen (PFS: 18.2 vs 17.5 months; OS: 100.5 vs 62.2 months)^(58,59). However, a peculiarity of this trial was that even the 62.2-month median OS survival in the control arm was much longer than in any of the platinum era GOG or European trials, especially given that the JGOG trial included patients with suboptimal cytoreductive surgery.

Additional questions about the external validity of the JGOG3016 trial were raised when the results of the MITO7 became available. This trial compared weekly carboplatin and paclitaxel (AUC = 2 and 60 mg/m², respectively) to conventional therapy (carboplatin AUC = 6; paclitaxel 175 mg/m²) every 3 weeks. There was no significant difference in the median PFS between the two arms (median PFS 17.3 months in the every 3 weeks group vs 18.3 months in the weekly arm)⁽⁶⁰⁾. In addition, preliminary results from GOG262 showed no difference in PFS in patients with stage I to IV ovarian cancer. This study included both optimally and suboptimally debulked patients, but both arms also allowed bevacizumab administration. Interestingly, patients not treated with bevacizumab had a 4-month improvement in PFS if they received the dose-dense regimen, while there was no difference in PFS in patients who received bevacizumab in addition to the assigned treatment regimen⁽⁶¹⁾.

Alternative Chemotherapeutic Agents

Docetaxel (Taxotere) is a semisynthetic compound structurally related to paclitaxel. The toxicity of docetaxel is similar to that of paclitaxel. However, docetaxel is associated with less neuropathy and more myelosuppression compared to paclitaxel. In addition, prolonged treatment with docetaxel increases skin and nail toxicity and can produce fluid retention and significant edema. Another important distinguishing feature is that docetaxel does not share the cremophor EL diluent used in the preparation of paclitaxel, which is the etiologic component responsible for many cases of paclitaxel hypersensitivity. A trial conducted by the Scottish Gynaecological Cancer Trials Group included 1,077 patients with FIGO stage IC to IV EOC who were randomized to receive carboplatin in combination with either paclitaxel or docetaxel. The median PFS for both arms was approximately 15 months⁽⁶²⁾. The authors concluded that the docetaxel combination appears to be a viable alternative to the paclitaxel combination as first-line chemotherapy in EOC because of an improved therapeutic index while maintaining similar efficacy.

Maintenance Therapy

The high risk of recurrent disease after treatment of advanced-stage EOC has prompted an intensive search for therapeutic strategies that can be given after standard-of-care therapy to improve patient outcomes. More than 12 phase III trials have been undertaken in this setting, including extension of frontline agents, administration of short-duration non-cross-resistant chemotherapy, high-dose chemotherapy, whole-abdominal or intraperitoneal radiotherapy, immunotherapy, vaccine therapy, biologic therapy, and single-agent paclitaxel; however, none has shown a survival advantage against various controls

Adjuvant Therapy	<ul style="list-style-type: none">• Paclitaxel 135 mg/m² IV continuous infusion over 24 hours day 1; CISplatin 75-100 mg/m² IP day 2; Paclitaxel 60 mg/m² IP day 8. (usually no treatment) ⁽⁶³⁾. The S9701/GOG178 phase III trial that administered paclitaxel intravenously for 12 months (vs 3 months) after an initial response to first-line chemotherapy showed improved PFS. However, the design of the trial (with PFS as the primary end point) led to early closure and lack of data on the effect of this consolidation strategy on OS. This improvement in PFS was associated with significant neurotoxicity, and overall this strategy has not been widely adopted in routine clinical practice ⁽⁶⁴⁾. The chemotherapy regimens utilized at MD Anderson are outlined in Fig. 31-6.

Follow-up and Treatment of Recurrent Disease

Despite multimodality therapy, 75% to 80% of women with advanced-stage epithelial cancer will have a recurrence. Regular follow-up with tumor marker can detect disease recurrence ^(65, 66). In women with previously treated ovarian cancer that is in clinical remission, the NCCN has recommended assessment of serum CA125 concentration at every follow-up visit if this concentration was raised at initial diagnosis. After documentation of CA125 increase in such women, the median time to a clinical relapse of ovarian cancer is 2 to 6 months. There is, however, controversy over the benefit of early treatment versus treatment later. The results of a large study showed no survival benefit from early treatment on the basis of a raised serum CA125 concentration alone and therefore questioned the value of routine measurement of CA125 in the follow-up of patients with EOC ⁽⁶⁶⁾. Some authors also

suggested that smaller tumors are more often responsive to treatment, but this does not eliminate the lead-time bias. It is also argued that larger tumors have an inferior primary response and grow rapidly. Recurrent ovarian cancer is a mortal disease, but—in the absence of data showing that treatment improves quality of life—this does not justify haste in treating patients. At MD Anderson, we follow patients with CA125 levels in surveillance but in general do not treat patients based solely on a rising value (see Fig. 31-5).

One of the problems with recurrent ovarian cancer is the lack of a truly effective salvage therapy. The other problem is the inability to identify a predictive marker for recurrence. The treatment of recurrent ovarian cancer is stratified by the amount of time from completion of primary platinum-based chemotherapy. Patients who have a recurrence with a PFS of 6 months or longer are defined as having platinum-sensitive disease. Patients who have a recurrence less than 6 months from primary chemotherapy are classified as having platinum-resistant disease. Patients whose disease progresses on primary chemotherapy have tumors classified as platinum refractory and have a poor prognosis ⁽⁶⁷⁾. A list of treatment regimens utilized at MD Anderson in platinum-sensitive and platinum-resistant disease can be found in Fig. 31-6.

Treatment of Platinum-Sensitive Disease

As mentioned, patients who have a treatment-free interval of 6 months or greater prior to recurrence are more likely to respond to repeat platinum treatment. As noted, depending on the pattern and extent of

recurrence, some of these patients may also be good candidates for secondary cytoreductive surgery. While there are several options for second-line chemotherapy in platinum-sensitive disease, all regimens have a platinum backbone. Combination therapy has been shown to have an improved OS compared to single-agent therapy in this patient population and should be considered in patients with an acceptable performance status. As long as patients continue to respond to platinum and have more than a 6-month interval between each treatment, it seems reasonable to continue treatment with platinum, either as a single agent or in a combination regimen (see Fig. 31-5).

Carboplatin and Paclitaxel

Two phase III trials have shown the benefit of carboplatin and paclitaxel in the setting of platinum-sensitive recurrence, and the results were published together. The ICON4 and AGO-OVAR-2.2 studies randomized patients to receive conventional platinum-based chemotherapy or platinum plus paclitaxel or platinum plus a nontaxane⁽⁶⁸⁾. Results from this study showed an OS benefit (HR 0.82, $P = .02$), which led to a 7% absolute survival difference (57% vs 50%) and a 5-month improvement in median survival (29 vs 24 months) in favor of platinum plus paclitaxel. There were higher rates of neuropathy and alopecia in the platinum-plus-paclitaxel treatment group but a lower rate of myelosuppression⁽⁶⁸⁾. One critique of this study is that a large proportion of patients (30%) were not previously treated with taxane therapy, which may have led to an improved response in this patient population. Other options that may be utilized in the setting of platinum-sensitive ovarian cancer include docetaxel as well as the use of weekly paclitaxel, both in combination with carboplatin^(69, 70).

Carboplatin and Liposomal Doxorubicin

A phase III study (CALYPSO) showed that a pegylated liposomal doxorubicin and carboplatin combination was better than paclitaxel with carboplatin in terms of PFS in relapsed platinum-sensitive cancer (11.3 vs 9.4 months); however, there was no difference in OS (30.7 vs 33 months). The combination of carboplatin plus liposomal doxorubicin led to fewer cases of severe neutropenia, fewer episodes of mild myalgias/arthralgias, and less neuropathy but did lead to more cases of severe thrombocytopenia, nausea/vomiting, hand-foot syndrome, and mucositis. Interestingly, the study combination also led to fewer episodes of carboplatin hypersensitivity reactions⁽⁷¹⁾.

Carboplatin and Gemcitabine

A phase III trial was performed by the Gynecologic Cancer InterGroup (GCIg) to evaluate carboplatin alone versus carboplatin plus gemcitabine in patients

with platinum-sensitive disease. Treatment with the combination regimen showed an improved PFS (8.6 vs 5.8 months), but no improvement in OS. Not surprisingly, there were more toxicities seen in the combination arm, with increased neutropenia and thrombocytopenia. A second trial, OCEANS, was a randomized phase III trial that evaluated carboplatin plus gemcitabine with or without the addition of bevacizumab. Patients received the assigned treatment for 6 to 10 cycles and were then continued on bevacizumab or placebo maintenance until progression. The addition of bevacizumab led to an improved PFS (12.4 vs 8.4 months) with an improved objective response rate (78.5% vs 57.4%; $P < .001$). As seen with other antiangiogenesis studies, the addition of bevacizumab led to higher rates of hypertension and proteinuria⁽⁷²⁾.

Poly-ADP Ribose Inhibitors

The role for maintenance therapy with poly-ADP ribose (PARP) inhibitors has been evaluated in platinum-sensitive disease. In a randomized trial (Study 19), maintenance therapy with olaparib was given to patients who achieved a complete response to second-line therapy⁽⁷³⁾. Patients with germline *BRCA* mutations were found to have improved PFS (11 vs 4 months) with few adverse events⁽⁷⁴⁾. While there was no difference in OS, there was a 22.6% crossover rate in this study, which may prevent a true difference from being seen in this study population. While this did have significant results, olaparib is currently only approved by the Food and Drug Administration (FDA) for the treatment of advanced ovarian cancer in patients with germline *BRCA* mutation who have failed three or more prior lines of chemotherapy in the United States.

Treatment of Platinum-Resistant Disease

There are several treatment options for the treatment of platinum-resistant recurrent EOC. In general, single-agent treatment regimens are utilized in this patient population to minimize adverse effects, given incurable disease. While there are several options, no one therapy has been shown superior to others as first-line treatment for platinum-resistant disease. A Cochrane review of three of the most commonly used agents (paclitaxel, pegylated liposomal doxorubicin, and topotecan) showed similar efficacy. Thus, choice of first-line therapy is driven by side effect profiles of each of the therapies.

Liposomal Doxorubicin

A pegylated liposomal formulation of doxorubicin was first tested in patients with platinum-refractory disease; the resulting response rate was approximately 26%. Compared to topotecan in a phase III setting, liposomal doxorubicin was associated with lower

toxicities, including lower rates of grade 3/4 neutropenia and thrombocytopenia, but with equivalent efficacy, with similar response rate (20% vs 17%) and time to progression (22 vs 20 weeks) ⁽⁷⁵⁾. Based on the data from Gordon et al, the drug was FDA approved for use in ovarian cancer.

Gemcitabine

In a phase III study comparing gemcitabine and liposomal doxorubicin, both drugs had similar overall response rates (6.1% vs 8.3%), PFS (3.6 vs 3.1 months), and OS (12.7 vs 13.5 months) ⁽⁷⁶⁾. Gemcitabine has been frequently studied in combination with cisplatin. The response rates ranged from 40% to 70%. However, the small number of patients treated as well as their heterogeneity disallows any further conclusion. Furthermore, it is difficult to justify the use of combination chemotherapy in patients without evidence that responses correlated with improvements in quality of life.

Weekly Paclitaxel

Paclitaxel is part of the backbone of treatment for advanced ovarian cancer. Several studies have shown activity of paclitaxel in platinum-resistant patients; however, a proportion of these studies were performed prior to the incorporation of paclitaxel in primary adjuvant therapy. Most recently, weekly paclitaxel produced a 21% response rate in patients with platinum-resistant disease. Not surprisingly, the main toxicity associated with this regimen is peripheral neuropathy ⁽⁷⁷⁾.

Topotecan

Compared to paclitaxel in patients with refractory ovarian cancer, topotecan was found to produce a response rate of 20%, compared to the 13% in patients who received paclitaxel. This resulted in its approval for use by the FDA. In patients with relapsed platinum-resistant ovarian cancer, the overall response rates on treatment with topotecan ranged from 5% to 18%. The proportion of these patients who achieved stable disease was 17%. In phase III studies, topotecan was shown to have an efficacy equal to both paclitaxel and liposomal doxorubicin as second-line therapy in patients with relapsed ovarian cancer ⁽⁷⁸⁾.

Etoposide

Etoposide, a topoisomerase II inhibitor, has the advantage of being administered as an oral agent. In patients with platinum-refractory disease who were given 100-mg doses of etoposide orally for 14 days every 21 days, the response rate was about 26%. Lower doses of etoposide, at 50 mg/d, produced similar response rates, ranging from 10% to 27%. The combination of cyclophosphamide and bevacizumab has also been shown to be active in this patient population. A phase II trial showed partial response in 24%

of patients, with 56% of patients predicted to be alive and progression free at 6 months ⁽⁷⁸⁾.

Bevacizumab

The phase III AURELIA study evaluated bevacizumab in addition to single-agent chemotherapy in platinum-resistant ovarian cancer. Patients with disease that progressed less than 6 months after completing adjuvant therapy were eligible, but platinum-refractory patients were excluded. The patients received the treating physician's choice of liposomal doxorubicin, weekly paclitaxel, or topotecan and were then randomized to chemotherapy alone or chemotherapy plus bevacizumab. Patients who received bevacizumab had an improved response rate (31% vs 13%) and a reduction in risk of disease progression (6.7 vs 3.4 months). There was no difference in OS; however, patients were allowed to cross over to receive bevacizumab following progression on chemotherapy alone, which may mask the survival advantage ⁽⁷⁹⁾. Based on the results of this trial, bevacizumab is now FDA approved for use in combination with chemotherapy for the treatment of platinum-resistant recurrent EOC.

Low-Grade Serous Ovarian Carcinoma

The primary management of low-grade serous ovarian carcinoma, like its high-grade counterpart, is surgical with comprehensive surgical staging. However, low-grade serous carcinoma is relatively chemoresistant when compared to high-grade serous carcinoma ^(43, 80). Despite this, carboplatin and paclitaxel remain first-line adjuvant therapy in advanced disease as there is currently no better alternative. Recurrent disease can be treated with surgery, chemotherapy, hormone therapy, and targeted therapies, including MEK inhibitors. In a retrospective review of recurrent low-grade serous carcinoma, 78% of patients who had secondary cytoreduction had no gross residual disease at the conclusion of surgery, which translated into an improved PFS compared to patients who were left with gross residual disease ⁽⁸¹⁾. Similar to the adjuvant setting, low-grade serous carcinoma is also chemoresistant in the recurrent setting, with a response rate of less than 4%; however, 60% of patients did have stable disease ⁽⁸²⁾. Numerous hormonal agents have been utilized in the treatment of recurrent low-grade serous carcinoma, with response rates that are only slightly improved compared to chemotherapy. Retrospective series have shown an overall response rate of 9%; however, similar to chemotherapy, 62% of patients achieved stable disease ⁽⁸²⁾. Given the frequency of *KRAS* and *BRAF* mutations in this histologic subtype, a single-arm phase II trial of selumetinib, a MEK 1/2 inhibitor, was performed in recurrent low-grade serous carcinoma.

Table 31-5 World Health Organization Classification of Ovarian Germ Cell Tumors

Primitive Germ Cell Tumors	Biphasic or Triphasic Teratoma	Monodermal Teratoma and Somatic-Type Tumors
Dysgerminoma Endodermal sinus tumor (yolk sac tumor) Embryonal carcinoma Polyembryona Nongestational choriocarcinoma Mixed germ cell tumor	Immature teratoma (grades 1-3) Mature teratoma (solid, cystic, or fetiform teratoma)	Thyroid (struma ovarii) Carcinoid Neuroectodermal Carcinoma Melanocytic Sarcp, a Sebaceous Pituitary type Other

The objective response rate was 15%, and 65% of patients had stable disease. Interestingly, there was no correlation between *KRAS* and *BRAF* mutational status and response to the study drug. Current trials are ongoing to evaluate therapy with MEK inhibitors in comparison to chemotherapy and hormonal therapy in the recurrent setting.

MALIGNANT GERM CELL TUMORS

Malignant ovarian germ cell tumors (MOGCTs) recapitulate normal embryonic and extraembryonic cells and structures and are derived from the primitive germ cells of the embryonic gonad. The MOGCTs comprise 2% to 3% of all ovarian malignancies, and they usually develop in girls, adolescents, and women of reproductive age. Advances in chemotherapy have yielded cure in the vast majority of patients with these tumors, and modifications in surgical technique have allowed fertility preservation in most patients⁽⁸³⁾. These tumors should always be considered in the differential diagnosis in a young woman with a solid ovarian mass, as the median age of diagnosis is 16 to 20 years (range 6-60 years), and the highest incidence occurs in 15- to 19-year-old girls.

The current classification of ovarian germ cell tumors includes both benign and malignant neoplasms. Most benign ovarian germ cell tumors are mature teratomas. The MOGCTs include primitive germ cell tumors, biphasic or triphasic teratomas, and monodermal teratomas (Table 31-5). Immature teratomas should be extensively sampled to determine the amount of immature neural, nonneural, and yolk sac elements and thereby malignant potential. While we continue to report grading criteria for immature teratomas using a three-tier system, we agree that a biphasic system may allow for greater consistency.

Etiology

The etiology of MOGCT is related to gonadal dysgenesis in a minority of patients. Patients with a mosaic variant of Turner syndrome including a Y chromosome may develop gonadoblastoma⁽⁸⁴⁾. Patients with complete gonadal dysgenesis who have a 46, XY genotype and a female phenotype (Swyer syndrome) have up to a 30% risk of developing MOGCT, especially dysgerminomas, and prophylactic removal of both gonads is indicated if the diagnosis is made⁽⁸⁵⁾.

Diagnosis

The diagnosis of MOGCT may be suspected based on the young age of the patient with a solid, palpable ovarian mass, but histologic confirmation is required for the diagnosis. Eighty-five percent of patients present with abdominopelvic pain associated with a palpable mass. Other presenting symptoms and signs include abdominal distention, fever, ascites, and vaginal bleeding. Ten percent of patients present with acute abdominal pain associated with rupture, hemorrhage, or torsion of the mass. Isosexual pseudoprecocity may be caused by chorionic gonadotrophin (β -hCG) production by the tumor⁽⁸⁶⁾. Evaluation of the pelvic mass in the young patient may be aided by transvaginal ultrasound and magnetic resonance imaging (MRI). Supradiaphragmatic disease or pure choriocarcinoma is an indication for MRI of the brain⁽⁸³⁾.

Tumor markers may be especially helpful in MOGCT to suggest individual tumor histology, provide prognostic information, and provide a basis to follow the response of the disease to therapy (Table 31-6). Therefore, when MOGCT is suspected, these markers should be measured preoperatively. A karyotype should be performed if gonadal dysgenesis is suspected, as bilateral oophorectomy is indicated if the diagnosis is confirmed. The appropriate minimum diagnostic evaluation for

Table 31-6 Tumors Markers Helpful in MOGCT

Tumor	AFP	β-HCG	Lactic Dehydrogenase
Pure dysgerminoma	Normal	May be elevated	Elevated
Endodermal sinus tumor	Elevated	Normal	May be elevated
Embryonal carcinoma	Elevated	Elevated	Elevated
Choriocarcinoma	Normal	Elevated	Normal
Immature teratoma	May be elevated	Normal	Normal

the young woman with a suspicious adnexal mass should include routine blood studies, serum tumor marker analysis, chest radiography, and imaging of the abdomen and pelvis⁽⁸³⁾.

Management

Surgery is the mainstay of diagnosis and initial treatment of MOGCT. Laparotomy has been the standard of care, but minimally invasive surgery appears to be feasible when the tumor can be removed intact and complete staging can be performed⁽⁸⁷⁾. Patients who have completed childbearing should undergo total hysterectomy and bilateral salpingo-oophorectomy. However, most patients with MOGCT are of reproductive age, and since outcomes with conservative surgery are comparable to hysterectomy with bilateral salpingo-oophorectomy, fertility-sparing surgery should be considered in every patient of reproductive age. Whenever possible, the normal-appearing contralateral adnexa and uterus should be conserved. If both ovaries are grossly involved, bilateral salpingo-oophorectomy may be warranted, but this is the exception rather than the rule. Some discussion has centered on ovarian preservation with postoperative chemotherapy to treat this chemosensitive residual disease, thus allowing fertility preservation even with advanced disease or bilateral ovarian involvement. Even if both ovaries are removed, the uterus may be preserved to allow assisted reproduction with a donor egg.

Several treatment conundrums are encountered not infrequently. If a MOGCT is diagnosed postoperatively following an ovarian cystectomy for disease thought to be benign, subsequent removal of the remaining ovarian tissue may be avoided. Excellent survival has been reported in this setting, although most patients did receive adjuvant chemotherapy⁽⁸⁸⁾. In addition, the occasional patient presents with widespread bulky abdominopelvic disease, and aggressive debulking surgery is followed by rapid tumor regrowth. While not yet considered standard, neoadjuvant chemotherapy after percutaneous biopsy has been increasingly utilized to allow for less-morbid, more effective, fertility-sparing interval cytoreductive surgery⁽⁸⁹⁾.

Staging for MOGCT follows FIGO staging for EOC (see Table 31-4). However, the extent of comprehensive surgical staging is controversial. Comprehensive surgical staging has traditionally been performed in adult patients, including peritoneal cytology, biopsies, omentectomy, bilateral pelvic and para-aortic lymphadenectomy, and removal of any suspicious tissue. In the pediatric setting, staging is typically limited to pelvic washing, tumor removal, and biopsy of suspicious implants. While proponents of limited staging cite the exquisite sensitivity of MOGCT to chemotherapy in the event of recurrence in untreated patients, we have performed comprehensive staging to administer chemotherapy up front in patients with nodal involvement and avoid chemotherapy in fully staged patients without metastatic disease. Regardless, patients with nondysgerminomatous MOGCT should receive chemotherapy unless their disease is stage IA with comprehensive surgical staging. Surveillance in low-risk patients has been proposed, and studies are ongoing.

Adjuvant Therapy

While patients with stage I dysgerminoma and stage IA grade 1 immature teratoma may be safely observed after surgery without chemotherapy, combination chemotherapy with three to four courses of bleomycin, etoposide, and cisplatin (BEP) results in the cure of most other patients with MOGCT (Table 31-7). Patients with completely resected disease usually receive three cycles of BEP, while patients with macroscopic residual disease receive four cycles, sometimes omitting bleomycin from cycle 4. Care should be taken to evaluate for bleomycin-related pulmonary toxicity, with periodic lung auscultation, chest radiography, and pulmonary function testing if the patient experiences symptoms. Rales, pulmonary consolidation, or a 30% decrease in the diffusion capacity of carbon monoxide prompts deletion of bleomycin from the regimen⁽⁸³⁾. Radiation therapy is effective in the treatment of dysgerminoma but is rarely used due to the impact on ovarian function and subsequent fertility.

While most patients are cured, worse outcomes are related to advanced stage, yolk sac (endodermal sinus) tumor histology, incomplete surgical resection, and advanced age⁽⁹⁰⁾. Patients with higher risk or who

Table 31-7 Regimen for Administration of Bleomycin, Etoposide, and Cisplatin (BEP)

Following prehydration and premedications:
 Cisplatin: 20 mg/m² per day in 1L normal saline with 50 g mannitol IV over 4 hours on days 1-5
 Etoposide: 100 mg/m² per day in 1L 5% dextrose in normal saline IV over 2 hours on days 1-5
 Bleomycin: 20 U/m² in 250 mL normal saline over 24 hours on day 1
 OR
 Bleomycin: 10 U/d on days 1-3
 OR
 Bleomycin: 10 U/d on days 1, 8, and 15 (United States)
 OR
 Bleomycin: 30,000 IU weekly for 12 weeks, with the fourth course consisting of EP alone (Europe/United Kingdom)^a

^aMaximum total bleomycin dose not to exceed 270 mg. Regimen repeated every 21 days.

do not respond to BEP rapidly may be considered for alternate therapies, including paclitaxel combined with BEP (T-BEP) or dose-dense BEP (⁸³).

Follow-up

Following treatment, patients receive imaging of the chest, abdomen, and pelvis and evaluation of tumor markers. Subsequently, they are monitored every 3 months for the first year, every 4 months for the second year, and every 6 months for years 3 to 5. We do not obtain routine imaging, although in high-risk patients transvaginal ultrasounds may be followed and initial abdominopelvic imaging may be obtained.

Treatment of Recurrent Disease

In the small percentage of patients who are thought to have a recurrence, evaluation must include repeat imaging of the chest, abdomen, and pelvis and evaluation of tumor markers, and a biopsy must confirm the diagnosis of recurrent disease since immature teratomas can recur with only mature benign elements (growing teratoma syndrome) or with benign gliosis. Both of these entities are benign and do not automatically require chemotherapy or surgical resection. In the event of true recurrence, surgical resection should be considered and appropriate salvage chemotherapy should be considered. Over half of patients who have a recurrence after 6 weeks following initial therapy (platinum sensitive) can achieve cure with VeIP (vinblastine, ifosfamide, and cisplatin) or TIP (paclitaxel, ifosfamide, and cisplatin); high-dose chemotherapy may also be administered (⁸³). Patients who progress during treatment or have a recurrence within 4 to 6 weeks (platinum resistant) are not curable; standard-dose VeIP may be administered, and in the event

of response, high-dose etoposide and carboplatin with stem cell rescue may be given (⁸³). Other agents with activity include ifosfamide, taxanes, and gemcitabine.

Reproductive Outcomes

Reproductive outcomes following surgical or chemotherapeutic treatment for MOGCT are excellent, with little effect on menstrual cycling, reproductive function, conception, or childbirth. Chemotherapy-induced infertility appears to occur in 18% or less of patients treated with BEP and is unrelated to cisplatin dose. Eighty percent of women resume normal menstrual function. Long-term quality of life and psychosocial outcomes of survivors of MOGCT are also excellent.

SEX CORD STROMAL TUMORS

Sex cord stromal tumors (SCST) of the ovary comprise 7% of all ovarian malignancies and have an annual adjusted incidence rate of 2.1 per 1 million women (⁹¹). These tumors can occur in females of all ages, but most occur in peri- and postmenopausal women. Some histologic subtypes, such as juvenile granulosa cell tumors (GCTs) and Sertoli-Leydig cell tumors (SLCTs) have a propensity to develop in adolescents; all histologic subtypes may develop in women of reproductive age. Overall, many of these tumors tend to be indolent, progressing slowly over decades.

Sex cord stromal tumors are a heterogeneous group of tumors classified in [Table 31-8](#) (⁹²). The GCTs are the

Table 31-8 Classification of Ovarian Sex Cord Stromal Tumors

Ovarian stromal tumors with sex cord elements
Adult granulosa cell tumor
Juvenile granulosa cell tumor
Sertoli-Leydig cell tumor
Gynandroblastoma
Sex cord tumor with annular tubules
Pure stromal tumors
Fibroma and thecomas: typical, cellular, mitotically active
Malignant tumors (fibrosarcoma)
Other ovarian stromal tumors
Ovarian stromal tumor with minor sex cord elements
Sclerosing stromal tumor
Signet ring stromal tumor
Microcystic stromal tumor
Ovarian myxoma
Stromal-Leydig cell tumor
Steroid cell tumors
Stromal luteoma
Leydig cell tumor
Steroid cell tumor, not otherwise specified

most common and consist of adult and juvenile forms, which differ in their histologic appearance, age of onset, and natural history. Juvenile GCTs usually affect adolescent females, may present with precocious puberty, may be associated with breast cancer, and have high mitotic activity. Adult GCTs represent 95% of GCTs, tend to occur in older women, produce estrogen, may be associated with endometrial hyperplasia or cancer, and are often quite indolent⁽⁹²⁾. Sertoli-Leydig cell tumors arise from mesenchyme and sex cords, which recapitulate testicular development and may include various proportions of Sertoli and Leydig elements. Pure Sertoli cell tumors and pure Leydig cell tumors are benign, while tumors with Sertoli and Leydig cell components demonstrate degrees of malignant behavior and are classified based on differentiation. The benign differentiated form typically produces androgens; intermediate differentiated forms have immature Sertoli cells; and poorly differentiated forms with sarcomatoid or retiform patterns tend to be more aggressive. Gynandroblastomas are rare, tend to be virilizing, and are usually benign, but large tumors occurring in women aged 30 to 50 years may exhibit malignant behavior⁽⁹²⁾. A sex cord tumor with annular tubules (SCTAT) may be associated with Peutz-Jeghers syndrome (PJS).

Etiology

The etiology for all SCSTs is unknown. However, a cytosine-to-guanine point mutation in the *FOXL2* 403 gene has been identified as pathognomonic for adult granulosa cell tumor formation⁽⁹³⁾. In addition, mutations in *DICER1* appear to be present in some patients with Sertoli-Leydig cell tumors (SLCT) and in patients with pleuropulmonary blastoma (PPB); children with SLCTs may be screened for *DICER1* mutations and thereby undergo early treatment for PPB, a potentially lifesaving intervention⁽⁹⁴⁾. The SCTATs may be associated with PJS and potentially linked to *STK11* mutations in these patients.

Diagnosis

Most patients with SCSTs present with pelvic pain, pelvic pressure, and menstrual irregularities, including precocious puberty, menometrorrhagia, or postmenopausal bleeding⁽⁹²⁾. While these tumors cannot be diagnosed without histologic confirmation of surgical findings, preoperative studies such as pelvic ultrasound and analysis of certain tumor markers may suggest the diagnosis of SCST. When suspected, preoperative CT of the abdomen and pelvis is warranted. Preoperative laboratory testing should include analysis for serum hCG and routine laboratory testing.

Serum markers may be useful in the preoperative diagnosis of SCST when suspected or in establishing a

baseline level with which to follow the tumor status of the patient during treatment and surveillance. Inhibin A, inhibin B, and antimüllerian hormone (AMH) are useful markers, and AMH may be highly specific for GCT in postmenopausal women or women whose ovaries have been removed. A karyotype should be obtained in cases of gonadoblastoma due to the risk of dysgenetic gonads, which should be removed based on the risk of subsequent neoplasia.

Management

Surgery remains the cornerstone of diagnosis and treatment for patients with SCSTs. While surgery has historically been performed via laparotomy, minimally invasive surgery appears to be safe and feasible for initial limited surgery and staging as well as restaging in many patients with SCSTs, as long as the tumor can be removed intact without contamination of the peritoneal cavity, using a specimen bag for removal⁽⁹²⁾. Staging procedures include examination of the entire abdominopelvic cavity, peritoneal washings, infracolic omentectomy, biopsy of any suspicious lesions and the diaphragmatic peritoneum, paracolic gutters, and pelvic peritoneum, but lymphadenectomy is omitted in the absence of suspicious lymph nodes due to absence of lymphatic metastasis^(92, 95). While postmenopausal women and women who have completed childbearing should undergo total hysterectomy and bilateral salpingo-oophorectomy, young women and women of reproductive age who have not completed childbearing may undergo conservative surgery. This refers to removal of the entire involved adnexa and surgical staging. There is no role for ovarian cystectomy in definitive surgical treatment⁽⁹⁶⁾. Evaluation of the endometrium should be a part of any surgery for SCSTs as 55% of patients with GCTs have endometrial hyperplasia and 4% to 20% have endometrial adenocarcinoma⁽⁹⁷⁾. The FIGO staging for SCST is the same as that for EOCs (see Table 31-4)⁽⁹²⁾.

Adjuvant Therapy

Patients with stage IA and IB SCSTs do not require adjuvant therapy after surgery. Therapy for patients with stage IC disease is controversial and may include chemotherapy or hormonal therapy for patients with a high mitotic index. Patients with stage I SLCTs who have poorly differentiated tumors or heterologous elements should be treated with adjuvant chemotherapy. Any patient with advanced-stage (II or above) SCSTs should receive treatment with chemotherapy⁽⁹²⁾. The type of chemotherapy administered has historically been three to four cycles of BEP, but retrospective reports suggest that taxanes, especially when administered with platinum-based chemotherapy, have efficacy

and less toxicity than BEP (^{96,98}). The GOG is currently comparing these two regimens in advanced-stage up front and recurrent chemonaive SCST patients.

Follow-up

Most patients with SCST are cured, but 20% have a recurrence; these patients may succumb to their disease (⁹²). Tumor stage, tumor rupture, age over 50 years, and tumor size are reported prognostic factors (⁹⁹). The SCSTs tend to have an indolent nature with a propensity for late recurrence. Therefore, patients require long-term surveillance. Our strategy is to follow patients every 3 months for the first year, every 4 months for the second year, every 6 months for years 3 to 5, then annually. At each visit, history, physical examination including pelvic examination, and tumor marker values (inhibin A, inhibin B, AMH, and sometimes CA125) are obtained; imaging is reserved for patients with new symptoms, signs, or elevated marker values.

Treatment of Recurrent Disease

Patients who have a recurrence require a biopsy to prove the initial recurrence. These patients may benefit from surgical resection in the event of limited resectable recurrent disease. Radiotherapy may also be an option. Treatment with hormonal agents may induce response or long-term stable disease. Chemotherapy utilizing BEP or taxane-platinum combinations may be useful. Most recently, bevacizumab has been shown to be an active agent in the recurrent setting (¹⁰⁰).

EPITHELIAL UTERINE TUMORS

Epidemiology

Endometrial cancer is the most common gynecologic malignancy in the United States. In 2015, the American Cancer Society estimated there were 54,870 new cases and over 10,170 endometrial cancer-related deaths ⁽¹⁾. Approximately 75% of women diagnosed with endometrial cancer are diagnosed at an early stage and have a 5-year overall survival of 74% to 91% ⁽²⁾. For women with stage III or IV disease, reported 5-year overall survival rates are 57% to 66% and 20% to 26%, respectively ⁽²⁾. This disease primarily affects women in their postmenopausal and perimenopausal years, and the average age at diagnosis is 61 years ⁽²⁾.

Risk Factors

The main risk factors for endometrial cancer are age, obesity, diabetes, and exposure to excess estrogen without adequate opposition by progesterone. This includes the historical use of exogenous unopposed estrogen therapy, the use of estrogen agonists (such as tamoxifen), and physiological states that lead to excess endogenous estrogen. Excess endogenous estrogen can be found in women with obesity, chronic anovulation, early age at menarche, nulliparity, late age of menopause, and in the setting of rare estrogen-secreting tumors.

Tamoxifen is a selective estrogen receptor modulator that is used for chemoprevention of breast cancer and as a part of adjuvant therapy for

estrogen-receptor-positive breast cancer; it may also be used to treat metastatic breast cancer. It acts as an antagonist on estrogen receptors in the breast but also has a weak agonist effect on the estrogen receptors in the endometrium. These estrogenic effects on the endometrium lead to a significant increase in the risk of developing endometrial cancer, with a relative risk of 2.13 and an absolute annual risk of about 2 per 1,000 patients taking tamoxifen ⁽³⁾. In a study by the National Surgical Adjuvant Breast and Bowel Project (NSABP), women taking tamoxifen (20 mg/d) developed endometrial cancer at a rate of 1.6 per 1,000 patient years, compared to 0.2 per 1,000 patient years among women taking a placebo. At the same time, the 5-year survival rate from breast cancer was 38% higher among women taking tamoxifen compared to women in the placebo group. This suggested that the relatively small risk of developing endometrial cancer was outweighed by the greater survival benefit for women with breast cancer ⁽⁴⁾.

Obesity is a well-established risk factor for the development of endometrial cancer. A meta-analysis of 19 prospective studies showed that for every 5 kg/m² increase in body mass index (BMI), a women's risk of developing endometrial cancer significantly increases ⁽⁵⁾. One explanation for these findings is that women who are obese have higher levels of endogenous estrogen because of the conversion of androstenedione into estrone and the aromatization of androgens to estradiol, which occurs in the peripheral adipose tissue. There are additional proposed mechanisms for this association, including alterations in insulin signaling and insulin resistance, alterations in

expression of circulating adipokines, as well as alterations in pathways involving inflammation ⁽⁶⁻⁸⁾. Obesity increases the risk of endometrial cancer in both post- and premenopausal women. In fact, the majority of young, premenopausal women diagnosed with endometrial cancer have a BMI greater than 30 ⁽⁹⁾.

Lynch syndrome is an autosomal dominant hereditary cancer syndrome characterized by an increased risk in endometrial cancer, colon cancer, and several other malignancies. It is associated with a germline defect in a DNA mismatch repair gene (MutL homolog 1 [*MLH1*], MutS homolog 2 [*MSH2*], MutS homolog 6 [*MSH6*], postmeiotic segregation 2 [*PMS2*]). Women who have Lynch syndrome have a 15% to 66% lifetime risk of developing endometrial cancer, a 15% to 68% lifetime risk of developing colon cancer, and a 1% to 20% lifetime risk of developing ovarian cancer, depending on the specific mutation involved ^(10, 11).

Diagnosis and Screening

Screening

Except for patients who have been diagnosed with Lynch syndrome, there is insufficient evidence to support screening for endometrial cancer in asymptomatic women in the general population, even those with risk factors such as tamoxifen use, history of unopposed estrogen, obesity, or diabetes. The American Cancer Society currently recommends that all women be informed about the risks and symptoms of endometrial cancer at menopause. Women should alert their physicians of any unexpected bleeding or spotting in the postmenopausal years and abnormal uterine bleeding in the pre- or perimenopausal years.

The American Cancer Society recommends yearly screening with endometrial biopsy beginning at age 35 for women who are known to carry Lynch syndrome-associated mutations, those who have a family member known to carry this mutation, or women from families with an autosomal dominant predisposition to colon cancer in the absence of genetic testing for Lynch syndrome ⁽¹²⁾. Prophylactic hysterectomy and salpingo-oophorectomy have

been shown to be effective in decreasing the risk of endometrial and ovarian cancer and should be offered to women with Lynch syndrome after child-bearing is complete ⁽¹³⁾.

Diagnosis

The primary symptom of endometrial cancer is postmenopausal bleeding or abnormal uterine bleeding in pre- or perimenopausal women. A histologic diagnosis is most commonly obtained by office endometrial sampling or dilation and curettage.

Histopathology

Endometrial Hyperplasia

Women with histologic diagnoses of endometrial hyperplasia often present with postmenopausal bleeding or menometrorrhagia. The risk factors associated with the development of endometrial hyperplasia, including obesity and unopposed estrogen, are similar to those associated with endometrial cancer ⁽¹⁴⁾. The World Health Organization defined endometrial hyperplasia based on two characteristics: (1) simple or complex glandular/stromal architectural pattern and (2) the presence or absence of nuclear atypia. The presence of nuclear atypia correlates highest with the risk of developing malignancy. In this spectrum, those with simple hyperplasia without atypia are least likely to develop endometrial carcinoma, while women with complex hyperplasia with atypia are most likely to develop carcinoma. In a long-term follow-up study conducted by Kurman et al, endometrial carcinoma occurred in simple, complex, simple atypical, and complex atypical hyperplasia in 1%, 3%, 8%, and 29% of cases, respectively ⁽¹⁵⁾. A report from one meta-analysis showing a wider range of risk of cancer progression based on four prospective follow-up studies is summarized in Table 32-1 ⁽¹⁶⁾.

Endometrioid Carcinoma

Endometrioid adenocarcinoma is the most common subtype of endometrial cancer, accounting for 75% to 80% of endometrial cancer. Endometrioid

Table 32-1 Risk of Progression From Endometrial Hyperplasia to Endometrial Cancer

Hyperplastic Type	No. of Cases	Risk of Progression (%)	Mean Risk (%)
Simple hyperplasia	164	0-10	4.3
Complex hyperplasia	193	3-22	16.1 ^a
Simple hyperplasia with atypia	27	7.8	7.4 ^a
Complex hyperplasia with atypia	151	29-100	47.0

^aComplex hyperplasia architecture carries a higher risk of progressing to carcinoma than does atypical simple hyperplasia.

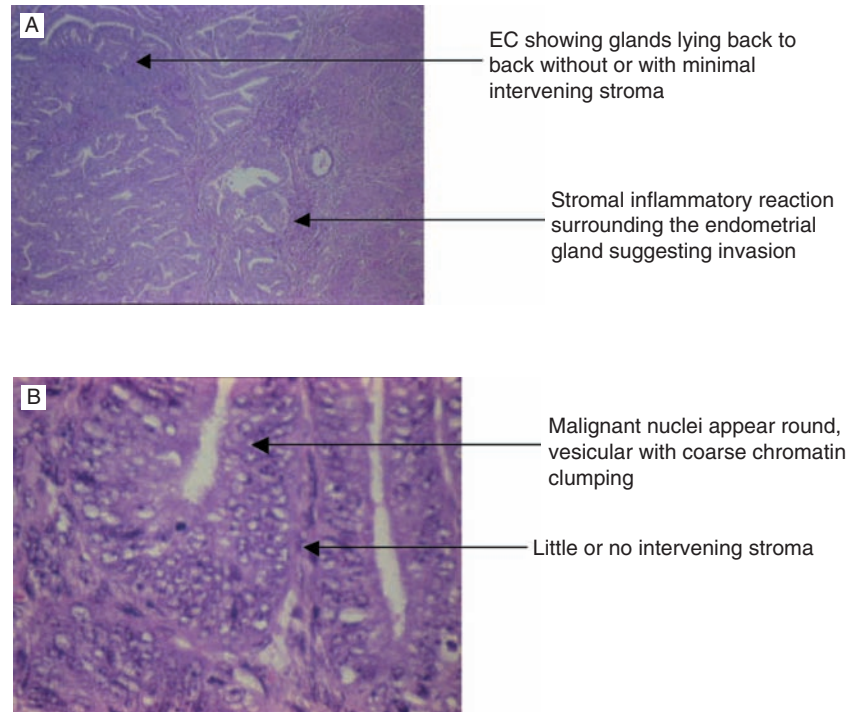

FIGURE 32-1 Endometrioid adenocarcinoma: **A.** Endometrial cancer with superficial myometrial invasion. The stromal inflammatory reaction surrounding the endometrial gland can aid in the diagnosis in some equivocal cases. **B.** High-power magnification shows malignant nuclei in the endometrial glands.

adenocarcinomas are graded 1 to 3, based on degree of differentiation. Grade 1 tumors are well differentiated, composed of glands resembling normal endometrial tissue (Fig. 32-1A). In less-differentiated tumors, glandular formations are less evident or are replaced with solid areas (Fig. 32-1B). The percentage of tumor consisting of these nonsquamous or nonmorular solid areas is the criterion for grading, with grade 1 having a 5% or less solid component, grade 2 having more than 5% but less than or equal to 50%, and grade 3 having greater than 50%. Notably, the presence of nuclear atypia that does not correlate with the architectural features should lead to a one-step upgrade of the tumor.

Papillary Serous Carcinoma

Papillary serous carcinomas are highly aggressive tumors that should be distinguished from other types of uterine carcinoma. Papillary serous carcinomas tend to occur in older women, are usually present in advanced stages, and represent 1% to 5% of cases. Deep myometrial invasion, extensive lymphovascular space invasion (LVSI), and extrauterine spread are common. Intraperitoneal involvement is often observed even when the primary lesion is localized. The histologic features of papillary serous carcinoma resemble those of ovarian or tubal carcinoma. Cytologic atypia is

so prominent that papillary serous carcinomas should always be graded as poorly differentiated tumors.

Clear Cell Carcinoma

Another aggressive form of uterine carcinoma, clear cell carcinoma, represents 5% to 10% of endometrial cancer cases and should also be considered a high-grade tumor. Clear cell carcinoma tends to occur in older women. Morphologically, it resembles clear cell carcinoma arising from other sites (eg, vagina, cervix, ovary), but clear cell carcinoma of the uterine corpus, unlike that of the vagina or cervix, is not associated with intrauterine exposure to diethylstilbestrol. The microscopic appearance varies and can include solid clear cell features, prominent glycogen content, and a glandular, tubulocystic, or papillary pattern. The cells have abundant clear or eosinophilic cytoplasm, sometimes containing periodic acid–Schiff–positive hyaline globules (Fig. 32-2). The nuclei show marked atypia with frequent mitotic figures. The characteristic “hobnail” appearance is seen as cells with scanty cytoplasm and nuclei protruding into the lumen of the gland. At least half of the clear cell carcinomas are admixed with uterine papillary serous carcinoma (UPSC); this has contributed to ideas that the poor prognosis associated with clear cell carcinoma is due to the presence of UPSC.

FIGURE 32-2 Clear cell carcinoma: A more aggressive type of endometrial cancer than the usual endometrioid carcinoma. The clear cytoplasmic content is glycogen rather than mucin.

Mixed Cell Type

As the name implies, mixed-cell endometrial cancers contain more than one type of tumor. The proportion of the minor component should exceed 10% for a tumor to be designated a mixed cell type.

Carcinosarcomas

Carcinosarcomas (also called mixed müllerian malignant tumors, MMMTs), consist of two components: malignant epithelial and mesenchymal tissue. In homologous MMMT, the sarcomatous component can be tissue that is normally found in the uterus; endometrial stromal sarcoma (ESS) or leiomyosarcoma are common. The so-called heterologous type of MMMT consists of tissue that does not normally appear in the uterus; rhabdomyosarcoma and chondrosarcoma are two common types ⁽¹⁷⁻¹⁹⁾. The MMMTs are believed to be aggressive carcinomas, rather than true sarcomas.

Staging

In 1988, the International Federation of Gynecology and Obstetrics (FIGO) committee established a surgical staging system for endometrial cancer (FIGO1988) (Table 32-2). In 2009, this staging system was updated to better stratify patients based on clinically relevant prognostic factors (FIGO 2009, Table 32-3).

Prognostic Factors

There are clinical and pathologic factors that can be used to predict the behavior of endometrial cancer. Clinical factors include age, ethnicity, and stage of

Table 32-2 The 1988 FIGO Staging System

Stages	Characteristics
I	Tumor limited to uterus
IA	Confined to endometrium
IB	Invades ≤1/2 the myometrial depth ^a
IC	Invades >1/2 the myometrial depth ^a
II	Cervical extension
IIA	Involves endocervical gland only
IIB	Invades cervical stroma
III	Pelvic structures or intra-abdominal lymph node involvement
IIIA	Invades serosa or adnexa or is peritoneal cytology positive
IIIB	Vaginal metastasis
IIIC	Pelvic or para-aortic lymph node metastasis
IV	Other organ involvement
IVA	Invades bladder or rectal mucosa
IVB	Distant metastasis, including inguinal lymph node involvement

^aIdeally, width (depth) of myometrial invasion should be measured and recorded with the depth (thickness) of the entire myometrium.

disease. Pathologic factors include histologic type, grade, depth of myometrial invasion, LVSI, and spread of tumor outside the uterine cavity, including the retroperitoneal lymph nodes.

Clinical Factors

Studies have shown that outcomes for women with endometrial cancer are more favorable among younger patients. A retrospective study showed that patients less than 45 years old were statistically more likely to have endometrioid histology, grade I tumors, and stage IA disease, while women over age 65 were significantly more likely to have papillary serous histology and grade 3 tumors. A subset analysis of patients greater than 75 years of age showed an increase in the percentage of patients with aggressive papillary serous histology, higher-grade (grade 3) disease, and advanced-stage disease compared to those less than 45 years old. Evaluation of patients with endometrioid tumors revealed a similar pattern of deeper myometrial invasion and higher tumor grade as age increased ⁽²⁰⁾. Other studies have shown that the risks of locoregional relapse and death among patients older than 60 years were twice as high as the risks among those aged 60 years or younger ⁽²¹⁾.

Studies in the United States have demonstrated that white women are more likely to be diagnosed with endometrial cancer than black women. Interestingly, however, black women diagnosed with endometrial

Table 32-3 The 2009 FIGO Surgical Staging for Endometrial Carcinoma

Stages	Characteristics
I ^a	Tumor confined to the corpus uteri
IA ^a	No or less than half myometrial invasion
IB ^a	Invasion equal to or more than one-half the myometrium
II ^a	Tumor invades cervical stroma but does not extend beyond the uterus ^b
III ^a	Local and/or parametrial involvement ^c
IIIA ^a	Tumor invades serosa and/or adnexae ^c
IIIB ^a	Vaginal and/or parametrial involvement ^c
IIIC ^a	Metastases to pelvic and/or para-aortic lymph nodes ^c
IIIC1 ^a	Positive pelvic nodes
IIIC2	Positive para-aortic lymph nodes with or without positive pelvic lymph nodes
IV ^a	Tumor invasion of bladder and/or bowel mucosa and/or distant metastases
IVA ^a	Tumor invasion of bladder and/or bowel mucosa
IVB ^a	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

cancer are more likely to die of their disease. They tend to be diagnosed at a later stage, with higher-grade tumors, and are more likely to have papillary serous histology. However, after controlling for these factors as well as other comorbid factors, a higher disease-specific mortality rate among black women still exists (²²).

Pathologic Factors

With regard to histologic subtype, papillary serous carcinoma and clear cell carcinoma are associated with worse prognosis than endometrioid carcinoma. Increasing tumor grade is associated with increased myometrial invasion, pelvic and para-aortic node involvement,

recurrence, and a poorer overall survival (²³) (Table 32-4, Fig. 32-3).

Lymphovascular space invasion, an independent risk factor for recurrence, is present in about 15% of endometrial cancer cases. Multivariate analyses have shown angioinvasion to be associated with survival in endometrial cancer regardless of disease stage. Independent of tumor grade or depth of myometrial invasion, LVSI is also associated with risk of pelvic and para-aortic node involvement and thus should lead to surgical nodal assessment or empiric radiation in patients with unstaged disease (²³).

The depth of myometrial invasion is associated with degree of tumor differentiation, LVSI, lymph node involvement, extrauterine spread, recurrence, and

Table 32-4 Pathologic Features of Endometrial Carcinoma Grades and Their Association With Depth of Myometrial Invasion

Grade	Pathologic Features	Percentage of Patients With Each Depth of Myometrium Invasion			
		Endometrial Only	Superficial	Middle	Deep
1	5% or less of nonsquamous solid area	24	53	12	10
2	6%-50% of nonsquamous solid area	11	45	24	20
3	>50% of nonsquamous solid area	7	35	16	42

FIGURE 32-3 Tumor grade and survival in endometrial cancer. Use of the two-tier grading system is favored because of less interobserver variability and similar outcome for patients with grade 1 or 2 tumors (n = 243). (Reproduced with permission from Scholten AN, Creutzberg CL, Noordijk EM, Smit VT. overall survival (Fig. 32-4, Table 32-5). Adnexal metastasis correlates strongly with metastatic involvement of pelvic and para-aortic nodes; in one study, 32% of patients with adnexal involvement had positive pelvic nodes, as compared with 8% of those without adnexal

FIGURE 32-4 Recurrence-free survival rates for 282 patients with stage I endometrial cancer were significantly reduced when the depth of myometrial invasion exceeded two-thirds of the total thickness of the myometrium ($P < .001$). disease (²³). However, the alternative possibility of simultaneous ovarian and endometrial primaries must be ruled out as the surgical management and prognosis are vastly different. Up to 11% of patients with clinical stage I or II disease have lymph node involvement (²³). The risk of para-aortic node involvement increases if the pelvic nodes are positive for tumor.

The current FIGO staging system does not incorporate peritoneal washings as the evidence for their prognostic value is weak. Positive findings on peritoneal cytology are often associated with other unfavorable prognostic factors, such as deep myometrial invasion, cervical extension, and extrauterine spread. In particular, UPSC demonstrates a high rate

FIGURE 32-5 Five-year survival rates for patients with endometrial cancer confined to the uterus with positive findings on peritoneal cytology (91%) were not different from those with cytonegative findings (95%) ($n = 280$). (Reproduced with permission from Kasamatsu T, Onda T, Katsumata N, et al. Prognostic significance of positive peritoneal cytology in endometrial carcinoma confined to the uterus. *Br J Cancer*. 2003;88:245-250.)

of positive washings. Even in clinical stage I disease that is confined to the uterus, cytologic findings have been positive in as many as 16% to 17% of cases⁽²⁴⁾. However, in at least two studies, the 5-year survival rates for patients with cytologically positive disease but no other risk factors have been higher than 90%⁽²⁴⁾ (Fig. 32-5).

In conclusion, these prognostic factors correlate with clinical course of disease, recurrence, and risk of death. However, the relative importance of each factor is not always clear because of interrelations and interdependence among them. Results of a multivariate analysis by Zaino and colleagues of factors affecting survival in stages I and II endometrial cancer are summarized in Table 32-6⁽²⁵⁾.

Evaluation

When evaluating a patient diagnosed with endometrial cancer, in addition to a history and physical examination, a chest x-ray should be performed, and imaging of the abdomen and pelvis should be considered. The measurement of cancer antigen 125 (CA125) may occasionally be useful (Fig. 32-6).

At MD Anderson, for patients with disease confined to the uterus, we recommend primary surgery with total hysterectomy and bilateral salpingo-oophorectomy, except in cases with significant medical comorbidities (see Fig. 32-6). Lymph node evaluation is based on intraoperative evaluation of grade and depth of invasion. Patients with gross cervical involvement may either undergo radical hysterectomy, bilateral

salpingo-oophorectomy, with full staging, including pelvic and para-aortic lymph node sampling, or they may undergo primary radiation therapy (see Fig. 32-6). For disease that is not confined to the uterus, surgical debulking is considered (see Fig. 32-6).

Surgery

The standard staging procedure for endometrial cancer includes total hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy. However, the indications for performing a pelvic and para-aortic lymphadenectomy for staging remain controversial among gynecologic oncologists. Some surgeons practice routine pelvic or pelvic and para-aortic lymphadenectomy for all patients with endometrial cancer, whereas others perform these procedures only for those patients with an increased risk of lymph node metastases based on preoperative and intraoperative assessments. The decision to selectively perform lymph node staging is based on multiple concerns. First, many believe there has been insufficient or unconvincing evidence in the literature that routinely performing lymphadenectomy for all patients results in improved overall survival. Second, performing a lymphadenectomy is associated with additional risks for the patient, including the risk of additional surgical complications and the long-term development of lower extremity lymphedema. Finally, there is a very low rate of lymph node metastases in patients with early disease, specifically those with low-grade endometrioid adenocarcinoma with less than 50% invasion of the myometrium. The absence of LVSI and a tumor size of 2 cm or less in diameter also add reassurance that the lymph nodes are not involved⁽²⁶⁾.

Because of this, intraoperative gross inspection and frozen section of the uterus are commonly performed to evaluate the extent of uterine disease (see Fig. 32-6). This information may be used to further guide whether a lymph node dissection will be performed. The preoperative histologic findings and intraoperative pathologic findings that correlate with an increased risk of nodal involvement include grade 3 endometrioid histology; other aggressive histologies, including clear cell, serous, or squamous carcinoma; tumor invasion of more than half of the myometrium; tumor size greater than 2 cm; and the presence of extrauterine disease⁽²³⁾. In the presence of these variables, there is a benefit for surgical resection of the pelvic and para-aortic lymph nodes (see Fig. 32-6).

In the process of lymph node evaluation, mere palpation of the fatty tissue of node-bearing areas is inadequate for the evaluation of nodal status because only about half of metastatic nodes are enlarged, and fewer than 30% can be identified as abnormal on palpation⁽²³⁾. A representative lymph node sampling or lymph node

Table 32-6 Associations Between Pathologic Prognostic Factors and Relative Risk and Survival Rates

dissection should be performed to adequately evaluate the nodal basins.

The use of sentinel lymph node biopsy to identify patients with lymph node metastases without performing a complete lymph node dissection is currently under study. Theoretically, this could be performed even in patients at low risk for metastases, thereby avoiding the additional risks associated with performing a lymphadenectomy while accurately identifying those in need of additional adjuvant therapy.

Minimally Invasive Approaches

In two reports by the Gynecologic Oncology Group (GOG), laparoscopic surgical methods were compared to conventional laparotomy. The GOG LAP-2 study is the largest randomized trial ever performed in endometrial cancer. In this phase III prospective, multi-institutional, randomized study, 2,616 patients with

stage I to IIA uterine cancer were assigned to laparoscopy ($n = 1,696$) or laparotomy ($n = 920$). Study end points were morbidity and mortality at 6 weeks, length of hospitalization, failure to complete laparoscopy, site of recurrence, and recurrence-free survival. Consistent with previous studies, laparoscopy required longer operative time but led to fewer postoperative adverse events and shorter hospitalization. The rate of intraoperative complications was similar. One unexpected outcome was that as many as 26% of patients in the laparoscopy arm were converted to laparotomy. Laparoscopic failure was associated with increasing age and body mass index (²⁷).

In a companion report, patients undergoing surgical staging via laparoscopy versus laparotomy were assessed with quality-of-life (QOL) measures. The study's objective was to compare the QOL of patients with endometrial cancer undergoing surgical staging via laparoscopy versus laparotomy. Although patients

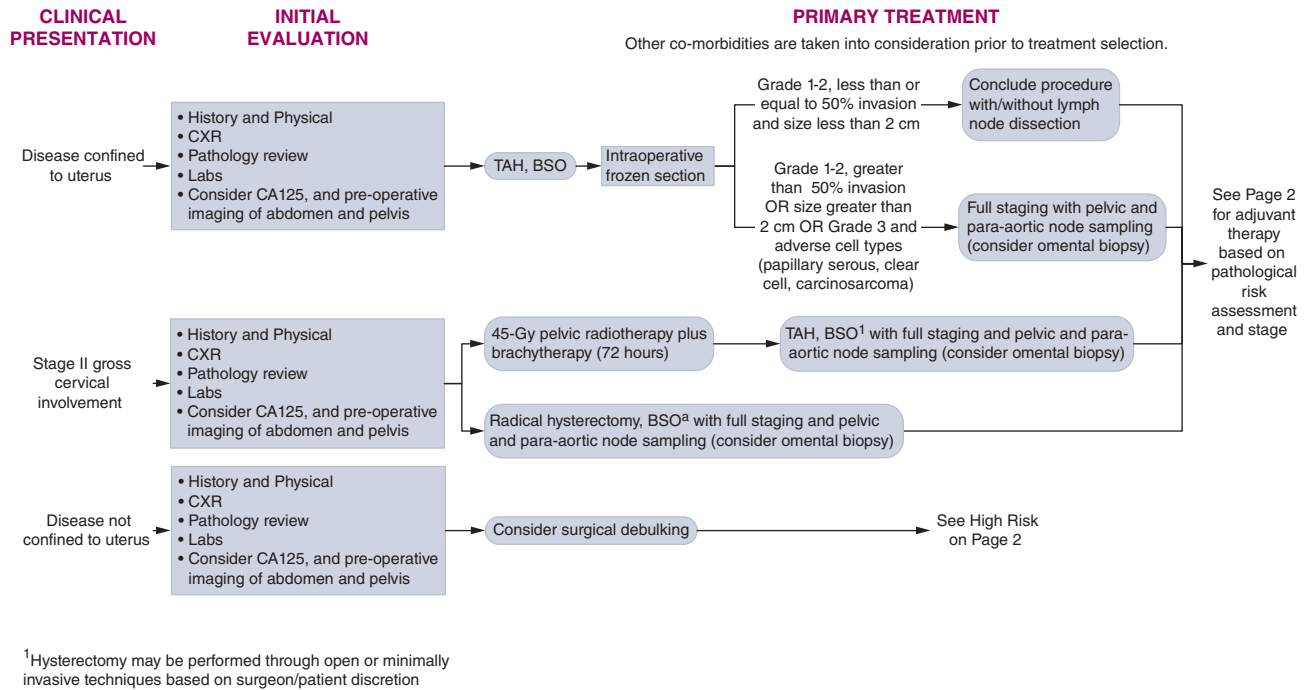

FIGURE 32-6 MD Anderson schema for initial evaluation and treatment of patients with endometrial cancer. TAH, Total Abdominal Hysterectomy; BSO, Bilateral Salpingo-Oophorectomy.

in the laparoscopy arm had overall better QOL measures at 6 weeks postsurgery, except for better body image in the laparoscopy arm, no difference was detected between the two arms at 6 months ⁽²⁸⁾.

Robot-assisted surgery is a newer minimally invasive technique commonly offered to women with endometrial cancer. A recent systematic review included eight studies, with a total of 589 patients undergoing surgery for endometrial cancer. When robot-assisted surgery was compared to laparotomy, it was found to be associated with lower estimated blood loss at time of surgery, lower rates of wound complications, and lower rates of other postoperative complications (including stroke, ileus, nerve palsy, lymphedema). The duration of surgery was significantly longer in robot-assisted surgery compared to laparotomy ⁽²⁹⁾.

The decision to perform open or minimally invasive surgery depends on patient preference, the skill and experience of the surgeon, the availability of the equipment, the size of the uterus, the parity of the patient, and the patient's medical condition. At MD Anderson, minimally invasive approaches, both laparoscopic and robotic, are becoming the standard of care for the majority of women with endometrial cancer.

Adjuvant Therapy

At MD Anderson, we stratify patients according to features of the disease and various prognostic factors (Fig. 32-7). The risk group helps guide the choice of adjuvant treatment. Women with grade 1 or 2

endometrioid tumors with no myometrial invasion or LVSI are considered to have *low-risk* disease. Low-risk disease is associated with an excellent prognosis, with 5-year survival approaching 90% and a low risk for recurrence after surgery. Therefore, in general, we do not recommend adjuvant therapy for this group of patients (see Fig. 32-7). Women with stage III disease, regardless of histology or grade, and women with serous carcinoma or clear cell carcinoma at any stage are considered to have *high-risk* disease and typically undergo adjuvant therapy. *Intermediate-risk* disease, therefore, includes women with endometrial cancer confined to the uterus that invades the myometrium or the cervix. The intermediate-risk group can be further stratified based on the presence of specific prognostic factors, including outer one-third myometrial invasion, grade 2 or 3 disease, and the presence of LVSI. Women are considered to have *high-intermediate-risk* disease if they are (1) any age with all three factors, (2) age 50 to 69 with two factors, and (3) age greater than or equal to 70 years old with one factor. For patients with intermediate-risk disease, there are ongoing controversies regarding the benefit of adjuvant therapy.

Low-Risk Disease

As mentioned, most patients with low-risk disease are unlikely to benefit from adjuvant therapy. Therefore, it is not generally recommended for this group (see Fig. 32-7).

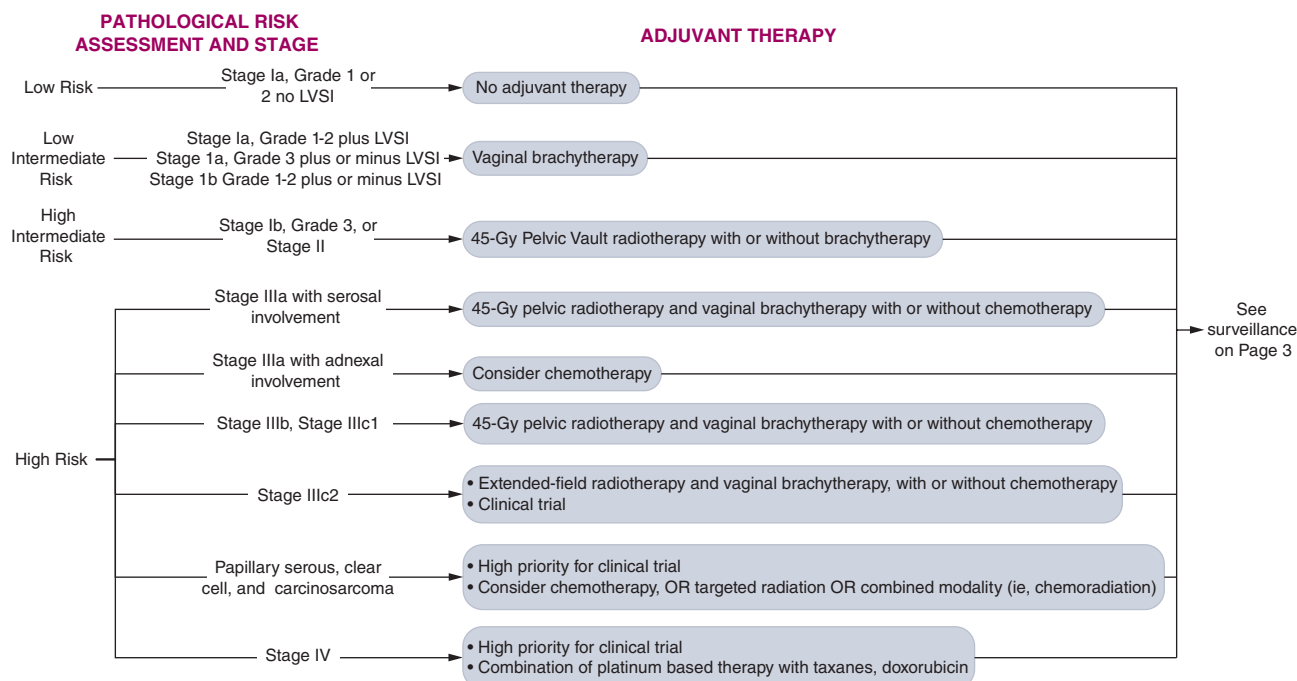

FIGURE 32-7 MD Anderson algorithm for adjuvant therapy in endometrial cancer based on postoperative pathological risk assessment and stage. LVSI, Lymphovascular space invasion.

Intermediate-Risk Disease

A number of trials have addressed the question of adjuvant therapy in intermediate-risk endometrial cancers. *At this time, there is no evidence that adjuvant therapy improves overall survival for women with intermediate risk disease.* For intermediate-risk patients, adjuvant radiation therapy reduces the incidence of pelvic recurrence without prolonging overall survival (Fig. 32-8)⁽³⁰⁾. Vaginal irradiation alone is adequate for preventing pelvic recurrence in patients who are at risk of only isolated vaginal recurrence. At MD Anderson, vaginal irradiation alone is offered to patients with low-intermediate risk (see Fig. 32-7). Vaginal irradiation has a higher therapeutic ratio than whole-pelvis radiation because it produces fewer long-term sequelae. The rate of recurrence after vaginal irradiation is low in women with negative or unknown lymph node status^(31,32). Patients with high-intermediate-risk disease at MD Anderson are offered adjuvant external pelvic radiation with or without brachytherapy (see Fig. 32-7).

Two large, randomized controlled trials compared external beam radiotherapy following surgery to no adjuvant therapy in intermediate-risk endometrial cancer. For GOG-99, 392 surgically staged patients were randomized to external beam radiation (50.4 Gy) or no treatment (control)⁽³¹⁾. The study included patients with any degree of myometrial invasion, adenocarcinoma of any grade, with FIGO 1988 stages IB, IC, and occult stage II disease. The 2-year pelvic recurrence rate

was 3% in the radiation arm versus 12% in the control arm (relative hazard 0.42; $P = .007$). In subgroup analysis, the treatment difference was particularly evident among the high-intermediate-risk subgroup (2-year cumulative incidence rate 6% vs 26% in radiation vs no radiation arms; relative hazard ratio [HR] 0.42). In fact, it was this study that defined the high-intermediate-risk subgroup described previously. In this study, the high-intermediate-risk subgroup was defined as those with: (1) moderate to poorly differentiated tumor, presence of lymphovascular invasion, and outer third myometrial invasion; (2) age 50 or greater with any two risk factors listed; or (3) age of at least 70 with any risk factor listed. However, the estimated 4-year survival was 92% in the radiation arm versus 92% for the control arm, which was not significantly different (HR 0.86; $P = .557$). The authors concluded that adjunctive radiation in early-stage intermediate-risk endometrial carcinoma decreases the risk of recurrence but should be limited to patients whose risk factors fit a high-intermediate-risk definition.

The PORTEC-1 (Post-Operative Radiation Therapy in Endometrial Carcinoma) study randomized 714 women with intermediate-risk endometrial cancer following surgical staging to either external beam radiotherapy (46 Gy) or no adjuvant treatment⁽³⁰⁾. At 5 years, local recurrence was significantly lower for patients in the experimental arm (4%) versus the control arm (14%)⁽³⁰⁾. At 10-year follow-up, the local recurrence rates were similar: 5% in the radiotherapy

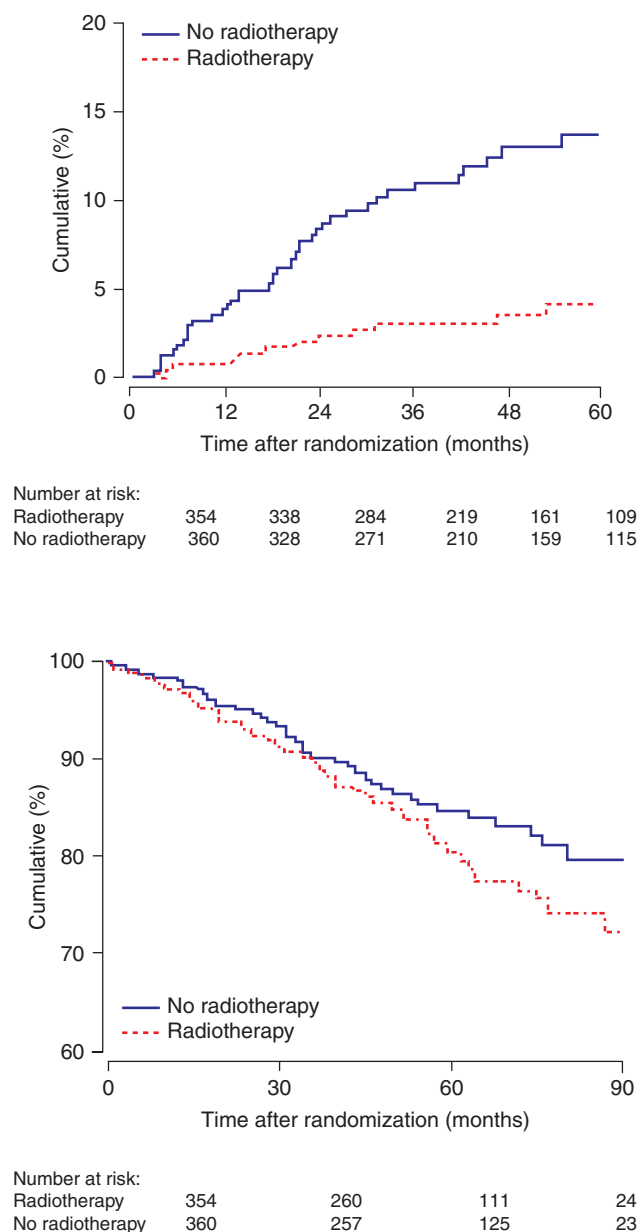

FIGURE 32-8 Pelvic radiotherapy in stage I endometrial cancer. The PORTEC Study Group multicenter randomized trial of 715 patients with stage I endometrial cancer of any type (excluding grade 3 tumors or those with >50% myometrial invasion) showed that pelvic radiotherapy reduced locoregional relapse rates (4% vs 14%, *top panel*) but did not affect 5-year overall survival rates (81% radiotherapy vs 85% observation, *bottom panel*). (Reproduced with permission from Creutzberg CL, van Putten WL, Koper PC, et al. Surgery and postoperative radiotherapy versus surgery alone for patients with stage-1 endometrial carcinoma: multicentre randomized trial. *PORTEC Study Group. Post Operative Radiation Therapy in Endometrial Carcinoma. Lancet.* 2000;355:1404-1411.)

arm versus 14% in the control arm (³³). There was no significant difference in distant recurrence rates at either 5 or 10 years and no overall survival benefit seen at either time point.

In both GOG-99 and PORTEC-1, patients with initial uterine-confined disease had local recurrences in the vagina, prompting evaluation of vaginal brachytherapy as a possible adjuvant therapy. Previously, Piver et al conducted a randomized controlled trial comparing (1) hysterectomy alone, (2) preoperative uterine radium followed by hysterectomy, and (3) hysterectomy and postoperative vaginal radium. This study reported no difference in local control rates, disease-free survival, or overall survival at a follow-up of 10 years (³⁴).

More recently, PORTEC-2 randomized 427 women with high-intermediate-risk disease to vaginal brachytherapy or pelvic radiation. At 45 months, there were no statistically significant differences between the two treatment modalities in terms of locoregional recurrence, distant metastases, or 5-year disease-free survival. Vaginal brachytherapy was associated with a significantly lower rate of side effects, including treatment-related diarrhea and other bowel symptoms (^{35,36}).

At this time, the use of adjuvant chemotherapy to treat intermediate-risk disease is not supported by clinical evidence. Interestingly, however, it has been proposed that chemotherapy with or without vaginal cuff radiation may provide superior results to pelvic radiation in intermediate-risk patients. There are ongoing randomized clinical trials, including GOG 249 and PORTEC-3, attempting to evaluate this combined modality therapy in the high-intermediate-risk patient population.

High-Risk Disease

Women with high-risk disease have either serous or clear cell adenocarcinoma (any stage) or have pathologic stage III disease with extrauterine involvement. There are fewer high-quality studies to guide adjuvant therapy in this group. Treatment may involve radiation, chemotherapy, or a combination of the two modalities, based on histology, stage, and other factors (see Fig. 32-7). For patients with nodal disease, at MD Anderson Cancer Center (MDACC), we typically treat with chemoradiation followed by chemotherapy with four cycles of carboplatin and paclitaxel. A recent meta-analysis evaluated the use of chemotherapy alone versus radiation alone versus chemoradiation in women with stage III or IV endometrial cancer. Compared with radiation, the use of a combination platinum-based chemotherapy regimen resulted in a statistically significant improvement of overall survival (HR 0.75; 95% CI, 0.57-0.99) and progression-free survival (HR = 0.74; 95% CI, 0.59-0.92) (³⁷). The MD Anderson algorithm further delineates our practice pattern for these patients (see Fig. 32-7).

Recurrent or Metastatic Disease

Women with disease outside the pelvis, either at their initial diagnosis or at the time of recurrence, are

considered to have metastatic endometrial cancer. In general, these patients carry a poor prognosis and may benefit from systemic chemotherapy.

The GOG 209 study compared carboplatin plus paclitaxel to the combination of paclitaxel, doxorubicin, and cisplatin (TAP) in 1,300 women with chemotherapy naïve stage III, IV or recurrent metastatic endometrial cancer. Both regimens were administered every 3 weeks for a total of seven cycles. The data are not yet mature; however, initial findings were presented at the 2012 Society of Gynecologic Oncology Annual Meeting. Compared to TAP, carboplatin plus paclitaxel had a similar overall response rate (51% in each arm), similar progression-free survival (median of 13 months in each arm), and similar overall survival (37 months for carboplatin and paclitaxel vs 40 months for TAP). Importantly, the toxicity in the carboplatin-and-paclitaxel arm was significantly lower than the TAP arm. Peripheral neurotoxicity was 19% in the carboplatin/paclitaxel arm compared to 26% in patients assigned to receive TAP. Based on this study, carboplatin plus paclitaxel may often be preferred.

There is ongoing research about the use of biologic therapies in this setting. Single-agent bevacizumab demonstrated clinical activity and was well tolerated in GOG 229E⁽³⁸⁾. It is currently being studied in combination with cytotoxic chemotherapeutic regimens in GOG 86P, a recently closed randomized trial. The use of mTOR inhibitors has also been under investigation. A recent phase II trial of the mTOR (mechanistic target of rapamycin) inhibitor everolimus plus letrozole demonstrated a high clinical benefit rate and response rate⁽³⁹⁾. Additional research with these agents is also under way.

Endocrine Therapy

Progestins have been used to treat advanced endometrial cancer for over 50 years. These medications tend to be well tolerated with relatively minor side effects, including weight gain, thrombophlebitis, headache, and occasional hypertension. Response rates tend to be modest, ranging from 11% to 24%^(40, 41). In GOG 121, women with no previous chemotherapy or hormonal treatment were given megestrol acetate (800 mg/d). The overall response rate was 24%, with progression-free survival of 2.5 months and overall survival of 7.6 months⁽⁴⁰⁾. Unlike in breast cancer, there does not appear to be a dose-response effect for progestins in endometrial cancer. In a randomized trial of oral medroxyprogesterone acetate (GOG 81), women who received a low-dose regimen (200 mg/d) actually had a higher response rate compared to women who received the high-dose regimen (1,000 mg/d)⁽⁴¹⁾.

Certain characteristics improve the likelihood that a patient will have a favorable response to hormone therapy. These include having a low tumor grade (1 or 2), endometrioid histology, the presence of estrogen and progesterone receptors, having a longer disease-free interval, and being asymptomatic or minimally symptomatic.

Tamoxifen has been shown to have some efficacy in this population, with improved rates among women with hormone receptor-positive disease. Interestingly, it has been shown that short-term use of tamoxifen may lead to an increase in progesterone receptors. In GOG 153, women were given a regimen of tamoxifen for 3 weeks, alternating with megestrol acetate for 3 weeks. The overall response rate was 27%, with a median progression-free survival of 2.7 months and overall survival of 14 months⁽⁴²⁾. Letrozole and anastrozole are both aromatase inhibitors that have been evaluated in advanced or recurrent endometrial cancer in phase II trials. Both agents have shown a response rate of less than 10%^(43, 44).

Surgery for Relapsed Disease

At MD Anderson, we evaluate all patients who have experienced an isolated central pelvic recurrence after radiotherapy for radical pelvic surgery or pelvic exenteration; these procedures remain the only potentially curative options that offer the possibility of long-term survival. However, given the high incidence of major postoperative complications, such as urinary/intestinal tract fistulas, pelvic abscesses, septicemia, pulmonary emboli, and cerebrovascular accidents, we consider only selected patients with isolated central recurrences for this treatment.

Postoperative Surveillance

There are no prospective studies to guide frequency of postoperative follow-up. At MD Anderson, for patients with low-risk disease, we schedule office visits every 6 months for the first year and annually during years 2 to 5. For patients with intermediate- and high-risk disease, we schedule office visits every 3 months for year 1, every 4 months for year 2, and every 6 months for years 3 to 5 (Fig. 32-9). At each visit, patients undergo a physical and pelvic examination. Performing routine vaginal cytology in endometrial cancer survivors is not recommended by the SGO. This is because multiple studies have suggested that Papanicolaou tests are not as effective in detecting endometrial cancer recurrences compared to physical examination alone^(45, 46) and are costly and inefficient⁽⁴⁷⁾. In one of these studies, abnormal vaginal cytology had a sensitivity of 40% and specificity of 88% for detecting a vaginal recurrence. The positive predictive value was 7.3%, and negative predictive value was 98.4%⁽⁴⁶⁾.

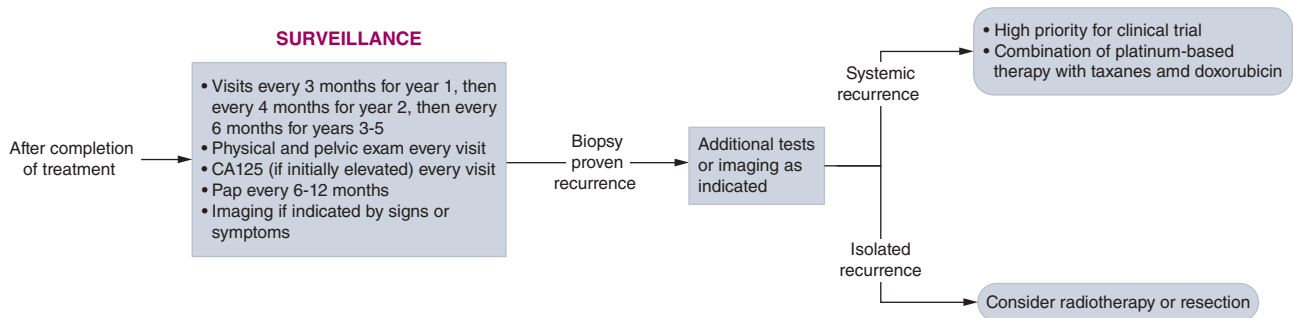

FIGURE 32-9 Sample surveillance protocol for patients with intermediate- and high-risk disease.

Serum CA125 level measurements may be helpful for certain patients. In patients with elevated serum CA125 levels at diagnosis, they can be used as a marker for recurrent disease. In one study, among patients with advanced endometrial cancer who initially had high CA125 levels, 26% to 58% showed elevated CA125 levels at recurrence⁽⁴⁸⁾. The use of serial CA125 assays is most beneficial in diagnosing recurrence in a high-risk population, although there have been no studies to show that their use improves survival. False elevations may occur following radiation therapy.

Hormone Replacement Therapy Following Treatment

The use of estrogen replacement therapy in women who have been treated for endometrial cancer is controversial. Most of the evidence regarding the effects of hormone replacement therapy in women with previously treated endometrial cancer comes from retrospective studies. In one study, Chapman et al found no significant difference in disease-free survival rates between women who used estrogen replacement therapy and those who did not⁽⁴⁹⁾. However, in this study, the group that used estrogen had earlier-stage disease with less depth of invasion compared to the control group. A subsequent cohort study by Suriano et al, who matched cases for tumor status and treatment, also found lower recurrence rates and longer disease-free survival among women who used estrogen⁽⁵⁰⁾. Notably, 49% of patients in the estrogen replacement group in that study were also given progestin, which might have influenced the apparent improvement in outcome.

In a study reported in 2006, the GOG conducted a double-blind, randomized, phase III trial to evaluate the safety of estrogen replacement therapy following treatment for endometrial cancer (GOG 137)⁽⁵¹⁾. Within 20 weeks following surgery, 1,236 women with a history of stage I or occult stage II endometrial cancer were enrolled. All enrolled patients had an indication for treatment with estrogen replacement therapy,

including hot flashes, vaginal atrophy, increased risk of cardiovascular disease, or an increased risk of osteoporosis, and were randomized to receive estrogen replacement or placebo for 3 years following surgery. This study closed early when the results of the Women's Health Initiative (WHI) study showed increased overall risks in the estrogen and progestin arm⁽⁵²⁾. Based on the results of the WHI study, GOG 137 closed prematurely, and the study was left with insufficient power to detect a difference in patients with intermediate- or high-risk early endometrial cancers. The results of this study are inconclusive. However, the authors noted that in the low-risk population, the absolute recurrence rate (2.1%) was low. The relative risk of recurrence/death in the estrogen replacement therapy group was 1.27 compared with the placebo group (80% CI, 0.916-1.77).

At MD Anderson, we approach the use of estrogen replacement therapy on an individual basis. Overall risk of disease recurrence in low-risk patients is low, even in the setting of exogenous estrogen replacement. Therefore, estrogen replacement therapy may be considered for this population. If adjuvant therapy is given following surgery, we recommend a 6- to 12-month waiting period prior to initiation of hormone replacement therapy.

Carcinosarcomas

Carcinosarcomas, or MMMTs, account for less than 5% of malignant neoplasms of the uterus⁽⁵³⁻⁵⁷⁾. The gross appearance of a polypoid carcinosarcoma mass protruding into the endometrial cavity is shown in Fig. 32-10. Although not pathognomonic of carcinosarcoma, this feature in a postmenopausal woman should alert the clinician to the possibility of carcinosarcoma.

Carcinosarcomas, although historically classified as a sarcoma, are now thought to represent a dedifferentiated variety of endometrial carcinoma⁽⁵⁸⁾. Epidemiologically, carcinosarcomas usually appear in older women aged 60 or above^(53, 54, 59).

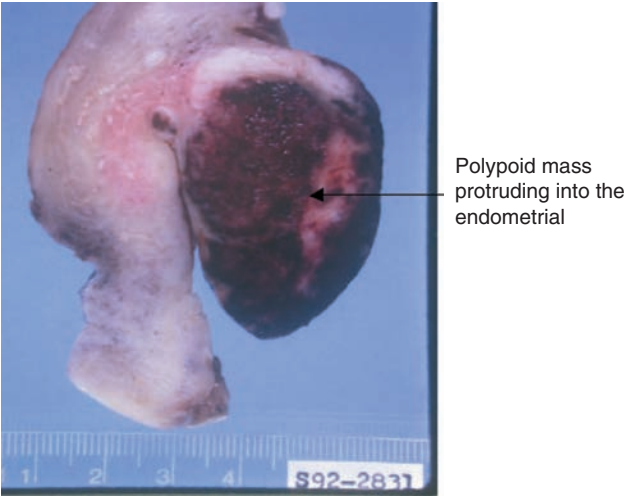

FIGURE 32-10 Gross appearance of a fleshy hemorrhagic polypoid MMMT protruding into the endometrial cavity in a hemiuterus specimen. Such tumors, which typically present with vaginal bleeding, must be distinguished from submucous myoma. Several endometrial tissue biopsies are sometimes needed for diagnosis because of the necrotic and hemorrhagic nature of this tumor.

Treatment

Surgery

Carcinosarcoma is an aggressive type of endometrial carcinoma, and surgical management of carcinosarcoma includes total abdominal hysterectomy with bilateral salpingo-oophorectomy and pelvic and aortic lymph node dissection (60-63). Peritoneal cytology, omentectomy, and peritoneal biopsies are also recommended (60, 64-67). Approximately 20% to 60% of patients will have more advanced disease during surgical staging (55, 68, 69). A recent study reported that in patients with stages I to III uterine carcinosarcomas, 5-year overall survival, disease-free survival, and median survival were significantly improved for patients receiving lymph node dissection compared to those who did not (70). In regard to the role

of cytoreductive surgery in carcinosarcoma, a recent series of 44 patients demonstrated increased overall survival in those patients who had a complete cytoreductive surgery versus those that had residual disease (52.3 vs 8.6 months, respectively) (71). Complete cytoreductive surgery should be attempted, when possible, in patients with carcinosarcoma.

Adjuvant Therapy

Adjuvant therapy for stage IA tumors is left to the discretion of the provider as studies have been inconclusive, and the benefit of adjuvant therapy in these patients is unclear (72, 73). A phase III study by the European Organization for Research and Treatment of Cancer of radiotherapy versus observation in early-stage uterine sarcomas showed a trend toward improved local control but higher rates of distant recurrence in carcinosarcomas (73). There was also no significant difference seen in overall survival (73). Another study of adjuvant therapy in early-stage carcinosarcomas showed treatment with chemotherapy to significantly increase progression-free survival; however, overall survival was not significantly increased (72).

For stage IB and greater carcinosarcomas, adjuvant chemotherapy is generally recommended. A meta-analysis showed improved overall survival (HR 0.75; 95% CI 0.60-0.94) and reduced disease progression (HR 0.72; 95% CI, 0.58-0.90) with combination chemotherapy versus single-agent ifosfamide (74-76). Combination regimens included ifosfamide plus paclitaxel or cisplatin (76). A phase II study of combination carboplatin and paclitaxel also showed an overall response rate of 54% and median progression-free survival of 7.6 months (77). A phase III study, GOG 261, is currently being conducted to further evaluate combination chemotherapy. This study compares combination ifosfamide and paclitaxel to carboplatin and paclitaxel in patients with stage I through IV previously untreated carcinosarcomas (NCT00954174). Examples of these combination chemotherapy regimens are shown in Table 32-7.

Table 32-7 Drug Combinations Used to Treat Uterine Carcinosarcomas

Type of Tumor	Drug Regimen	First Author and Year of Study (Reference)	No. of Patients	Intent	Results
Carcinosarcoma	Ifosfamide vs ifosfamide + cisplatin	Sutton, 2000 (154)	194	Pall	36% vs 54%, median PFS 4 vs 6 months ($P < .05$)
	Ifosfamide vs ifosfamide + paclitaxel	Homesley, 2007 (155)	88	Pall	OR 29% vs 45%
	Paclitaxel + carboplatin	Powell, 2010 (157)	46	Pall	OR 54%

OR, overall response rate; Pall, palliative; PFS, progression-free survival.

NONEPITHELIAL UTERINE TUMORS

Uterine sarcoma is uncommon, accounting for only 3% to 9% of all tumors arising from the uterine corpus^(55, 58, 68). Most uterine sarcomas originate from mesodermal tissue, although some are derived from specialized müllerian mesenchyme, such as endometrial stroma, and a few originate from nonspecific or nonmüllerian mesenchyme

(eg, smooth or skeletal muscle, vessels, or lymphoid tissue). The three most common types of uterine sarcoma are leiomyosarcoma, endometrial stromal sarcoma (ESS), and adenosarcomas. Overall, uterine sarcomas are aggressive tumors with a 5-year overall survival rate of 17.5% to 54.7%⁽⁷⁸⁾.

The 2009 FIGO staging system includes three classifications for staging uterine sarcomas (Table 32-8)⁽⁷⁹⁾.

Table 32-8 FIGO Staging for Uterine Sarcomas

Leiomyosarcomas and Endometrial Stromal Sarcomas ^a	
Stage	Definition
I	Tumor limited to uterus
IA	≤5 cm
IB	≥5 cm
II	Tumor extends beyond the uterus, within the pelvis
IIA	Adnexal involvement
IIB	Involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)
IIIA	One site
IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis
Adenosarcomas	
Stage	Definition
I	Tumor limited to uterus
IA	Tumor limited to endometrium/endocervix with no myometrial invasion
IB	Less than or equal to half myometrial invasion
IC	More than half myometrial invasion
II	Tumor extends beyond the uterus, within the pelvis
IIA	Adnexal involvement
IIB	Involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)
IIIA	One site
IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis
Carcinosarcomas	
Carcinosarcomas should be staged as carcinomas of the endometrium.	

^aNote: Simultaneous endometrial stromal sarcomas of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.

FIGO, International Federation of Gynecology and Obstetrics.

Reproduced with permission from Prat J: FIGO staging for uterine sarcomas, *Int J Gynaecol Obstet* 2009 Sep;106(3):277.

EPIDEMIOLOGY

Leiomyosarcoma and ESS usually affect women in their early 50s. Adenosarcomas have been reported in women 14 to 84 years old; the median age at appearance is in the late 50s⁽⁸⁰⁻⁸²⁾.

Although uterine sarcoma differs somewhat from endometrial cancer in its clinical and pathologic characteristics, some risk factors—such as hypertension, diabetes mellitus, and obesity—are common to both. Previous history of pelvic irradiation has been associated with carcinosarcomas and undifferentiated sarcomas, occurring in 2% to 29% of patients so exposed at an interval ranging from 1 to almost 40 years^(83,84). Prior exposure to pelvic radiation, however, is not felt to be associated with leiomyosarcomas⁽⁸⁴⁾. Although the link between estrogen and endometrial cancer is well established, no such clear relationship is evident for estrogen and uterine sarcoma. An association between tamoxifen use and uterine sarcoma was confirmed in a study by Bergman et al, showing increased numbers of uterine sarcomas among women taking tamoxifen and sarcomas constituting about 10% of total malignancies in these cases⁽⁸⁵⁾.

Leiomyosarcoma

Histology

Leiomyosarcomas represent only 1% to 2% of uterine malignancies; however, they are the most frequent of the uterine sarcomas^(55-58, 86, 87). Gross features of leiomyosarcoma (Fig. 32-11) are typified by variegation at the cut surface (unlike the whorllike surface typical of a benign leiomyoma).

Cells are spindle shaped and arranged in fascicles with eosinophilic cytoplasm. The nuclei are usually elongated with rounded ends, appearing hyperchromatic with coarse chromatin and prominent nucleoli. The most important criterion for the

diagnosis of leiomyosarcoma is a high mitotic rate, generally exceeding 15 mitotic figures per 10 high-power fields. Other features, such as extrauterine extension, large size, and infiltrating border, necrosis, and atypical mitotic figures can also aid in the diagnosis⁽⁵⁸⁾.

Other variants of leiomyosarcoma include myxoid and epithelioid leiomyosarcoma. In myxoid leiomyosarcoma, tumor cellularity is low, cells are separated by myxoid material, and the tumor cells are still characterized by nuclei atypia and high mitotic index^(58, 88, 89). The tumor cells in epithelioid leiomyosarcoma, in contrast, exhibit epithelioid features distinct from the usual characteristics of leiomyosarcoma⁽⁹⁰⁾.

Smooth Muscle Tumor of Uncertain Malignant Potential

Uterine smooth muscle tumors with histologic features of necrosis, nuclear atypia, or mitoses that do not meet all diagnostic criteria for leiomyosarcoma fall into the category of smooth muscle tumor of uncertain malignant potential (STUMP)⁽⁹¹⁾. The STUMPs are a group of smooth muscle tumors for which a diagnosis of sarcoma cannot be made because of their uncertain malignant characteristics. Most of these tumors are associated with favorable prognosis, and only follow-up of the patients is recommended⁽⁹²⁾. In a study conducted at MD Anderson of 41 cases of STUMP, the recurrence rate was 7%. One of the three recurrences was a leiomyosarcoma; the others were STUMPs⁽⁹³⁾.

Clinical Presentation

Vaginal bleeding is the most common presenting symptom of uterine sarcomas. Other symptoms, such as back pain, urinary retention or hematuria, gastrointestinal symptoms, or weight loss may indicate an invading or metastasizing tumor⁽⁹⁴⁻⁹⁶⁾.

FIGURE 32-11 Gross appearance of a leiomyosarcoma in the upper uterus. The cut surface shows a grayish-tan tumor with hemorrhage and necrosis, without the whorllike appearance typical of benign leiomyoma. The mass clearly involves most of the myometrium but not the endometrium.

Diagnosis

Definitive diagnosis of uterine sarcomas is usually made following hysterectomy, with the diagnosis based on histologic examination. Methods utilizing pulsed Doppler ultrasonography to preoperatively distinguish between a benign leiomyoma and uterine sarcoma are reported, but not clinically useful⁽⁹⁷⁾. Although useful for detecting extrauterine disease, imaging studies such as computed tomography and magnetic resonance imaging are not specific for diagnosing sarcomas⁽⁹⁸⁾.

Prognosis and Clinical Course

Many prognostic factors affect outcome in uterine sarcoma, but the most important is the clinical stage at presentation^(56, 87, 99-102). Disease stage directly affects disease-free and overall survival rates^(56, 102, 103).

Leiomyosarcomas are aggressive tumors with a recurrence rate of 50% to 70% even at early stages⁽⁶⁸⁾. The overall 5-year survival rate ranges from 15% to 25%, and the 5-year survival rate for patients with stages I and II is 40% to 70%^(104, 105). There has been no consensus on prognostic indicators for leiomyosarcoma. Previous studies have reported mitotic index, cellular atypia, vascular invasion, and tumor size to correlate with survival.

Treatment

Surgery

Surgery remains the mainstay of treatment for uterine sarcoma, regardless of histologic type. However, there is some controversy regarding the need for oophorectomy or lymph node dissection for each subtype of uterine sarcoma. In general, hysterectomy, including oophorectomy with or without lymph node dissection, is the treatment of choice. In addition, morcellation should not be utilized in women undergoing surgery for uterine sarcoma or suspected uterine sarcoma.

Oophorectomy for early-stage leiomyosarcomas, particularly in premenopausal women, is controversial, as the incidence of adnexal metastases is low⁽⁶⁸⁾. In one study, multivariate analysis showed that oophorectomy for leiomyosarcoma was associated with significantly worse disease-specific survival. Furthermore, case-control investigations implied that ovarian preservation does not adversely affect survival⁽¹⁰⁶⁾. In another study, ovarian metastases were found in about 10% of all cases, despite most having been detected at an early stage⁽¹⁰⁷⁾. Hence, the choice of oophorectomy for the treatment of early-stage leiomyosarcoma should be judged on an individual basis.

The need for lymph node dissection is also controversial. Leiomyosarcoma has substantially lower risk of nodal involvement than clinical stage I or stage II

endometrial cancer with other risk factors. A GOG study of early-stage sarcoma found that nodal metastases were present in only 3.5% of leiomyosarcoma cases, and the pelvic nodes were twice as likely to be involved as the para-aortic nodes⁽⁹⁴⁾. However, the patients in this series underwent lymph node sampling rather than intended dissection, so the reported incidence may be falsely low. Goff et al found lymph node involvement in about 27% of leiomyosarcoma cases, but only in those cases that involved recurrent or disseminated intraperitoneal disease⁽⁹⁴⁾. Two more recent studies identified lymph node metastases in 7% to 11% of patients who underwent lymph node dissection^(106, 107). In the series by Kapp et al, the 5-year disease-specific survival rate was 26% in patients who had positive lymph nodes compared with 64% in those who had negative nodes⁽¹⁰⁷⁾.

Adjuvant Therapy

For early-stage leiomyosarcomas, there has been no clear benefit shown for adjuvant chemotherapy⁽¹⁰⁸⁻¹¹⁰⁾. In these patients, surveillance versus referral to a clinical trial are reasonable treatment options. Currently, the GOG is conducting a study of stage I completely resected leiomyosarcomas comparing adjuvant chemotherapy to observation (GOG 277). The chemotherapy arm consists of gemcitabine on days 1 and 8 and docetaxel on day 8 repeated every 21 days for up to four cycles (NCT01533207).

Advanced-stage leiomyosarcomas, on the other hand, have a high risk of recurrence, and individuals so affected are typically offered adjuvant therapy. We work closely with our sarcoma medical oncology colleagues for treatment recommendations. Combination chemotherapy, specifically, for leiomyosarcoma improves response rates. Various combinations have been investigated, with response rates ranging from 18% to 53%^(109, 111-114). The two most common combination regimens used at MD Anderson are doxorubicin plus ifosfamide or gemcitabine plus paclitaxel. Examples of these combination chemotherapies are shown in [Table 32-9](#).

ENDOMETRIAL STROMAL SARCOMA

Histology

Endometrial stromal sarcoma accounts for about 23% of all uterine sarcomas⁽⁵³⁻⁵⁷⁾. The ESSs originate from endometrial stromal cells that invade the myometrium. Low- and high-grade variants differ in their clinical behavior. Gross features of a low-grade ESS presenting as multiple, small, lobulated tumor masses in the myometrium are shown in [Fig. 32-12A](#).

In fresh specimens, tumor invading the lymphovascular spaces can sometimes be compressed out of

Table 32-9 Drug Combinations Used to Treat Leiomyosarcomas

Type of Tumor	Drug Regimen	First Author and Year of Study (Reference)	No. of Patients	Intent	Results
Leiomyosarcoma	Dox vs dox + dacarbazine	Omura, 1983 (111)	48	Pall	OR 25% vs 30%
	Dox + ifosfamide	Sutton, 1996 (113)	33	Pall	OR 30.3%
	Eto + hydroxyurea + dacarbazine	Currie, 1996 (112)	39	Pall	OR 18.4%
	Mitomycin C + dox + cisplatin	Edmonson, 2002 (114)	23	Pall	OR 23%
	Gemcitabine + docetaxel	Hensley, 2009 (109)	25	Adj	2-year PFS 45%

Adj, adjuvant; dox, doxorubicin; eto, etoposide; OR, overall response rate; Pall, palliative; PFS, progression-free survival.

the vascular lumen, giving a vermiform appearance. Tumor cells resemble endometrial stromal cells during the proliferative phase of the menstrual cycle and are monotonous and of uniform shape and size ⁽⁹³⁾. The presence of spiral arteriole-like vessels is a characteristic finding of ESS, as is the propensity of the tumor cells to invade the lymphovascular spaces (Fig. 32-12B). Endometrial stromal sarcoma tumors contain both estrogen and progesterone receptors ⁽⁵⁸⁾. In addition, these

tumors are generally positive for CD10 and frequently have a t(1;17) chromosomal translocation that expresses a fusion protein composed of JAZF1 and JJAZ1 ⁽⁵⁸⁾.

Clinical Presentation

Like leiomyosarcomas, vaginal bleeding is the most common presenting symptom. Another common presenting symptom in ESS and adenosarcoma is the

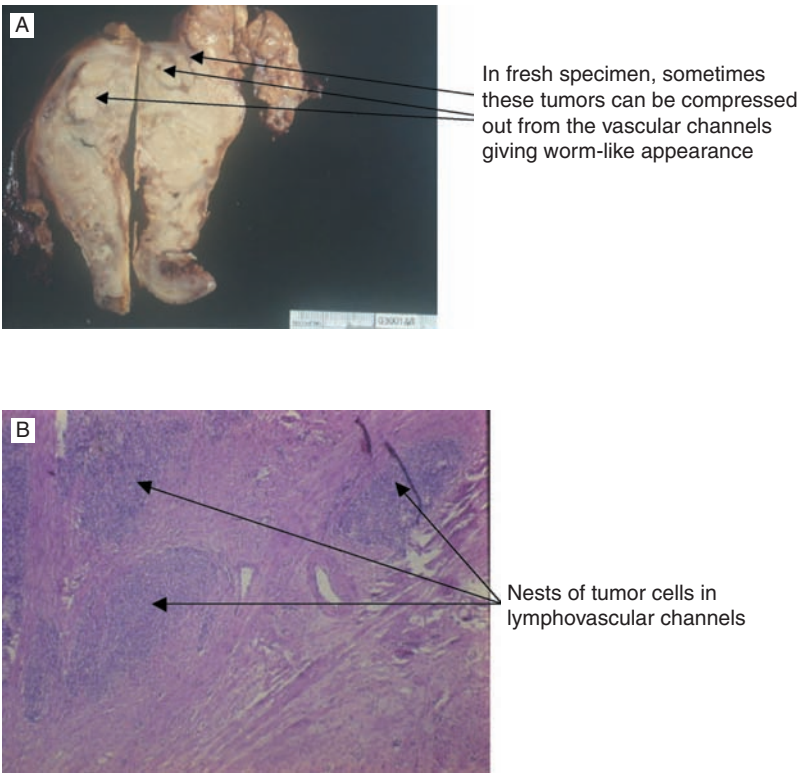

FIGURE 32-12 A. Gross appearance of an endometrial stromal sarcoma infiltrating most of the myometrium. The lobulated appearance corresponds with the presence of tumor in the lymphovascular spaces, as verified on microscopy in panel B. B. Endometrial stromal sarcoma cells with invasion of the intralymphatic spaces.

appearance of a prolapsed polypoid mass through the cervical os⁽⁹⁴⁻⁹⁶⁾.

Prognosis and Clinical Course

Low-grade ESSs are indolent tumors⁽¹¹⁵⁾. Generally, patients with ESS have favorable prognoses; however, recurrence can appear late after primary diagnosis and treatment, even in stage I disease^(116, 117). The FIGO stage, depth of myometrial invasion, tumor grade, positive margins, and patient characteristics such as age, race, and menopausal status have been reported to be prognostic factors^(53, 118-120). Mitotic activity and cytologic atypia were found to be important by some^(53, 104, 121) but not by others^(122, 123). Extrauterine and nodal disease is prevalent in ESS.

Treatment

Surgery

Initial treatment for ESS is largely surgical, and hysterectomy with bilateral salpingo-oophorectomy is recommended. Endometrial stromal sarcoma is often sensitive to hormones, and patients with intact ovaries may be at a higher risk for recurrence⁽¹²⁴⁻¹²⁷⁾. However, there is no consensus on the absolute need for oophorectomy in early-stage ESS. In a study by Li et al, bilateral salpingo-oophorectomy did not appear to affect time to recurrence or overall survival in patients with stage I ESS⁽¹²⁵⁾. In a recent report of 384 women with low-grade ESS, lymph node metastasis and ovarian preservation were not significant prognostic factors for survival in this study. Lymph node metastasis was found in 7% of patients⁽¹²⁶⁾. In two smaller series, only two of the nine patients with ESS who had undergone lymph node sampling were found to have lymph node metastases^(94, 121). The choice of lymph node dissection for ESS should be individualized.

Adjuvant Therapy

Observation is generally recommended for stage I ESS. More advanced stages are typically offered additional therapy after surgical resection, although the data are limited given this rare tumor type. As these tumors typically express estrogen and progesterone receptors, hormonal therapy is considered first-line treatment. Limited retrospective data have reported response of metastatic and recurrent ESS to hormonal agents such as medroxyprogesterone acetate or letrozole^(124, 128). Tamoxifen is contraindicated in the treatment of ESS due to its stimulatory effect on the endometrial stromal cells⁽¹²⁸⁾.

Because of its rarity and because low-grade ESS usually responds well to hormonal therapy, ESS has not been well studied in chemotherapeutic trials. A cisplatin-based chemotherapy regimen was tested

in a study of uterine sarcoma in which about 10% of the cases were ESS⁽¹²⁹⁾. Despite a relatively high response rate of 54%, the regimen was too toxic to be clinically useful. Radiotherapy may help to improve local control, but its role as adjuvant therapy in ESS is unclear⁽¹³⁰⁾.

Undifferentiated Endometrial Sarcoma

Histology

In undifferentiated endometrial sarcomas, previously considered high-grade ESS, the tumor cells tend to be larger, with more vesicular nuclei, coarse clumps of chromatin, and more prominent nucleoli⁽¹³¹⁾. Mitotic counts are usually low in low-grade ESS, and this is the principal criterion for distinguishing between the low- and high-grade forms⁽¹³¹⁾. However, numerous mitotic figures can be present in otherwise-typical low-grade tumors, and high-grade tumors can have only a few mitotic figures^(123, 132). Flow cytometry with DNA ploidy seems to be associated more with the behavior of the tumor than with mitotic count⁽¹³³⁾. In the 2002 classification of ESS by the World Health Organization, high-grade tumors were considered as pleomorphic or undifferentiated sarcoma rather than as a type of ESS because of their distinctive and aggressive clinical behavior. Undifferentiated sarcomas generally stain for Ki67, p16, and p53 and not for estrogen and progesterone receptors. These tumors also do not have any known chromosomal abnormalities⁽⁵⁸⁾.

Prognosis and Clinical Course

In contrast to low-grade ESS, individuals with undifferentiated sarcomas have poor overall survival regardless of stage. The median progression-free survival, in one series, was 7.3 months, and overall survival was only 11.8 months⁽¹³⁴⁾. Patients are also likely to progress quickly despite an initial response to treatment⁽¹³⁴⁾.

Treatment

Surgery

Undifferentiated endometrial sarcomas are treated with up-front surgical management, including hysterectomy and oophorectomy with or without lymphadenectomy. Due to the aggressive nature of this disease, these patients require adjuvant therapy.

Adjuvant Therapy

Unlike ESS, undifferentiated endometrial sarcomas are not responsive to hormone therapy. Adjuvant chemotherapy is similar to that for leiomyosarcoma, as discussed previously.

Adenosarcoma

Histology

Adenosarcomas have two tissue components: The mesenchymal tissue is malignant, and the epithelial part is benign. The epithelial component commonly resembles a proliferative or inactive endometrial gland, often appearing as cleftlike spaces dispersed throughout the proliferative stroma in a phyllode pattern. Slight atypia may be present⁽⁸¹⁾. The mesenchymal stromal component is usually homologous tissue, such as stromal sarcoma, fibrosarcoma, or leiomyosarcoma^(81, 135). The pattern of stromal cell hypercellularity surrounding the glands is characteristic, and the stromal cells show variable atypia and mitosis⁽⁸⁰⁾. Adenosarcomas with extensive stromal sarcoma proliferation are called *adenosarcoma with sarcoma overgrowth* if the sarcomatous component constitutes more than 25% of the tumor^(80, 81). This subtype should be recognized because its prognosis is worse than that of a typical adenosarcoma and more similar to that of carcinosarcoma⁽¹³⁶⁾.

Prognosis and Clinical Course

Adenosarcoma is considered a low-grade malignant tumor with an excellent prognosis⁽⁸⁰⁻⁸²⁾. Most cases are confined to the uterus at time of diagnosis and require no adjuvant therapy. Distant metastases have been reported in 5% of cases, and the recurrence rate is approximately 23%, with about one-third of recurrences occurring more than 5 years after initial treatment^(80, 81, 137). Extra-uterine spread at diagnosis, deep infiltrating tumors, sarcomatous overgrowth, and tumor cell necrosis have all been associated with increased risk of recurrence, but again are rare^(80, 104, 120, 138).

Treatment

Surgery

Management of adenosarcomas consists of hysterectomy and, as discussed previously, additional therapy is generally not required given the excellent prognosis.

Adjuvant Therapy

Only a few reports have described cases in which adenosarcoma was successfully treated with chemotherapeutic drugs such as liposomal doxorubicin⁽⁸²⁾. Krivak and colleagues reported adjuvant chemotherapeutic treatment of nine patients with residual or recurrent adenosarcoma with sarcomatous overgrowth. The drugs used were cisplatin and ifosfamide; doxorubicin; and cisplatin and doxorubicin. The progression-free interval for four patients ranged from 7 to 22 months; all patients had died of recurrent or progressive disease by 39 months⁽¹³⁶⁾.

Kathleen M. Schmeler
Pedro T. Ramirez

EPIDEMIOLOGY

Demographics

Cancer of the cervix is the third most common gynecologic malignancy in the United States. In 2015, a total of 12,900 new cases of cervical cancer and 4,100 deaths are estimated ⁽¹⁾. The incidence of this disease has decreased steadily over the past several decades. However, cervical cancer remains one of the most common cancers in women worldwide with approximately 527,600 new cases diagnosed each year and 265,700 related deaths ⁽²⁾.

Squamous cell carcinoma (SCC) of the cervix may occur at any age from the second decade of life onward. The mean age at diagnosis is approximately 51.4 years, with the number of cases evenly divided between patients at 30 to 39 and 60 to 69 years of age ⁽³⁾. Adenocarcinoma makes up to 15% to 25% of all invasive cervical cancers.

Etiology and Risk Factors

Risk factors for cervical cancer are listed in [Table 33-1](#).

Human Papillomavirus

To understand the current methods for cervical screening, a basic understanding of the nature of cervical abnormalities is essential. Human papillomavirus (HPV) is the critical factor for the development of preinvasive and invasive cervical lesions. More than 14 million incident cases are reported annually, the majority

of which occur in persons age 15 to 24 years ⁽⁴⁻⁶⁾. HPV is a small, nonenveloped, double-stranded DNA virus predominantly transmitted through sexual intercourse. The most consistent risk factors for acquiring HPV are number of sexual partners, age of first sexual intercourse, and a partner infected with HPV.

More than 40 genotypes of HPV infect the epithelial lining of the anogenital tract and other mucosal areas of the body ⁽⁷⁾. These subtypes are further classified into high-risk HPV (HR-HPV) and low-risk HPV (LR-HPV) depending on their oncogenic potential for cervical cancer and its precursors. Low-risk HPV genotypes include HPV-6 and -11 and typically cause benign anogenital warts, although they may occasionally be associated with neoplastic cervical changes ⁽⁸⁾. Invasive lesions, on the other hand, are much more commonly caused by HR-HPV including, in order of frequency, types 16, 18, 31, 45, 52, and 33 ⁽⁹⁾. Although the majority of premalignant and invasive disease can be directly attributed to types 16 or 18, HPV DNA from any genotype is detectable in greater than 99% of all cervical cancer specimens ⁽⁸⁾.

Immunodeficiency Status

Many studies have reported an increased risk of HPV infection and preinvasive and invasive cervical cancer in women who have low immunity, such as those with human immunodeficiency virus (HIV) infection ⁽¹⁰⁾. It was found that rare HR-HPV types are more common in cervical dysplasia of HIV-infected women. It is possible that these other HPV types (35, 45, 52, and 59) are not able to evade the immune system as efficiently as

Table 33-1 Risk Factors for Cervical Cancer

Gynecologic Factor	Male Factor	Others
Human papillomavirus	History of penile cancer	Immunodeficiency
Number of sexual partners	Cervical cancer in ex-wife	Smoking
Age at first intercourse	Multiple sexual partners	Genetic predisposition
Multiparity		Nutrient deficiency
Sexually transmitted disease		
Oral contraception		

HPV types 16 and 18, except in HIV-infected individuals who are immunocompromised ⁽¹¹⁾.

Number of Sexual Partners

The number of sexual partners is an important risk factor for both preinvasive and invasive cervical cancer. Many studies have found an increased relative risk of cervical cancer in women who have had more than six sexual partners ⁽¹²⁾. This is related to a higher risk of acquiring HPV infection.

Age at First Intercourse

Women who have intercourse early in life (<16 years of age) are more prone to develop cervical cancer ⁽¹³⁾. This increase in risk has been proposed because the process of transformation of columnar epithelium to squamous epithelium is active and is vulnerable to carcinogenic agents during early adolescence. However, these women frequently have other associated risk factors, such as multiple sexual partners and HPV infection.

Contraception

Many studies have produced controversial results on the effect of oral contraception on cervical cancer risk. The relative risk of cervical cancer is increased in current users of oral contraceptives and declines after use ceases ⁽¹⁴⁾.

Smoking

Tobacco use is a well-established risk factor for cancer of the cervix. Cigarette smoking confers a 1.5- to 2.5-fold increase in cancers of the cervix. Overall, tobacco smoking is estimated to account for 21% of

cancer deaths worldwide, of which 2% (2% in high-income countries and 11% in low- and middle-income countries) are due to cervical cancer. Therefore, it is the most preventable risk factor for smoking-related cancer deaths ⁽¹⁵⁾.

Male Factors

Women with cervical cancer frequently report a history of having a male partner who has multiple other female partners, a history of condyloma infection, a history of intercourse with prostitutes, or an ex-wife or former partner with cervical cancer ⁽¹²⁾.

HISTOPATHOLOGY

Squamous Cell Tumors and Precursors

Squamous Intraepithelial Lesions

Cervical SCCs are believed to develop from precursor or preinvasive lesions, which have been classified in a variety of ways but are generally based on the degree of disruption of epithelial differentiation. The oldest such system is the dysplasia–carcinoma in situ (CIS) system, with mild dysplasia at one end and severe dysplasia/CIS at the other. Another is the cervical intraepithelial neoplasia (CIN) classification, with mild dysplasia termed CIN1 and CIS termed CIN3. The Bethesda System for reporting cervical/vaginal cytologic abnormalities categorizes squamous abnormalities as follows: low-grade squamous intraepithelial lesion (LSIL), encompassing HPV infection and CIN1; high-grade squamous intraepithelial lesion HSIL, encompassing CIN2 and CIN3; and SCC. These systems are compared in Table 33-2 ⁽¹⁶⁾.

Microinvasive Carcinoma

Microinvasion has been defined variably depending on the recommendations of the International Federation of Gynecology and Obstetrics (FIGO) (“preclinical invasive carcinoma diagnosed microscopically only”; depth of lesion, ≤5 mm; width, ≤7 mm) or Society of Gynecologic Oncology (depth of invasion, ≤3 mm with no lymphovascular space invasion [LVSI] or confluent pattern) ⁽¹⁷⁾. The depth of stromal invasion is measured from the base of the epithelium, either squamous or glandular, to the deepest point of invasion. Microinvasion can be diagnosed only with a conization specimen containing the entire lesion, having uninvolved margins, and having a sufficient number of sections examined by the pathologist.

The histology of invasive foci is usually better differentiated than that of the nearby squamous intraepithelial lesion (Figs. 33-1 and 33-2).

Table 33-2 Classification of HPV-Associated Intraepithelial Lesions of the Cervix and Cytologic Classification

Comparison of Classification Systems			
HPV Risk Category	Dysplasia/CIN	Pap System	Bethesda System
—	Normal	Class I	Normal
Low risk	Inflammation	Class II	LSIL
Low risk	Inflammation	Class II	LSIL
Low and high risk	Inflammation	Class II	LSIL
Low and high risk	Mild dysplasia/CIN1	Class III	LSIL
High risk	Moderate dysplasia/CIN2	Class III	HSIL
High risk	Severe dysplasia/CIS/CIN3	Class IV	HSIL
	Cancer	Class V	

CIN, cervical intraepithelial neoplasia; CIS, carcinoma in situ; HPV, human papillomavirus; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion.

FIGURE 33-1 Microinvasive squamous cell carcinoma (hematoxylin and eosin stain, ×100).

FIGURE 33-2 Squamous cell carcinoma in situ with glandular involvement (hematoxylin and eosin stain, ×400). This should not be interpreted as invasive carcinoma.

Invasive squamous cell carcinoma appears as sheets of tumor tissue invading into the cervical stroma

FIGURE 33-3 Invasive squamous cell carcinoma (hematoxylin and eosin stain, ×10).

Invasive Squamous Cell Carcinoma

The histopathology of SCC is shown in Figs. 33-3 and 33-4.

Glandular Tumors and Precursors

The World Health Organization (WHO) has classified cervical adenocarcinoma into eight categories: (1) adenocarcinoma in situ, (2) early invasive adenocarcinoma, (3) adenocarcinoma not otherwise specified, (4) mucinous adenocarcinoma (including endocervical, intestinal, minimal deviation adenocarcinoma or adenoma malignum, signet ring cell, and villoglandular adenocarcinoma), (5) endometrioid adenocarcinoma, (6) clear cell adenocarcinoma, (7) serous adenocarcinoma, and (8) mesonephric adenocarcinoma.

Adenocarcinoma in Situ

Adenocarcinoma in situ (AIS) is an intraepithelial glandular neoplasm that occurs in women at a younger age than invasive adenocarcinoma⁽¹⁸⁾. Adenocarcinoma in situ is typically located at the transformation zone, although it may be present high up in the endocervical canal (between 20 and 30 mm, measured from the maximum convexity of the portio vaginalis). The

principal morphologic features are cytologic malignant glandular epithelium with stratification, atypia, mitotic activity, and frequent apoptosis without stromal invasion. The cellular changes may be found focally in the glands and may have features of endocervical, endometrioid, intestinal, or mixed cell types. The distinction between AIS and nonneoplastic glandular epithelium may at times be difficult; some authors have coined terms such as *glandular dysplasia* and *glandular atypia* for these lesser changes.

Early Invasive or Microinvasive Adenocarcinoma

Although the concept of microinvasive adenocarcinoma has not been universally accepted, published literature suggests that patients with LVSI-negative cervical adenocarcinoma with depth of stromal invasion of <5 mm and a tumor volume of <500 μ L can be treated with nonradical management (extrafascial hysterectomy with excision of the anterior leaf of the vesicouterine ligament, without lymph node dissection and oophorectomy)⁽¹⁹⁾.

Adenocarcinoma

Various subtypes of adenocarcinoma have been noted due to their differentiation, as their respective names

Focal area of keratin pearl demonstrated in the sheet of neoplastic epithelium

FIGURE 33-4 High-power magnification (×40) of epithelial sheets of squamous cell carcinoma.

FIGURE 33-5 Endocervical papillary adenocarcinoma (hematoxylin and eosin stain, $\times 10$).

imply, such as mucinous adenocarcinoma, which can have endocervical or intestinal goblet cell features and the appearance of endometrioid, clear cell, serous, or mesonephric types. Adenoma malignum is usually an extremely benign-appearing cancer that is often diagnosed late and thus has a clinically poor prognosis. Clear cell adenocarcinomas may or may not be associated with diethylstilbestrol exposure in utero, but they have no known association with HPV ⁽²⁰⁾. Serous adenocarcinoma is rare, with histology identical to its ovarian counterpart, and it carries a similarly bad prognosis. Mesonephric carcinomas are rare and are found in embryonal remnants of wolffian ducts, such as the uterine cervix, broad ligament, mesosalpinx, and exceptionally in the uterine corpus. The primary histologic pattern is tubular glands that vary in size and are lined by one to several layers of columnar cells ⁽²¹⁾ (Fig. 33-5).

SCREENING

Pap Smear and Bethesda System

Pap Smear

Guidelines for screening have been put forth by American College of Obstetricians and Gynecologists ⁽²²⁾ and are summarized below:

- Cervical cancer screening should begin at age 21 years. Women younger than age 21 years should not be screened regardless of the age of sexual initiation or the presence of other behavior-related risk factors.
- Women age 21 to 29 years should be tested with cervical cytology alone, and screening should be performed every 3 years. Human papillomavirus testing should not be performed in women younger than 30 years.
- For women age 30 to 65 years, co-testing with cytology and HPV testing every 5 years is preferred.
- In women age 30 to 65 years, screening with cytology alone every 3 years is acceptable. Annual screening should not be performed.

- Women who have a history of cervical cancer, have HIV infection, are immunocompromised, or were exposed to diethylstilbestrol in utero should not follow routine screening guidelines.
- Both liquid-based and conventional methods of cervical cytology collection are acceptable for screening.
- In women who have had a hysterectomy with removal of the cervix (total hysterectomy) and have never had CIN2 or higher, routine cytology screening and HPV testing should be discontinued and not restarted for any reason.
- Screening by any modality should be discontinued after age 65 years in women with evidence of adequate negative prior screening results and no history of CIN2 or higher. Adequate negative prior screening results are defined as three consecutive negative cytology results or two consecutive negative co-test results within the previous 10 years, with the most recent test performed within the past 5 years.

Since the Pap smear was initially developed, there have been several changes in nomenclature and interpretation to make the results more clinically relevant. At present, the Bethesda System is being used worldwide for cytologic diagnosis (see Table 33-2).

Bethesda System

The Bethesda System is another procedure used for the cytologic diagnosis of cervical cancer. It was developed in 1988 and last updated in 2001 and is now used widely ⁽²³⁾. The Bethesda System report is divided into three sections:

1. *Specimen adequacy*
Satisfactory for evaluation
Unsatisfactory for evaluation
2. *General categorization (optional)*
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormality
Other
3. *Interpretation/result*
Negative for intraepithelial lesion or malignancy
Organism

Other nonneoplastic findings (optional to report; list not comprehensive)

Reactive cellular changes associated with (descriptive findings)

Glandular cells status post hysterectomy

Atrophy

Epithelial cell abnormalities

Squamous cell

Atypical squamous cells (ASCs); ASC of undetermined significance (ASC-US) and ASC cannot exclude HSIL (ASC-H)

LSIL

HSIL

Glandular cell (specify endocervical, endometrial, or not otherwise specified)

Atypical glandular cells (AGCs)

AGCs, favor neoplastic

Endocervical AIS

Adenocarcinoma

Other (list not comprehensive)

Endometrial cells in a woman ≥ 40 years of age

Automated review and ancillary testing (include as appropriate)

Educational notes and suggestions (optional)

Note the following:

1. ASC: Some cells were seen that cannot be called normal but do not meet the requirements to call them precancerous. The abnormal cells may be caused by an infection, irritation, or intercourse or may be precancerous.
 - a. ASC-US
 - b. ASC-H
2. Squamous intraepithelial lesion: Changes were seen in the cells that may show precancerous signs.

Squamous intraepithelial lesion can be low or high grade.

- a. LSIL: Early, mild changes in the size or shape of cells were seen.
 - b. HSIL: Moderate or severe cell changes are seen; HSIL changes on a Pap smear suggest an increased risk of "precancer" when compared with LSIL changes.
3. AGC: Cell changes were seen that represent an abnormality that must be evaluated more closely. The type of evaluation depends on patient age and other factors.

Example of cytologic features of HPV and CIN are shown in Fig. 33-6.

NATURAL HISTORY

The natural history of growth of a cervical lesion is believed to progress through a state of microscopic invasion into the stroma and radial growth on the surface. Ultimately, a mass is formed, which, in general, grows locally to invade first the deeper stroma and later the paracervical and parametrial tissues. If left untreated, the disease will expand through these tissues to involve the lateral pelvic side wall and nearby viscera, such as the urinary bladder and rectum. Cancer arising from the cervix has been reported to involve the uterine corpus in 10% to 30% of cases. The incidence of ovarian metastasis in patients with cervical cancer is estimated at 0.22% for stage IB, 0.75% for stage IIA, and 2.2% for stage IIB with SCC, and 3.7%, 5.3%, and 9.9%, respectively, in adenocarcinoma⁽²⁴⁾.

Perinuclear halo cytologic changes, characteristic feature of HPV infection

Features of an increased nuclei-cytoplasmic ratio, irregular nuclear membrane, coarse clumping chromatin, and prominent nucleoli are evidenced

FIGURE 33-6 Cytologic changes associated with cervical intraepithelial neoplasia (CIN), including A. CIN1 with koilocytotic feature of human papillomavirus (HPV) infection ($\times 600$ magnification), B. CIN2 ($\times 1,000$ magnification), and C. CIN3 ($\times 1,000$ magnification).

A retrospective review of 360 patients with carcinoma of the cervix with clinical stage IB and IIA who had undergone radical hysterectomy and pelvic node dissection showed that lymph node metastasis was present in 21.9% of patients. In patients with and without lymph node metastasis, lymphovascular space invasion positivity, full-thickness stromal invasion, involvement of the uterine isthmus, positive parametrium, positive vaginal margins, and involvement of uterine corpus were seen in 25.3% and 9.2% ($P < .001$), 63% and 32% ($P < .001$), 32.9% and 13.8% ($P < .001$), 15.2% and 5% ($P < .004$), 24% and 14.2% ($P < .005$), and 17.7% and 13.8% ($P = .11$) of patients, respectively. In patients with lymph node metastases, 79.7% had grade 3 tumor compared with 69.5% of patients without lymph node metastases ($P = .19$). Multiple logistic regression indicated that only LVSI and full-thickness stromal invasion were statistically significant ($P < .001$ and $P < .002$, respectively) for lymph node metastasis⁽²⁵⁾. Distant metastasis to bones, lungs, breast, brain, and abdominal viscera often has a late presentation. Variant cell types, such as neuroendocrine and glassy cell carcinoma, may be associated with distant disease in the absence of local involvement.

CLINICAL PRESENTATION

Symptoms

The clinical signs and symptoms of patients with cervical cancer vary depending on the stage and characteristic features of their lesions. Patients with early-stage disease may not have any abnormal symptoms; rather, their lesions may be discovered incidentally on a Pap smear. In patients with gross lesions, the most common presenting symptom is vaginal bleeding, which may have a characteristic pattern of mucous bloody discharge, postcoital bleeding, and/or intermenstrual, intermittent, or continuous vaginal bloody discharge. Vaginal bleeding is often found with exophytic cervical lesions. Tumor necrosis with superimposed infection may cause a mucopurulent bloody discharge with a foul smell due to anaerobic organisms. The symptoms in patients with more advanced disease include leg swelling due to compression of the venous or lymphatic system, pain due to nerve or bone involvement, and other urinary or bowel symptoms due to cancer invasion, such as hematuria or hematochezia.

INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS STAGING

Cervical cancer is currently staged clinically using the FIGO system⁽¹⁷⁾. Routine evaluation includes

physical examination, pelvic and rectal examination, and pathologic review of cervical or cone biopsy specimens. Basic imaging studies such as chest x-ray, intravenous pyelography, cystoscopy, and proctoscopy are allowed in order to classify the disease into four stages, as shown in Table 33-3.

DIAGNOSTIC IMAGING

Imaging plays an important role in the pretreatment evaluation of patients with common gynecologic malignancies. Magnetic resonance imaging (MRI) is the best imaging technique for evaluation of extent of disease in patients with cervical cancer. Magnetic resonance imaging is also useful in the pretreatment evaluation of young women with small-volume disease who wish to preserve fertility. Computed tomography (CT) is able to identify extra-uterine spread of disease, including enlarged pelvic and/or retroperitoneal lymph nodes, extension to the pelvic sidewalls and hydronephrosis, fistulation into bladder or into rectum, and the presence of distant parenchymal metastases. Positron emission tomography (PET)/CT is useful in the detection of lymph node metastases, with sensitivities of 75% to 100% and specificities of 87% to 100%, demonstrating abnormal tracer uptake even in normal-size nodes⁽²⁶⁾.

PROGNOSTIC FACTORS

Stage IA

The depth of stromal invasion correlates with the risk of pelvic lymph node metastases and progression-free interval. In tumors with a depth of invasion <1 , 1 to 3, and <3 mm, the risk of lymph node involvement (LNI) was 0% to 1.6%, 0% to 5.3%, and 1.3% to 13.8%, respectively; the risk of parametrial invasion was 0%, 0% to 2.3%, and 0% to 3.3%, respectively⁽²⁷⁾. Positive LVSI status has significant adverse prognostic effects on relapse-free survival and overall survival in tumors with increasing depth of invasion ($P < .001$)⁽²⁸⁾. In a study by Milam et al⁽²⁹⁾, the authors aimed to determine the association between findings on review of preoperative biopsy specimens and the risk of LNI at radical hysterectomy in patients with early-stage (stage IA-IB1) cervical cancer. In that study, the authors found that 12 patients (14.8%) had LNI at radical hysterectomy. Stage, grade, and histologic subtype were not associated with LNI. Lymphovascular space invasion and depth of invasion >4 mm were both significantly associated with LNI (25.6% vs 4.8%, $P = .01$; and 25.0% vs 4.5%, $P = .01$, respectively). Patients with LVSI with >4 mm invasion were 6.6 times more likely to have LNI at the time of radical hysterectomy (relative risk, 6.6; 95% confidence interval [CI], 2.1-21.9).

Table 33-3 FIGO Staging of Cervical Carcinoma

Stage I	The carcinoma is strictly confined to the cervix (extension to the uterine corpus should be disregarded).
Stage IA	Invasive cancer identified only microscopically. (All gross lesions even with superficial invasion are Stage IB cancers.) Invasion is limited to measured stromal invasion with a maximum depth of 5 mm ^a and no wider than 7 mm.
Stage IA1	Measured invasion of stroma ≤ 3 mm in depth and ≤ 7 mm in width.
Stage IA2	Measured invasion of stroma > 3 mm and < 5 mm in depth and ≤ 7 mm in width.
Stage IB	Clinical lesions confined to the cervix, or preclinical lesions greater than stage IA.
Stage IB1	Clinical lesions no greater than 4 cm in size.
Stage IB2	Clinical lesions > 4 cm in size.
Stage II	The carcinoma extends beyond the uterus, but has not extended onto the pelvic wall or to the lower third of vagina.
Stage IIA	Involvement of up to the upper 2/3 of the vagina. No obvious parametrial involvement.
Stage IIA1	Clinically visible lesion ≤ 4 cm
Stage IIA2	Clinically visible lesion > 4 cm
Stage IIB	Obvious parametrial involvement but not onto the pelvic sidewall.
Stage III	The carcinoma has extended onto the pelvic sidewall. On rectal examination, there is no cancer-free space between the tumor and pelvic sidewall. The tumor involves the lower third of the vagina. All cases of hydronephrosis or nonfunctioning kidney should be included unless they are known to be due to other causes.
Stage IIIA	Involvement of the lower vagina but no extension onto pelvic sidewall.
Stage IIIB	Extension onto the pelvic sidewall, or hydronephrosis/nonfunctioning kidney.
Stage IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder and/or rectum.
Stage IVA	Spread to adjacent pelvic organs.
Stage IVB	Spread to distant organs.

^aThe depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface of glandular, from which it originates. Vascular space invasion should not alter the staging.

The authors concluded that patients with preoperative LVSI are at higher risk for LNI at radical hysterectomy and should be counseled regarding potential implications for management.

Stage IB-IIA

The incidence of lymph node metastasis in patients with stage IB1 and IB2 cervical cancer has been reported to be as high as 15% to 20% and 30% to 50%, respectively. Parametrial invasion is related to the grade of the tumor, depth of stromal invasion, and presence of LVSI. A study by Frumovitz et al ⁽³⁰⁾ evaluated the incidence of parametrial involvement and the factors associated with parametrial spread in women with early-stage cervical cancer. In that study, the authors sought to also identify a cohort of patients at low risk for parametrial spread who may benefit from less radical surgery. Three hundred fifty patients met the inclusion criteria. Overall, 27 women (7.7%) had parametrial involvement. The majority of specimens with parametrial involvement (52%) had tumor

spread through direct microscopic extension. Patients with parametrial involvement were more likely to have a primary tumor size larger than 2 cm (> 2 cm, 14%; < 2 cm, 4%; $P = .001$), higher histologic grade (grade 3, 12%; grades 1 and 2, 3%; $P = .01$), LVSI (positive, 12%; negative, 3%; $P = .002$), and metastasis to the pelvic lymph nodes (positive, 31%; negative, 4%; $P \leq .001$). One hundred twenty-five women (36%) had squamous, adenocarcinoma, or adenosquamous lesions, all grades, with primary tumor size ≤ 2 cm and no LVSI. In this group of patients, there was no pathologic evidence of parametrial involvement. Significant prognostic factors include tumor diameter, positive lymphangiography, and adenocarcinoma histology.

VACCINATIONS

Preventive Setting

Koutsky et al ⁽³¹⁾ conducted a double-blinded randomized study in 2,392 women at risk for infection who received three doses of a placebo or HPV-16-like

particle vaccine (40 mg/dose). After a median follow-up duration of 17.4 months from administration of the last dose, the incidence of HPV-16 infection was significantly lower in the study group (3.8% in the placebo group, 0.0% in the vaccinated group; $P < .001$).

The first HPV vaccine was licensed for use in the United States in June 2006. At present, there are two HPV vaccines available in the United States. Human papillomavirus quadrivalent, or HPV4 (types 6, 11, 16, 18), vaccine, recombinant (Gardasil) and HPV bivalent, or HPV2 (types 16 and 18), vaccine, recombinant (Cervarix). Both vaccines have greater than 95% efficacy in preventing HPV-16- and HPV-18-related cervical precancer lesions⁽³²⁾.

The WHO has changed its previous recommendation of a three-dose schedule to a two-dose schedule, with increased flexibility in the interval between doses, which may facilitate vaccine uptake. For both the bivalent and quadrivalent HPV vaccines, a two-dose schedule with a 6-month interval between doses is recommended for females younger than 15 years. Those who are >15 years old at the time of the second dose are also adequately covered by two doses. There is no maximum recommended interval between doses. However, an interval no greater than 12 to 15 months is suggested in order to complete the schedule promptly and before becoming sexually active. If the interval between doses is shorter than 5 months, a third dose should be given at least 6 months after the first dose. A three-dose schedule (at 0, 1-2, and 6 months) is recommended for females age 15 years and older and for those known to be immunocompromised and/or infected with HIV (regardless of whether they are receiving antiretroviral therapy)⁽³³⁾.

The data from the National Health and Nutrition Examination Surveys (NHANES) continue to show good efficacy for the HPV vaccines. Data comparing 2003 to 2006 with 2007 to 2010, the first 4 years of the HPV vaccination program in the United States, have shown that there was a 56% reduction in prevalence of HPV types 6, 11, 16, and 18 in girls age 14 to 19 years and 36% reduction in genital warts in US girls age 15 to 19 years from 2006 to 2010⁽³²⁾.

Apter et al⁽³⁴⁾ conducted the double-blinded randomized PATRICIA trial on the immunogenicity and efficacy of the HPV-16/18 AS04-adjuvanted vaccine in young women age 15 to 25 years. The total vaccinated cohort (TVC) included all randomized participants who received at least one vaccine dose (vaccine, $n = 9,319$; control, $n = 9,325$) at months 0, 1, and/or 6. The TVC-naïve group (vaccine, $n = 5,822$; control, $n = 5,819$) had no evidence of high-risk HPV infection at baseline, approximating adolescent girls targeted by most HPV vaccination programs. It was concluded that vaccinating adolescents before sexual debut has a substantial impact on the overall incidence of high-grade

cervical abnormalities, and catch-up vaccination up to 18 years of age is most likely effective.

TUMOR MARKERS

Squamous Cell Carcinoma Antigen

A study was conducted to identify patient-, disease-, and treatment-related factors associated with unusual levels of SCC antigen (SCC-Ag) and to determine whether SCC-Ag is a useful tumor marker in patients. Among 129 patients with recurrence, 14 who showed a normal SCC-Ag level at diagnosis but an elevated level at recurrence were classified as group I; 22 patients with an elevated SCC-Ag level at diagnosis but not at recurrence were classified as group II; and 76 patients with an elevated SCC-Ag level at both diagnosis and recurrence were classified as group III. In univariate analysis, unusual SCC-Ag showed statistically significant relationships with pathology and biochemical response to treatment. However, in the multivariate analysis, none of the clinicopathologic factors showed a statistical relationship with unusual levels of SCC-Ag. The 5-year disease-free survival rates for groups I, II, and III were 7.1%, 9.1%, and 0% ($P = .418$), and the 5-year overall survival rates were 34.3%, 58.4%, and 33.3%, respectively ($P = .142$). It was found that patients with a high initial SCC-Ag and elevated SCC-Ag at relapse have poor prognosis due to high SCC-Ag level⁽³⁵⁾.

TREATMENTS

Management of Abnormal Pap Smears

The current consensus guidelines from the American Society for Colposcopy and Cervical Pathology (ASCCP) for the management of abnormal Pap tests and treatment of cervical dysplasia are summarized below⁽³⁶⁾.

Atypical Squamous Cells

Treatment of ASC depends on the subcategory based on the Pap smear: undetermined significance (ASC-US) or cannot exclude HSIL (ASC-H).

1. ASC-US: Atypical squamous cells of undetermined significance is the most common cytologic abnormality, but it carries the lowest risk of CIN3+, partly because one- to two-thirds of cases are not HPV associated. For women >25 years old with ASC-US cytology, HPV testing is recommended. If HPV-negative ASC-US is present, repeat co-testing (Pap and HPV testing) at 3 years is recommended.

If HPV-positive ASC-US is present, colposcopy is recommended. For women age 21 to 24 years with ASC-US, repeat cytology in 12 months is recommended. Immediate colposcopy or repeat HPV testing is not recommended. Management of pregnant women with ASC-US is identical to that described for nonpregnant women, with the exception that deferring colposcopy until 6 weeks postpartum is acceptable. Endocervical curettage in pregnant women should not be performed.

2. ASC-H: For women with ASC-H cytology, colposcopy is recommended regardless of HPV result.

Low-Grade Squamous Intraepithelial Lesion

For women with LSIL who are 21 to 24 years old, follow-up with cytology at 12-month intervals is recommended. For women >25 years old, colposcopy is recommended. For pregnant women with LSIL, colposcopy is preferred and can be performed immediately or deferred until 6 weeks postpartum.

High-Grade Squamous Intraepithelial Lesion

For women >25 years old with HSIL cytology, colposcopy or immediate treatment with loop electrosurgical excision or colposcopy is recommended. For women age 21 to 24 years with HSIL, colposcopy is recommended. When CIN2+ is not identified histologically, observation for up to 24 months using both colposcopy and cytology at 6-month intervals is recommended, provided the colposcopic examination is adequate and endocervical assessment is negative or CIN1.

Atypical Glandular Cells, Adenocarcinoma In Situ, and Benign Glandular Changes

For women with AGC or AIS on Pap test, colposcopy with endocervical sampling is recommended regardless of HPV result. Endometrial sampling is recommended in conjunction with colposcopy and endocervical sampling in women 35 years of age and older with all subcategories of AGC and AIS. Endometrial sampling is also recommended for women younger than 35 years with risk factors for endometrial cancer (obesity, chronic anovulation, Lynch syndrome, or family history of endometrial and/or colorectal cancer). For women with atypical endometrial cells, initial evaluation limited to endometrial and endocervical sampling is preferred, with colposcopy acceptable either at the initial evaluation or deferred until the results of endometrial and endocervical sampling are known; if colposcopy is deferred and no endometrial pathology is identified, colposcopy is then recommended.

For women with AGC not otherwise specified cytology in whom CIN2+ is not identified, co-testing

at 12 months and 24 months is recommended. If both co-tests are negative, return for repeat co-testing in 3 years is recommended.

For women with AGC “favor neoplasia” or AIS cytology, if invasive disease is not identified during the initial colposcopic workup, a diagnostic excisional procedure is recommended. It is recommended that the type of diagnostic excisional procedure used in this setting provide an intact specimen with interpretable margins. Endocervical sampling above the cone bed is recommended. The initial evaluation of AGC in pregnant women should be identical to that of nonpregnant women, except that endocervical curettage and endometrial biopsy are not performed.

For asymptomatic premenopausal women with Pap showing benign endometrial cells, endometrial stromal cells, or histiocytes, no further evaluation is recommended. For postmenopausal women with benign endometrial cells, endometrial biopsy is recommended.

TREATMENT OF CERVICAL INTRAEPITHELIAL NEOPLASIA

Cervical Intraepithelial Neoplasia Grade 1

The recommended management of women with a histologic diagnosis of CIN1 preceded by an ASC-US, ASC-H, or LSIL cytology is follow-up with either HPV DNA testing every 12 months or repeat cervical cytology every 6 to 12 months. If the HPV DNA test is positive or if repeat cytology shows ASC-US or greater, colposcopy is recommended. If the HPV test is negative or two consecutive repeat cytology tests are negative, return to routine cytologic screening is recommended. If CIN1 persists for at least 2 years, either continued follow-up or treatment with excision or ablation can be performed. Hysterectomy as the primary and principal treatment for histologically diagnosed CIN1 is not recommended. For CIN1 preceded by HSIL or AGC not otherwise specified cytology, either a diagnostic excisional procedure or observation with colposcopy and cytology at 6-month intervals for 1 year is acceptable. If observation with cytology and colposcopy is elected, a diagnostic excisional procedure is recommended for women with repeat HSIL or AGC not otherwise specified cytologic results at either the 6- or 12-month visit. The recommended management of pregnant women with a histologic diagnosis of CIN1 is follow-up without treatment.

Cervical Intraepithelial Neoplasia Grades 2 and 3

Both excision and ablation are acceptable treatment modalities for women with a histologic diagnosis of

CIN2/3 and satisfactory colposcopy. If the colposcopy is unsatisfactory or the lesion is large, excision should be performed with ablation not recommended.

For women <25 years of age with a histologic diagnosis of CIN2, either treatment or observation for up to 24 months using both colposcopy and cytology at 6-month intervals is acceptable, provided colposcopy is satisfactory. Treatment is recommended if CIN3 is subsequently identified or if CIN2/3 persists for 24 months.

In the absence of invasive disease, additional colposcopic and cytologic examinations are acceptable in pregnant women with a histologic diagnosis of CIN2/3 at intervals no more frequent than every 12 weeks. Repeat biopsy is recommended only if the appearance of the lesion worsens or if cytology suggests invasive cancer. Reevaluation with cytology and colposcopy is recommended 6 weeks postpartum.

Treatment of Adenocarcinoma In Situ

Hysterectomy is preferred for women who have completed childbearing and have a histologic diagnosis of AIS. Conservative management with cervical conization is acceptable if future fertility is desired. If the margins of the specimen are involved or endocervical sampling obtained above the cone bed contains CIN or AIS, reexcision to increase the likelihood of complete excision is recommended. Long-term follow-up is recommended for women who do not undergo hysterectomy.

Treatment of Invasive Cervical Carcinoma

Type of Treatment

Treatment of invasive cervical cancer depends on many factors, including disease stage, patient age, performance status, fertility of the patient, and skill and resources of the care providers. The treatment of cervical cancer is described by stage of disease in the following sections.

Hysterectomy Classification According to Piver et al ⁽³⁷⁾

In 1974, Piver et al ⁽³⁷⁾ categorized hysterectomy into five classes according to the extent of tissue resection.

Class I

Simple hysterectomy is removal of the uterus along with the cervix in an extrafascial manner without incision into the cervical or uterine tissue.

Class II

Modified radical hysterectomy is removal of the uterus with part of the paracervical and parametrial tissue in the lateral aspect of the cervix after dissecting the

ureters away. Half of the cardinal ligament (lateral aspect), the uterosacral ligament (posterior aspect), and one-third of the upper vagina are all removed. This is usually performed in cases of stage IA2 or persistent or local recurrent cervical cancer after radiation therapy.

Class III

Radical hysterectomy is removal of the uterus in a manner similar to that of class II hysterectomy, but the tissue structure is removed to a greater extent, generally close to the pelvic side wall laterally and sacrum posteriorly; the upper half of the vagina is also removed. Conventionally, this class of hysterectomy is done for cases of stage IB to IIA disease. However, it can be performed for persistent or recurrent cervical cancer after primary radiation therapy as an alternative procedure to exenteration in highly selected patients. These include patients with stage IB to IIA disease at primary diagnosis, no clinical parametrial involvement, and a tumor diameter of ≤ 4 cm at the time of recurrence.

Class IV

Extended radical hysterectomy is complete removal of the cervix, uterus, parametrial tissue, cardinal, and uterosacral ligaments. In addition, the ureter is completely dissected from the vesicouterine ligament, and the superior vesical artery is sacrificed. This is a possible procedure for central locoregional recurrence.

Class V

Partial exenteration is partial excision of the involved organs. In addition to the above procedures, this encompasses the removal of the distal ureter and urinary bladder. This procedure is performed in cases of central recurrence.

Hysterectomy Classification According to Cibula et al ⁽³⁸⁾

A more recent classification has been introduced by Cibula et al ⁽³⁸⁾.

Type A: Minimum Resection of Paracervix

This resection is an extrafascial hysterectomy, in which the position of the ureters is determined by palpation or direct vision (after opening of the ureteral tunnels) without freeing the ureters from their beds. The paracervix is transected medial to the ureter but lateral to the cervix. The uterosacral and vesicouterine ligaments are not transected at a distance from the uterus. Vaginal resection is generally at a minimum, routinely less than 10 mm, without removal of the vaginal part of the paracervix (paracolpos).

Type B: Transection of Paracervix at the Ureter

Partial resection of the uterosacral and vesicouterine ligaments is a standard part of this category. The ureter is unroofed and rolled laterally, permitting transection of the paracervix at the level of the ureteral tunnel. The caudal (posterior, deep) neural component of the paracervix caudal to the deep uterine vein is not resected. At least 10 mm of the vagina from the cervix or tumor is resected.

Type C: Transection of Paracervix at Junction With Internal Iliac Vascular System

The Q–M classification system distinguishes between a type C1 procedure, which corresponds to the nerve-sparing modification, and the type C2 procedure, which aims for a complete parametrial resection. Type C1 requires separation of two parts of the dorsal parametria; the medial part, which entails rectouterine and rectovaginal ligaments, and the lateral laminar structure, also called mesoureter, which contains the hypogastric plexus. Furthermore, type C1 requires only a partial dissection of the ureter from the ventral parametria, which is usually asymmetric towards more extensive resection of the medial leaf of the cranial (above the ureter) part of the ventral parametria. In the C2 type, the ureter is completely dissected from the ventral parametria up to the urinary bladder wall. Defining the resection limits on the longitudinal (deep parametrial or vertical) plane is crucial for distinguishing between types C1 and C2.

Type D: Laterally Extended Resection

This type differs from type C2 only in the lateral extent of the lateral parametria resection. Ureteral dissection and resection of both dorsal and ventral parametria is identical to the type C2. Laterally, however, it requires ligation and removal of the internal iliac artery and vein, together with their branches, including the gluteal, internal pudendal, and obturator vessels.

Treatment by Stage of Disease**Stage IA1**

Stage IA1 cervical cancer should be diagnosed using a conization specimen, because small tissue biopsy study may not be accurate enough to rule out other areas of a more extensive lesion. The treatment depends on the need for fertility preservation.

Conization

In a recent study, He et al.⁽³⁹⁾ evaluated the value of cold knife conization (CKC) as a conservative management in patients with microinvasive cervical SCC. A total of 108 patients with stage IA1 were enrolled. Eighty-three patients (76.9%) underwent further hysterectomy, out

of which 48 (57.8%) underwent extrafascial hysterectomy, 30 (36.1%) underwent extensive hysterectomy, and 5 (6.1%) underwent radical hysterectomy. All patients were followed up for 1 year. The 18 patients with positive resection margins had greater likelihood of cervical residual lesions (CIN1-3) than the 65 patients with clear resection margins, but there were no significant differences ($P = .917$). Twenty-five patients who underwent CKC as final therapy were followed up for 1 year. Two patients with positive resection margins had a second CKC surgery; one patient was diagnosed with CIN1, and the other was diagnosed with cervicitis by pathology. Twenty-three patients had clear resection margins; two patients underwent a second CKC 3 months after the first CKC because of the abnormal ThinPrep Cytologic Test (TCT) result, and they were both diagnosed with microinvasive cervical SCC (stage IA1) by pathology with clear resection margins. No one enrolled in this study presented with metastasis or progression within 1 year of follow-up. This provided the clinical evidence for the possibility of fertility-sparing treatments, especially CKC, as conservative treatment for microinvasive cervical SCC.

Simple Hysterectomy

Simple hysterectomy may be performed in women with stage IA1 cervical cancer in whom preservation of fertility function is not required. However, in patients with LVSI, a modified radical hysterectomy may be the procedure of choice.

Stage IA2

The incidence of LNI in patients with this stage of cervical cancer is as high as 7% with a recurrence rate of 3% to 5%, and these patients should be treated with a radical hysterectomy with pelvic lymph node dissection. In women who want to conserve fertility, another approach that has been reported to have a successful outcome is radical trachelectomy with laparoscopic pelvic lymphadenectomy, in which the body of uterus is preserved for fertility function⁽⁴⁰⁾. Individualization of therapy based on findings from extensive pathologic review of an adequate cone biopsy specimen is important for treatment planning.

Stage IB1

The standard surgical treatment for FIGO stage IB1 cervical cancer consists of a radical hysterectomy or trachelectomy and systematic pelvic lymphadenectomy.

Radical Hysterectomy

Traditionally, surgery for stage IB disease consists of radical hysterectomy performed in conjunction with pelvic lymphadenectomy. Lately, some have

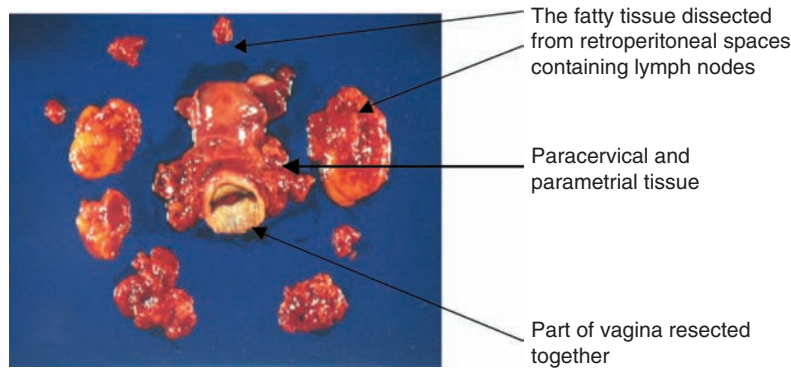

FIGURE 33-7 Gross specimen from a radical hysterectomy with lymph nodes dissected.

recommended class II hysterectomy rather than conventional class III hysterectomy in stages IB and IIA disease with a tumor size <2 cm due to fewer complications from the former and no difference in the 5-year survival ⁽⁴¹⁾ (Figs. 33-7 and 33-8).

Sentinel Lymph Node Mapping

The concept of the sentinel node (SN) was first clinically developed by Cabanas in association with penile carcinoma ⁽⁴²⁾. It is based on the principle that if the SN or the first node receiving drainage from tumor is negative, more extensive lymphadenectomy may be exempted to avoid the morbidity of the procedure.

Generally, the techniques used to map SNs involve identification of the lymphatic duct by injecting isosulfan blue dye or lymphoscintigraphy, using gamma probe detection of technetium 99m-labeled colloid, which is injected into the cervix. This can be done either before or during the operation. A number of studies of SN mapping for cervical cancer have been published; in these instances, the investigators used either blue dye, lymphoscintigraphy, or both with varying degrees of success. The introduction of indocyanine green (ICG) as another tool for SN mapping may be revolutionizing the field because it is now being used in patients undergoing minimally invasive surgery, both by the laparoscopic and robotics approach. Indocyanine green is a dye that fluoresces

in the near-infrared (NIR) spectrum when illuminated with 806-nm light. When a laser emitted from the NIR imager excites ICG, it produces a wavelength that is converted to a fluorescent image. The emitted fluorescence is captured with a video camera device that allows for the ICG to be displayed in the visible light spectrum ⁽⁴³⁾.

Jewell et al ⁽⁴⁴⁾ assessed the detection rate of SNs using ICG in patients with uterine and cervical cancer. A total of 227 cases were performed. The median SN count was 3 (range, 1-23). An SN was identified in 216 cases (95%), with bilateral pelvic mapping in 179 cases (79%). The authors found that there was no difference in the detection rate when ICG alone was used versus the combination of both dyes (ICG and isosulfan blue). The authors concluded that combined use of ICG and blue dye appears unnecessary.

In the SENTICOL study by Lécuru et al ⁽⁴⁵⁾, the authors aimed to determine if bilateral negative SNs accurately predict absence of lymph node metastasis in early cervical cancer patients with stage IA1 disease with LVSI to stage IB1. One hundred forty-five patients were enrolled, and 139 were included in a modified intent-to-diagnose analysis. Intraoperative radioisotope-blue dye mapping detected at least one SN in 136 patients (97.8%; 95% CI, 93.8%-99.6%), 23 of whom had true-positive results and two of whom had false-negative results, yielding 92.0% sensitivity

FIGURE 33-8 A radical hysterectomy specimen with a portion of upper vagina. Note that the ovaries need not be removed unless indicated by the associated pathology.

(23 of 25 patients; 95% CI, 74.0%-99.0%) and 98.2% negative predictive value (111 of 113 patients; 95% CI, 74.0%-99.0%) for node metastasis detection. No false-negative results were observed in the 104 patients (76.5%) in whom SNs were identified bilaterally. Therefore, the authors concluded that SN biopsy was fully reliable only when SNs were detected bilaterally.

Radical Trachelectomy

Radical trachelectomy (RT) is resection of the cervix together with paracervical and parametrial tissue, with retention of the corpus uteri. The procedure is indicated in reproductive-age women with disease stage IA1 (with LVSI), IA2, or IB1 (<2 cm) disease who wish to preserve fertility⁽⁴⁶⁾.

Abu-Rustum and Sonoda⁽⁴⁰⁾ analyzed a prospectively maintained database of all patients with FIGO stage IA1 to IB1 cervical cancer admitted to the operating room for planned fertility-sparing abdominal RT. Sentinel node mapping was performed through cervical injection. Between November 2001 and May 2010, 98 consecutive patients with FIGO stage IA1 to IB1 cervical cancer and a median age of 32 years (range, 6-45 years) underwent a fertility-sparing RT. The most common histology was adenocarcinoma in 54 patients (55%) and squamous carcinoma in 42 patients (43%). Lymphovascular invasion was seen in 38 patients (39%). The FIGO stages included IA1 (with lymphovascular invasion) in 10 patients (10%), IA2 in 9 patients (9%), and IB1 in 79 patients (81%). Only 15 patients (15%) needed immediate completion radical hysterectomy because of intraoperative findings. Median number of nodes evaluated was 22 (range, 3-54), and 16 patients (16%) had positive pelvic nodes on final pathology. Final trachelectomy pathology showed no residual disease in 44 patients (45%), dysplasia in 5 patients (5%), and AIS in 3 patients (3%). Overall, 27 patients (27%) needed hysterectomy or adjuvant pelvic radiation postoperatively. One documented recurrence (1%) was fatal at the time of this report. It was thus concluded that cervical adenocarcinoma and lymphovascular invasion are common features of patients selected for RT, and most patients can undergo the operation successfully, with approximately 65% having no residual invasive disease; however, nearly 27% of all selected cases will require hysterectomy or postoperative chemoradiation for oncologic reasons.

Diaz et al⁽⁴⁷⁾ compared the oncologic outcomes of women who underwent a fertility-sparing RT to those who underwent a radical hysterectomy for stage IB1 cervical carcinoma. Forty stage IB1 patients underwent an RT, and 110 patients underwent a radical hysterectomy. There were no statistical differences between the two groups for the following prognostic variables: histology, median number of lymph nodes removed, node-positive rate, LVSI, or deep stromal invasion.

The median follow-up time for the entire group was 44 months. The 5-year recurrence-free survival rate was 96% for the RT group compared with 86% for the radical hysterectomy group (*P* value not significant). On multivariate analysis in this group of stage IB1 lesions, tumor size <2 cm was not an independent predictor of outcome, but both LVSI and deep stromal invasion retained independent predictive value (*P* = .033 and *P* = .005, respectively). The authors concluded that for selected patients with stage IB1 cervical cancer, fertility-sparing RT appears to have a similar oncologic outcome to radical hysterectomy. Lymphovascular space invasion and deep stromal invasion appear to be more valuable predictors of outcome than tumor diameter in this subgroup of patients.

In 2013, Pareja et al⁽⁴⁸⁾ published a systematic literature review of patients with early-stage cervical cancer who underwent abdominal RT. A total of 485 patients age 6 to 44 years were identified. The most common stage was IB1 (71%), and the most common histologic subtype was SCC (70%). Operative times ranged from 110 to 586 minutes. Blood loss ranged from 50 to 5568 mL. Forty-seven patients (10%) had conversion to radical hysterectomy. One hundred fifty-five patients (35%) had a postoperative complication. The most frequent postoperative complication was cervical stenosis (*n* = 42; 9.5%). The median follow-up time was 31.6 months (range, 1-124 months). Sixteen patients (3.8%) had disease recurrence. Two patients (0.4%) died of disease. A total of 413 patients (85%) were able to maintain their fertility. A total of 113 patients (38%) attempted to get pregnant, and 67 of these patients (59.3%) were able to conceive. Therefore, the authors concluded that abdominal RT is a safe treatment option in patients with early-stage cervical cancer interested in preserving fertility.

Conservative Treatment

The possibility of less radical surgery may be appropriate not only for patients desiring to preserve fertility but also for all patients with low-risk early-stage cervical cancer. Recently, a number of studies have explored less radical surgical options for early-stage cervical cancer, including simple hysterectomy, simple trachelectomy, and cervical conization with or without SN biopsy and pelvic lymph node dissection. Criteria that define this low-risk group include squamous carcinoma, adenocarcinoma, or adenosquamous carcinoma, tumor size <2 cm, stromal invasion <10 mm, and no LVSI⁽⁴⁹⁾.

The ConCerv study is one of the several prospective studies evaluating the role of conservative surgery in women with newly diagnosed, early-stage cervical cancer.

Retrospective data have shown that low-risk cervical cancer may not require radical hysterectomy because the risk for parametrial involvement is less than 1% in

these patients. In this study, eligible women undergo CKC or simple hysterectomy and pelvic lymphadenectomy with SN based on their desire for future fertility. The primary outcome of this study is the safety and feasibility of a conservative approach ⁽⁴⁹⁾.

More recently, a Gynecologic Cancer Intergroup (GCIG) trial was led by the National Cancer Institute of Canada Clinical Trials Group, called the SHAPE trial. In this trial, patients with stage IA2 to IB1 cervical cancer with low-risk qualities (early-stage cervical cancer [IA2, IB1 <2 cm], limited stromal invasion <10 mm on loop electrosurgical excision procedure/cone biopsy, <50% stromal invasion on pelvic MRI) are randomized to either simple or radical hysterectomy. The study is currently ongoing and is aiming to accrue a total of 700 patients ⁽⁵⁰⁾.

Stage IB2-IVA

Concurrent Chemoradiation

In 1999, the US National Cancer Institute announced its support of concurrent cisplatin-based chemotherapy and radiation therapy in women who require radiation therapy for the management of cervical cancer. This was based on data from five randomized controlled trials that showed a significant benefit of concurrent chemoradiation either as postoperative adjuvant therapy in patients with high-risk factors or primary therapy in patients with locally advanced cervical cancer. All five trials used concurrent cisplatin either alone or in combination with 5-fluorouracil (5-FU) or 5-FU and hydroxyurea. Peters et al ⁽⁵¹⁾ applied concurrent chemoradiation as postoperative adjuvant therapy in patients with risk factors found from radical hysterectomy in stage IA2 to IIA disease and indicated that it was superior to radiation therapy alone. Keys et al ⁽⁵²⁾ compared chemoradiation and radiation with adjuvant hysterectomy as the definitive treatment in patients with stage IB2 disease. Significant improvement of 3-year survival was found in the chemoradiation group (83% vs 74%). Pathologic examination of the hysterectomy specimens demonstrated a significant decrease in persistent disease with chemoradiation.

Three other studies comprised patients with more advanced disease ⁽⁵³⁻⁵⁵⁾. The Radiation Therapy Oncology Group trial (RTOG) 9001 by Morris et al randomized stage IB-IVA patients to concurrent chemoradiation with cisplatin and 5-FU versus extended-field radiation ⁽⁵³⁾. Chemoradiation was superior, with an increase in overall survival of 73%, compared with 58% for radiation alone. Acute toxicity was more common with chemoradiation, but the rates of late complications (>60 days after treatment) were similar. A trial by Rose et al ⁽⁵⁴⁾ studied the optimal chemoradiation regimen by randomizing patients with stage IIB-IVA disease to receive radiation therapy concurrent with

one of the following chemotherapy regimens: cisplatin alone; cisplatin, 5-FU, and hydroxyurea; or hydroxyurea alone. With a median follow-up time of 35 months, the results demonstrated superior survival rates for both concurrent cisplatin regimens (66% and 64%, respectively) compared with concurrent hydroxyurea alone (39%). The toxicity of treatment was least with the single-agent cisplatin regimen. Another Gynecologic Oncology Group trial in stage IIB to IVA cervical cancer by Whitney et al ⁽⁵⁵⁾ compared the efficacy of a chemotherapy regimen in the concurrent chemoradiation setting. The results showed superiority of cisplatin and 5-FU over hydroxyurea; survival rates at a median follow-up of 8.7 years were 55% and 43%, respectively. Leukopenia occurred less often in the group receiving cisplatin and 5-FU than in those receiving hydroxyurea.

A summary of these five trials is presented in Table 33-4.

Neoadjuvant Chemotherapy

A review by the Neoadjuvant Chemotherapy for Locally Advanced Cervical Cancer Meta-Analysis Collaboration group discovered seven randomized controlled trials available for analysis, comprising 872 patients ⁽⁵⁶⁾. The overall analysis and analysis of each individual trial showed significant improvement of all outcomes with neoadjuvant chemotherapy: hazard ratio of 0.65 for survival, with 14% absolute improvement in 5-year survival rate (50% to 64%); hazard ratio of 0.68 for disease-free survival, with 13% absolute improvement of disease-free survival (45% to 58%); and hazard ratio of 0.63 for metastasis-free survival, with 15% absolute improvement in metastasis-free survival (45% to 60%). However, many confounding factors were inherent and unavoidable in this systematic analysis: these factors were that a number of patients, ranging from 28% to 90% in each trial, also received postoperative adjuvant radiation therapy or triple-modality treatment compared with radiation therapy, the route of cisplatin administration differed (intra-arterial in one trial), and patients recruited to each trial had different stages of disease.

Eddy et al ⁽⁵⁷⁾ published a phase III trial from the Gynecologic Oncology Group to determine whether neoadjuvant chemotherapy (NACT) prior to radical hysterectomy and pelvic/para-aortic lymphadenectomy (RHPPL) could improve progression-free survival and overall survival, as well as operability, with acceptable levels of toxicity. Two hundred eighty-eight eligible patients with bulky FIGO stage IB cervical cancer, tumor diameter ≥4 cm, adequate bone marrow, renal, and hepatic function, and performance status ≤2 were randomly allocated to RHPPL (n = 143) or NACT + RHPPL (n = 145). The NACT + RHPPL group had a similar recurrence rate (relative risk, 0.998) and death rate (relative risk, 1.008) compared with the RHPPL group. Seventy-nine percent of patients had surgery in

Table 33-4 Five Randomized Control Trials of Concurrent Chemoradiation for Cervical Cancer

Study (Protocol)	Setting	No. of Patients	Treatment	Outcome ^a	Remarks
Keys et al (⁵²), 1999 (GOG 123)	IB2	369	1. RT + weekly C 2. RT (followed by TAH in both groups)	RR of progression and death, 0.51 and 0.54 in CRT arm	Higher severe hematologic and GIT toxicity in CRT arm (21% vs 4% and 14% vs 5%)
Peters et al (⁵¹), 2000 (SWOG 8797/GOG 109)	PO IA2-IIA with risk factors	243	1. RT + CF 2. RT alone	4-year PFS and SVR, 80% and 81% in group 1 4-year PFS and SVR, 63% and 71% in group 2	ACA had similar outcomes as SCC in CRT arm; ACA did worse in RT arm
Whitney et al (⁵⁵), 1999 (GOG 85)	IIB-IVA	368	1. RT + CF 2. RT + HU	RR of progression and death, 0.79 and 0.74 of group 1 compared to group 2 (21% and 26% decreased risk of progression and death)	Severe leukopenia more common in HU arm (24% vs 4%)
Morris et al (⁵³), 1999 (RTOG 9001)	IB-IVA	388	1. RT + CF 2. RT + extended-field radiation	5-year OS and DFS, 73% and 67% 5-year OS and DFS, 58% and 40%	Higher reversible hematologic side effects in CRT arm
Rose et al (⁵⁴), 1999 (GOG 120)	IIB-IVA	526	1. RT + weekly C 2. RT + CF + HU 3. RT + HU	2-year PFS, 67% and 64% in groups 1 and 2 and 47% in group 3 RR of death, 0.61 and 0.58 in groups 1 and 2 compared with group 3	Group 1 least toxic

^aThere was a significant difference in all outcomes between the study and control groups.

ACA, adenocarcinoma; C, cisplatin; CF, cisplatin plus 5-fluorouracil; CRT, concurrent chemoradiation; DFS, disease-free survival; GIT, gastrointestinal tract; GOG, Gynecologic Oncology Group; HU, hydroxyurea; OS, overall survival; PFS, progression-free survival; PO, postoperative; RR, relative risk; RT, radiation therapy; RTOG, Radiation Therapy Oncology Group; SCC, squamous cell carcinoma; SVR, survival rate; SWOG, Southwest Oncology Group; TAH, total abdominal hysterectomy.

the RHPPL group compared to 78% in the NACT + RHPPL group. Fifty-two percent of patients received postoperative RT in the RHPPL group compared to 45% in the NACT + RHPPL group (not statistically significant). The authors concluded that NACT offered no additional objective benefit to patients undergoing RHPPL for stage IB cervical cancer.

Another phase III trial was conducted by Katsumata et al (⁵⁸) to determine whether NACT before radical surgery improved overall survival. A total of 134 patients with stage IB2, IIA2, or IIB SCC of the uterine cervix were randomly assigned to receive either BOMP (bleomycin, vincristine, mitomycin, cisplatin) plus radical surgery (NACT group) or radical surgery alone (radical surgery group). Patients with pathologic high-risk factors received postoperative radiotherapy. This study was prematurely terminated at the first planned interim analysis because overall survival in the NACT group was inferior to that in the radical surgery group. The 5-year overall survival was 70.0% in the NACT group and 74.4% in the radical surgery group ($P = .85$). Hence, it was concluded that NACT with BOMP

regimen before radical surgery did not improve overall survival but reduced the number of patients who received postoperative radiotherapy.

Stage IVB

In patients with stage IVB cervical cancer, which implies systemic disease, treatment is palliative rather than curative. Radiation therapy has a role for local primary disease to alleviate symptoms such as bleeding and pain. In patients who have distant metastasis, symptoms such as bone pain can be relieved with high-dose radiation. Chemotherapy is also an option for patients with stage IVB disease, but the response is modest because of factors like poor vascular supply and bone marrow reserve.

POSTTREATMENT SURVEILLANCE

The recommended surveillance is based on patients' risk for recurrence and personal preferences. History and physical examination are recommended every

3 to 6 months for 2 years, every 6 to 12 months for another 3 to 5 years, and then annually. Patients with high-risk disease can be assessed more frequently (eg, every 3 months for the first 2 years). Annual cervical/vaginal cytology tests can be considered as indicated for detection of lower genital tract dysplasia. Patient education regarding symptoms suggestive of recurrence is recommended (eg, vaginal discharge; weight loss; anorexia; pain in the pelvis, hips, back, or legs; persistent coughing). Patients who have received RT for cervical cancer may experience vaginal stenosis and dryness and should receive education on important issues regarding sexual health and vaginal health. Cervical cancer survivors are at risk for second cancers; therefore, careful surveillance is appropriate for these patients⁽⁵⁹⁾.

RECURRENT CERVICAL CANCER

It is generally accepted that any lesions detected within 6 months after treatment should be considered persistent. The diagnosis of recurrence is usually made after 6 months. If a lesion is noted within 3 months after radiation therapy, no treatment is recommended due to the ongoing effects of irradiation at this time period.

Choosing the type of therapy for recurrent cervical cancer depends on many factors, including site of recurrence, previous therapy, and performance status of the patients.

Locoregional

Concurrent platinum-based chemotherapy reduces the risk of pelvic recurrence by approximately 50% and extends overall survival by an absolute 5% to 20% compared to radiation therapy alone; this includes tumor-directed radiation therapy and platinum-based chemotherapy with (or without) brachytherapy; surgical resection can be considered if feasible. Typically, the chemoradiation for recurrence uses cisplatin as a single agent or cisplatin plus 5-FU. Patients with central pelvic recurrent disease after radiotherapy should be evaluated for pelvic exenteration, with (or without) intraoperative radiotherapy. Surgical mortality is generally 5% or less, with survival rates approaching 50% in carefully selected patients. Although exenteration is the common surgical approach in postradiation patients with isolated central pelvic relapse, radical hysterectomy or brachytherapy may be an option in patients with small central lesions (<2 cm)⁽⁵⁹⁾.

Westin et al⁽⁶⁰⁾ conducted a study to determine the impact of clinical and pathologic factors on 5-year survival after pelvic exenteration for gynecologic malignancies. A total of 160 women who underwent pelvic exenteration were evaluated. Five-year recurrence-free

survival was 33% (95% CI, 0.25-0.40). Factors that negatively impacted recurrence-free survival included shorter treatment-free interval ($P = .050$), vulvar primary ($P = .032$), positive margins ($P < .001$), LVSI ($P < .001$), positive lymph nodes ($P < .001$), and perineural invasion ($P = .030$). Factors that negatively impacted overall survival included vulvar primary ($P = .04$), positive margins ($P < .001$), LVSI ($P < .001$), positive lymph nodes ($P < .001$), and perineural invasion ($P = .008$). Hence, it was concluded that the 5-year overall survival after pelvic exenteration was 40%.

Distant

Distant recurrence with or without associated locoregional lesions denotes systemic disease and carries a poor prognosis and minimal chance of a cure. Monk et al⁽⁶¹⁾ published the phase III trial from the Gynecologic Oncology Group evaluating the toxicity and efficacy of cisplatin doublet combinations in advanced and recurrent cervical carcinoma. Patients were randomly assigned to paclitaxel 135 mg/m² over 24 hours plus cisplatin 50 mg/m² on day 2 every 3 weeks (PC, reference arm); vinorelbine 30 mg/m² on days 1 and 8 plus cisplatin 50 mg/m² on day 1 every 3 weeks (VC); gemcitabine 1,000 mg/m² on days 1 and 8 plus cisplatin 50 mg/m² on day 1 every 3 weeks (GC); or topotecan 0.75 mg/m² on days 1, 2, and 3 plus cisplatin 50 mg/m² on day 1 every 3 weeks (TC). Survival was the primary end point, with a 33% improvement relative to PC considered important (85% power, $\alpha = 5\%$). Quality-of-life data were prospectively collected. A total of 513 patients were enrolled when a planned interim analysis recommended early closure for futility. The experimental-to-PC hazard ratios of death were 1.15 (95% CI, 0.79-1.67) for VC, 1.32 (95% CI, 0.91-1.92) for GC, and 1.26 (95% CI, 0.86-1.82) for TC. The hazard ratios for progression-free survival were 1.36 (95% CI, 0.97-1.90) for VC, 1.39 (95% CI, 0.99-1.96) for GC, and 1.27 (95% CI, 0.90-1.78) for TC. Response rates for PC, VC, GC, and TC were 29.1%, 25.9%, 22.3%, and 23.4%, respectively. The arms were comparable with respect to toxicity except for leukopenia, neutropenia, infection, and alopecia. The authors concluded that none of the regimens studied was superior to PC in terms of overall survival. However, the trends in response rate, progression-free survival, and overall survival favored PC.

Until recently, no chemotherapy combination or single agent had shown a survival advantage in phase III trials. Tewari et al⁽⁶²⁾ evaluated the effectiveness of bevacizumab and nonplatinum combination chemotherapy in patients with recurrent, persistent, or metastatic cervical cancer. A total of 452 patients were randomly assigned to chemotherapy with or without bevacizumab at a dose of 15 mg/kg of body weight.

Groups were well balanced with respect to age, histologic findings, performance status, previous use or nonuse of a radiosensitizing platinum agent, and disease status. The addition of bevacizumab to chemotherapy was associated with increased overall survival (17.0 vs 13.3 months; hazard ratio for death, 0.71; 98% CI, 0.54-0.95; $P = .004$ in a one-sided test) and higher response rates (48% vs 36%, $P = .008$). Bevacizumab, as compared with chemotherapy alone, was associated with an increased incidence of hypertension of grade 2 or higher (25% vs 2%), thromboembolic events of grade 3 or higher (8% vs 1%), and gastrointestinal fistulas of grade 3 or higher (3% vs 0%). Therefore, it was concluded that the addition of bevacizumab to combination chemotherapy in patients with recurrent, persistent, or metastatic cervical cancer was associated with an improvement of 3.7 months in median overall survival.

Gestational Trophoblastic Disease

Jubilee Brown

Gestational trophoblastic disease (GTD) comprises a wide spectrum of neoplastic disorders that arise from placental trophoblastic tissue after abnormal fertilization (Fig. 34-1). The spectrum includes benign disease (complete and partial hydatidiform moles) and malignant gestational trophoblastic neoplasia (GTN), which includes choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT) (¹). Invasive moles may also occur and are best categorized as malignant, since they can metastasize. Gestational trophoblastic neoplasia is also described as gestational trophoblastic tumor (GTT) and is further designated as nonmetastatic or metastatic (²).

The hydatidiform mole is the most common type of GTD. It is essentially a benign condition with variable potential for malignant transformation. Most molar pregnancies resolve spontaneously after uterine evacuation, with no further events or adverse outcomes. At any time during or after gestation, approximately 20% undergo malignant transformation to invasive nonmetastatic or metastatic GTN and require further treatment (³). Nearly two-thirds of these lesions develop into persistent nonmetastatic GTN; the remaining one-third develop distant metastases (^{2,4}).

These tumors were first described around 400 B.C. by Hippocrates and subsequently termed “dropsy” of the uterus. During the 1950s, the 5-year survival of patients with choriocarcinoma was less than 5%. The treatment of these tumors has been revolutionized with effective chemotherapy, leading to a cure rate approaching 100% and fertility preservation in most patients (^{1,5,6}). Successful outcomes rely on

individualized management based on careful staging and treatment planning by a multidisciplinary team.

EPIDEMIOLOGY

The prevalence of GTD depends on geography, maternal age, previous GTD history, socioeconomic factors, dietary factors, and blood grouping. True estimates of the incidence of molar pregnancy are difficult to obtain because of the vast variation in presentation and management of normal and abnormal pregnancies around the world. In North America and in Europe, GTD develops in approximately 1 in 100 to 2,000 pregnancies (^{1,7,8}). A higher rate of 1.5 to 6 per 1,000 pregnancies has been reported in South America. Early observations comparing East and Southeast Asian countries with the United States suggest a 5- to 15-fold higher incidence, as high as 1 in 120 pregnancies in East Asia (^{1,8,9}). Native Alaskans have an incidence three- to fourfold that of white women. Native Americans had a higher incidence than other ethnic groups in New Mexico (¹⁰). Not all data confirm the importance of ethnic background. Recent analyses suggest that the incidence in Southeast Asia is similar to that in Europe, which may reflect modifications in diet, improved diagnosis, and improved capture of population statistics (^{1,2,8}).

Extremes of age at conception appear to influence the rate of GTD (^{1,2,11}). Women older than 40 years have a fivefold greater risk of molar pregnancy (¹¹); those younger than 20 years have a 1.5- to 2-fold relative risk (¹¹). Women with a history of hydatidiform

FIGURE 34-1 Gross specimen of two complete molar pregnancies. Note the absence of fetal tissue, which is replaced by abundant trophoblastic tissue.

mole have a 10-fold greater risk for a second molar pregnancy and a more than 1,000-fold greater risk of choriocarcinoma than women with normal pregnancies⁽¹¹⁾. The New England Trophoblastic Disease Center demonstrated the increased risk of subsequent molar pregnancy to be 1%⁽¹²⁾.

Women of lower socioeconomic status have a 10-fold greater rate of molar pregnancy than more affluent counterparts. This trend has been reported in East Asia, the Middle East, the United States, and Brazil^(2, 13). This relationship between GTD incidence and geographic region, culture, and socioeconomic status suggests that diet and nutrition may contribute to the etiology. Low β -carotene and high animal fat consumption are associated with GTD. There is strong association between cigarette smoking and GTD.

Historically 80% of GTDs are hydatidiform moles, 15% are invasive moles, and 5% are choriocarcinomas. Placental site trophoblastic tumor occurs in 0.2% to 2% of all GTD but is responsible for the highest mortality rate of all GTD histologies^(14, 15). Choriocarcinoma is associated with an antecedent complete hydatidiform mole in 50% of the cases, a history of abortion in 25%, term delivery in 20%, and ectopic pregnancy in 5%. Occurrence after partial mole is

rare^(1, 2). The precise rate of choriocarcinoma may be underreported because tissue is not recommended for the diagnosis based on the risk of hemorrhage with biopsy^(1, 2).

In the United States, molar pregnancies are reported in approximately 3,000 patients per year, and malignant transformation occurs in 2% to 19% of these cases^(1, 2, 4). Complete molar pregnancies occur 1 in 15,000 abortions and 1 in 150,000 normal pregnancies. The estimated incidence of twin pregnancy consisting of a molar pregnancy and a normal fetus is 1 per 22,000 to 100,000 pregnancies.

PATHOLOGY

A hydatidiform mole is confined to the uterine cavity. When a hydatidiform mole persists, it is termed malignant and may be designated GTT or GTN and may be metastatic or nonmetastatic. Most malignant GTDs occur after evacuation of a mole and exhibit the histologic features of either hydatidiform moles or choriocarcinomas. Choriocarcinomas are highly malignant and tend to metastasize extensively. Conversely, persistent GTD after a nonmolar pregnancy almost always has the histologic pattern of choriocarcinoma. Invasive moles and placental site tumors are locally invasive but rarely metastatic. Both tumors are rare, but they can be distinguished histologically⁽²⁾. Specific pathologic criteria exist for each of these histologic subtypes.

Complete Mole (See Fig. 34-1)

Based on morphologic and cytogenetic features, hydatidiform moles are divided into two unique syndromes: complete (classic) and partial (Table 34-1). Complete hydatidiform mole is characterized by the lack of a fetus and a characteristic abnormal budding edematous villous structure with nonpatchy trophoblastic hyperplasia, stromal karyorrhectic debris, and collapsed, abnormal villous blood vessels⁽²⁾. A complete mole is usually detected during the second trimester and is identified by total hydatidiform enlargement of the villi, which are enveloped by hyperplastic and atypical trophoblasts. There is a notable absence of any embryonic or amniotic remnant. In questionable cases, p57 immunohistochemistry can be useful in confirming the diagnosis⁽¹⁶⁾. Approximately 20% of complete moles give rise to persistent trophoblastic disease.

Partial Mole (Fig. 34-2)

Partial moles, in contrast to complete moles, are typically accompanied by an identifiable embryo or amniotic membranes. These moles are described as

Table 34-1 Features of Complete and Partial Hydatidiform Moles

	Complete	Partial
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Trophoblastic stromal inclusions	Absent	Present
Genetic parentage	Paternal	Biparental
Karyotype	46XX; 46XY	69XXY; 69XYY
Persistent β -hCG elevation	20%	0.5%

partial because the hydatidiform changes in the villi tend to be focal. They demonstrate patchy villous hydrops with scattered abnormally shaped and scalloped irregular villi with trophoblastic pseudo inclusions and patchy trophoblastic hyperplasia (²). The villous capillaries appear to be functional because they possess the same proportion of nucleated fetal erythrocytes as the embryo. In partial moles, hydatidiform change occurs at a slower rate, and the proportion of relatively normal villi appears to correlate with fetal survival rate.

Diagnosis of molar pregnancies based on histology alone can be problematic. Negative immunostaining for *P57KIP2*, an imprinted gene expressed by the maternal allele, is diagnostic of a complete mole, as the placenta of all other gestations demonstrates nuclear staining of cytotrophoblast and villous mesenchyme (^{2,6}). Ploidy analysis can help differentiate partial (triploid) from complete (diploid) mole, but cannot distinguish between this and other etiologies of triploidy. Selective molecular genotyping allows for definitive diagnosis when histologic review is equivocal, but the cost of such testing may prohibit widespread adoption of this technique.

Maturation of mesenchymal elements is only minimally delayed in partial moles, and there is a paucity of fibroblast karyorrhexis. Approximately 2% to 6% of partial moles undergo malignant degeneration (³). Because of this sporadic malignant potential, follow-up and treatment of patients with partial moles are the same as for patients with complete moles.

Invasive Mole

Locally invasive moles have the same histologic features as complete mole. In addition, they are characterized by myometrial invasion without involvement of intervening endometrial stroma. Invasive moles are typically diagnosed clinically approximately 6 months after molar evacuation when human chorionic gonadotropin (hCG) remains elevated. They tend to invade locally, causing hemorrhage and necrosis. Rarely, uterine perforation results. Hematogenous metastasis may

**FIGURE 34-2** Partial molar pregnancy removed along with partially formed fetal tissue.

occur, often to the lungs. Occasionally, metastatic deposits display hydropic villi rather than the sheets of anaplastic cells that typify metastatic choriocarcinoma. Invasive moles are scored using the World Health Organization (WHO) scoring system, and treatment is predicated based on the score. If childbearing is complete, hysterectomy is recommended, but if fertility preservation is desired, the appropriate form of chemotherapy based on the WHO score is administered.

Choriocarcinoma

Choriocarcinoma is a malignant tumor with a unique histology distinct from that of moles⁽²⁾. The tumor is grossly red and granular and exhibits extensive necrosis and hemorrhage. On microscopic examination, the neoplasm is composed of a disordered array of syncytiotrophoblastic and cytotrophoblastic elements, absence of chorionic villi, frequent mitoses, and multinucleated giant cells. Direct myometrial and vascular invasion occur early, with resultant metastases to the lungs, vagina, brain, kidneys, liver, pelvis, spleen, and gastrointestinal tract^(1,2,6).

Placental Site Trophoblastic Tumor

Placental site tumors are rare and most often develop after nonmolar gestations but can occur after evacuation of a complete hydatidiform mole⁽¹⁴⁾. These tumors occur at the placental implantation site and consist of numerous nodules in the endometrium or myometrium. Histologically, these consist of a homogeneous population of mononuclear intermediate trophoblast cells of the placenta infiltrating in sheets or cords between myometrial fibers, sometimes with a few syncytial elements⁽¹⁷⁾. The intermediate trophoblastic cells have oval nuclei with abundant eosinophilic cytoplasm, and no chorionic villi are seen. Syncytiotrophoblastic and cytotrophoblastic populations are absent, and less vascular invasion, necrosis, and hemorrhage are seen than in choriocarcinoma⁽¹⁷⁾. Lymphatic metastasis is common. Placental site trophoblastic tumor secretes placental lactogen and small amounts of β -hCG and is usually diploid^(1,2).

Epithelioid Trophoblastic Tumor

Epithelioid trophoblastic tumor is a rare variant of PSTT that mimics carcinoma but histologically is composed of chorionic-type intermediate trophoblast.

PATHOGENESIS

Pathologic characteristics alone generally do not allow adequate discrimination of molar pregnancies. With the advent of cytogenetic techniques, such as

chromosomal banding and restriction fragment length polymorphism analysis of DNA, unique chromosomal patterns of molar pregnancies were discovered⁽¹⁸⁾, allowing complete and partial moles to be distinguished from one another⁽¹⁹⁾.

Cell Biology (Fig. 34-3)

Normal fertilization results from the union of a single sperm and an egg, followed by rapid cellular division and the creation of a diploid embryo. Early embryonic differentiation gives rise to trophoblasts, specialized epithelial cells responsible for developing the placenta and the villi. Gestational trophoblastic tumors arise from abnormal unions of sperm with the ovum, resulting in distinct pathologic characteristics involving activated transcription factors, cytokines, hormone secretion, cell adhesion molecules, and immunologic activity⁽²⁰⁾.

A complete mole contains nuclear chromosomes of paternal origin and mitochondrial DNA of maternal origin^(2,21). Chromosomal banding studies reveal that complete moles contain only paternal chromosomes. This finding has been confirmed by showing that when paternal heterozygotes for the human leukocyte antigen (HLA) locus give rise to a mole, the HLA expression of the molar tissue is homozygous⁽²²⁾. Approximately 80% to 92% of complete moles have a 46,XX karyotype derived from fertilization of an empty egg, the chromosomes of which were lost during meiosis, by a haploid sperm (23X) that then undergoes duplication to create a diploid set of identical chromosomes (46,XX)⁽²³⁾. Complete moles can also result from postzygotic diploidization of a triploid conception. Approximately 4% to 20% of complete moles result from dispermy, in which two spermatozoa (each of which may be 23X or 23Y) fertilize an empty ovum, resulting in a 46,XX or 46,XY karyotype containing all paternal nuclear chromosomes^(2,24). Most are 46,XY, but approximately 5% of all complete moles are heterozygous 46,XX resulting from such dispermy. A 46,YY mole has not been reported, suggesting that the X chromosome is required for survival. There is no strong evidence that dispermic or Y chromosome-containing moles have greater malignant potential than the monospermic 46,XX karyotype⁽²¹⁾.

A partial mole results from the abnormal union of two spermatozoa with one ovum with intact chromosomes, resulting in a triploid karyotype. Occasionally, a normal ovum can be fertilized by an abnormal diploid sperm⁽²⁾. Therefore, the classic partial mole has a triploid karyotype (69 chromosomes), and both paternal and maternal chromosomes are present. The most common sex chromosome arrangement is XXY, but XXX and XYY do exist⁽²⁾. Of note, in

FIGURE 34-3 Schematic diagram of the pathogenesis of molar pregnancies. (A) Complete mole. Most common pathogenesis, in which a haploid sperm (23X) fertilizes an empty egg which then undergoes duplication (46,XX). (B) Complete mole. Dispermy, in which two spermatozoa (23X or 23Y) fertilize an empty egg yielding a complete mole (46,XX or 46,XY). (C) Partial mole. Two spermatozoa (23X or 23Y) fertilize an ovum (23X) yielding a triploid mole (69,XXY or 69,XXX).

triploid pregnancies, a partial mole results when the extra haploid chromosome is of paternal origin, and a fetus develops when the extra haploid chromosome is of maternal origin. In the event that a partial mole is reported as diploid, the diagnosis is usually a misdiagnosed complete mole, hydropic abortion, or twin pregnancy⁽²⁾.

Rarely, familial recurrent hydatidiform mole syndrome may be present, leading to recurrent molar pregnancies. This is an autosomal recessive disorder with mutations in *NLRP7* (70% of cases) or *KHDC3L* (5% of cases) resulting in diploid complete moles of biparental origin, as opposed to exclusively paternal origin. Live birth in these patients is rare, but egg donation from unaffected women may result in successful live birth⁽²⁵⁾.

Growth Factors and Oncogenes

Our improved understanding of the activities of proto-oncogenes, tumor suppressor genes, cytokines, and growth factors is contributing to our understanding of GTN and tumor progression⁽²²⁾.

The excess of paternal chromosomes in moles probably contributes to the induction of trophoblastic

hyperplasia. The genomic imbalance may cause changes in expression of growth factor genes located on the paternal allele. Both normal placentas and molar pregnancies contain paternal antigens. Upon implantation, an immunologic response is initiated, with infiltration of lymphocytes and macrophages and secretion of cytokines.

The growth of choriocarcinomas may be related to the abundant expression of epidermal growth factor (EGF) receptor. Macrophage-derived cytokines—interleukin-1 (IL-1- α , IL-1- β) and tumor necrosis factor—can suppress cell growth and increase the expression of EGF receptor in choriocarcinoma cell lines, thus acting as paracrine mediators of cell growth⁽²⁶⁾.

The contribution of several oncogenes to the malignant transformation of GTD has also been examined. Growth regulation in the trophoblast is associated with expression of the transcription factor Mash-2⁽²⁷⁾. Complete moles demonstrate increased expression of c-fms RNA compared with that in normal placentas⁽²⁸⁾. In choriocarcinoma, increased expression of oncogenes has been observed, and progression of some tumors has been associated with inactivation of tumor suppressor genes⁽²⁹⁾. The significance of these

Table 34-2 Genes That Have Been Implicated in Gestational Trophoblastic Disease

findings is uncertain. Because trophoblasts are by nature rapidly dividing and invasive, increased expression of these oncogenes may be essential for normal cell function. Table 34-2 lists other genes whose overexpression has been implicated in GTD⁽³⁰⁻³²⁾. Human placental growth hormone has recently been detected in all variants of GTD and may serve as a novel biomarker for diagnosis⁽³³⁾.

CLINICAL PRESENTATION

Complete Moles

The most common presenting symptom of the complete mole is vaginal bleeding in the first or early second trimester of pregnancy, although the classic signs of a molar pregnancy include vaginal bleeding as well as absence of fetal heart sounds and physical evidence of a uterus that is larger than expected for the gestational age⁽²⁾. A constellation of symptoms and signs has historically been associated with molar pregnancy, but such events are becoming less common due to routine ultrasonography in early pregnancy and the resulting early diagnosis of molar pregnancy⁽³⁴⁾. In the event that molar pregnancy is detected later in the first or early second trimester, patients may present with abdominal pain due to the enlarged uterus, which may be larger than expected for gestational age. Intrauterine blood clots may liquefy and produce the pathognomonic prune juice–like vaginal discharge. Because of recurrent bleeding, patients may also present with iron deficiency beyond that expected for a normal pregnancy. Symptoms of anemia have been noted in approximately 50% of patients at diagnosis⁽³⁵⁾. Theca lutein cysts, caused by β -hCG–induced hyperstimulation of both ovaries in about 50% of patients, may result in a sensation of pelvic pressure or fullness. Usually, these cysts regress spontaneously after uterine evacuation, although their rupture or tension can cause acute abdominal symptoms occasionally requiring surgery⁽³⁵⁾.

In the past, 20% to 30% of patients have presented with early pre-eclampsia, thought to be precipitated by the release of large amounts of vasoactive substances from necrotic trophoblastic tissue, but seizures are rare⁽¹²⁾. Ten percent of patients have presented with hyperemesis gravidarum, and 7% have presented with hyperthyroidism, presumably due to the structural similarities of β -hCG to thyroid-stimulating hormone^(36, 37). Thyroid storm has been reported. Other rare presentations include respiratory distress, disseminated intravascular coagulation, and microangiopathic hemolytic anemia⁽³⁵⁾.

Partial Moles

Unlike complete moles, fewer than 10% of patients with partial moles present with an enlarged uterus. An intact fetus can coexist with a partial mole, though this occurs in fewer than 1 in 100,000 pregnancies. Patients with partial moles typically do not have the hormonal symptoms experienced by patients with complete moles, and pre-eclampsia is rare. Among 81 patients with partial moles, none had prominent theca lutein cysts, hyperthyroidism, or respiratory insufficiency and only one had toxemia⁽³⁷⁾. Patients with partial moles present with signs and symptoms of a missed or incomplete abortion, and the diagnosis of a partial mole is made only after histologic review of curettage specimens.

Malignant Gestational Trophoblastic Disease

Although spontaneous remission occurs in approximately 80% of patients with GTD after evacuation, malignant GTD is most commonly diagnosed after evacuation of a molar pregnancy when serum β -hCG titers plateau or rise^(2, 15). Patients treated surgically for molar pregnancy should be monitored closely for malignant transformation with symptoms, signs, and serum evaluation. Previously referred to as persistent trophoblastic disease, a plateaued or rising β -hCG level (three consecutive measurements) indicates malignant change and the development of GTN. Fifty percent of all malignant GTNs follow molar pregnancy, 25% follow normal pregnancy, and the remaining 25% follow ectopic pregnancy or abortion. Persistent invasive nonmetastatic GTN usually presents with recurrence of symptoms or signs such as irregular vaginal bleeding, theca lutein cysts, asymmetric uterine enlargement, or persistently elevated serum β -hCG levels. The tumor may even perforate the myometrium causing intraperitoneal bleeding, or the tumor may invade into uterine vessels causing vaginal hemorrhage. Irregular vaginal bleeding may be due to a vascular uterine mass or a vaginal metastasis. Patients can also

present with sepsis and abdominal pain, as the uterine tumor presents a nidus for infection ⁽²⁾. Placental site trophoblastic tumor and ETT present in the same manner as invasive moles and nearly always present with abnormal vaginal bleeding, because the disease remains localized to the uterus prior to metastasis ⁽¹⁴⁾. Only small amounts of β -hCG are produced relative for their size, and in some cases, the β -hCG is normal ⁽²⁾.

Metastatic GTN occurs in about 20% of patients who have undergone molar evacuation ⁽³⁵⁾. Metastatic GTN most often arises from choriocarcinoma. Molar pregnancy is the most common antecedent of choriocarcinoma, but this tumor may also occur after normal pregnancy, ectopic pregnancy, or abortion. These highly vascular tumors tend to metastasize extensively and may cause spontaneous hemorrhage at the metastatic foci, causing symptoms. The metastases are sometimes histologically identical to molar disease, but the vast majority are choriocarcinomas. Metastatic spread is hematogenous. Because of its extensive vascular network, metastatic GTN often produces local spontaneous bleeding. Common metastatic sites of GTN as reported by the New England Trophoblastic Disease Center are summarized in Table 34-3 ⁽³⁸⁾.

Pulmonary metastases are common, occurring in 80% of patients with metastatic disease ⁽³⁸⁾, and result when trophoblastic tissue enters the circulation via uterine venous sinuses. Most often, this happens spontaneously, but it may also occur after molar evacuation. Because choriocarcinoma is a vascular tumor, hemoptysis is frequent with lung involvement. Other symptoms include chest pain, dyspnea, and cough.

Pulmonary hypertension and pleural effusions may develop. An asymptomatic lesion on a chest x-ray or computed tomography (CT) scan may be the only sign of pulmonary involvement. Radiologic features may be subtle and include alveolar, nodular, and miliary

FIGURE 34-4 Chest radiograph of a patient with metastatic choriocarcinoma. This patient had refused treatment and died of the disease.

patterns ⁽³⁹⁾. Pulmonary metastases (Fig. 34-4) can be extensive and can cause respiratory failure and death.

Patients may experience right-upper-quadrant pain when hepatic metastases stretch the Glisson capsule. Gastrointestinal lesions can result in severe hemorrhage or perforation with peritonitis, either of which requires emergency intervention. Vaginal examination may reveal bluish metastatic deposits. Biopsy of these and other metastatic sites is contraindicated because severe uncontrolled bleeding may occur ⁽³⁵⁾.

Central nervous system (CNS) involvement from metastatic GTN suggests widespread disease. Central nervous system metastases occur in 7% to 28% of patients with metastatic choriocarcinoma ^(38, 39). The presenting neurologic symptoms include headache, hemiparesis, vomiting, dizziness, coma, grand mal seizure, visual disturbances, aphasia, and slurred speech. Weight loss and anorexia may also occur. In one-third of cases with cerebral metastases, there is no vaginal bleeding ⁽²⁾. Cerebral metastases tend to respond favorably to both radiotherapy and chemotherapy (Fig. 34-5).

Data from Berkowitz RS, Goldstein DP. Pathogenesis of gestational trophoblastic neoplasms. *Pathol Annu.* 1981;11:391–411.

DIAGNOSIS

The diagnosis of molar pregnancy is usually made by the histologic examination of curettage specimens. The diagnosis of persistent GTN or malignant GTN is most often indicated by plateauing or rising hCG titers after evacuation during surveillance. Histologic diagnosis of invasive mole, choriocarcinoma, or metastatic deposits should never be attempted because a biopsy of these neoplasms can cause massive, life-threatening hemorrhage. The hCG level in this setting is sensitive enough to make the diagnosis of malignant GTN without histologic confirmation. Because PSTT and ETT do not typically arise after molar pregnancy, their diagnosis

FIGURE 34-5 Magnetic resonance imaging scan of patient with metastatic choriocarcinoma

is usually made upon examination of the curettage, biopsy, or hysterectomy specimens ⁽²⁾. Presenting symptoms of PSTT are most commonly irregular vaginal bleeding, amenorrhea, and a pelvic mass ⁽¹⁷⁾.

Radiologic Imaging

Ultrasonography is useful for the confirmation of molar pregnancy but is not diagnostic, because

diagnosis depends on histologic examination of evacuated material. Ultrasonography is the first modality of radiographic imaging used when GTD is considered and may reveal the classic “snowstorm” appearance, which is due to the numerous chorionic villi exhibiting diffuse hydatidiform swelling ⁽⁴⁰⁾ (see Fig. 34-5; Figs. 34-6 and 34-7). Such a classic appearance is less common now, because the diagnosis is often made in the first trimester prior to the development of significant hydropic change. More common is a mixed echogenic vascular mass. In the setting of partial mole, fetal parts may also be detected ⁽¹⁾.

A chest x-ray should be performed in all patients because 70% to 80% of patients with metastatic GTN have lung involvement ⁽³⁵⁾ (see Fig. 34-4). Brain imaging is not routinely warranted in the absence of symptoms or pulmonary abnormalities, because 97% to 100% of patients with CNS disease from choriocarcinoma have concomitant pulmonary metastases ⁽⁴¹⁾.

An abnormal chest x-ray associated with a β -hCG level that plateaus or rises during treatment is an indication for a more extensive evaluation for metastatic disease. Computed tomography scans of the brain, abdomen, and pelvis should be performed to evaluate other likely sites of metastatic spread.

Magnetic resonance imaging (MRI) is the preferred modality for localized disease to delineate invasiveness and tumor vascularity (Fig. 34-8) ⁽⁴²⁾.

FIGURE 34-6 Ultrasound of a gestational trophoblastic tumor

FIGURE 34-7 Doppler ultrasound of a gestational trophoblastic tumor

Laboratory Tests

Chorionic gonadotropin is a glycoprotein hormone secreted by the syncytiotrophoblast: it is essential for the maintenance of normal function of the corpus luteum during pregnancy. This hormone has an α subunit identical to the α subunit of the pituitary hormones and a β subunit (β -hCG) unique to trophoblastic tissue that confers its specific biologic activity. The hormone becomes detectable 8 days after ovulation, and its level doubles every 2 to 4 days, reaching

its peak at 10 to 12 weeks of gestation. After that, the β -hCG level declines steadily. Because all trophoblastic tumors secrete β -hCG, its level serves as an excellent marker for tumor activity in the nonpregnant patient^(2, 43).

In normal pregnancy, hCG exists intact with both subunits and is hyperglycosylated in the first trimester. In GTD, hCG can exist as a free β subunit, nicked free β subunit, c-terminal peptide, β -core, or hyperglycosylated forms⁽⁴⁴⁾. The assay used to detect or follow hCG in the setting of GTD must recognize all of these forms; for this reason, home pregnancy tests should be avoided in favor of commercial assays^(1, 2). Even some commercial assays only work well for pregnancy-related hCG. These assays may be unreliable for detecting hCG isoforms, occasionally leading to false-negative readings, or may cross-react with heterophile antibodies leading to false-positive results^(1, 2). Because the heterophile antibodies are large, they are filtered in the renal glomerulus and do not pass through into the urine. Therefore, urine pregnancy tests may be useful to exclude a false-positive result (serum positive, urine negative) but are not sufficient for making the diagnosis of GTD, only for excluding a false-positive result.

Monitoring of the serial β -hCG levels is mandatory during therapy for GTD to ensure adequate treatment. The level of β -hCG can be considered approximately proportional to the tumor burden and inversely proportional to therapeutic outcome. The 10% to 20% of patients with hydatidiform mole who are not cured by local therapy or do not achieve a spontaneous remission can be identified by a rising or plateaued β -hCG

FIGURE 34-8 Magnetic resonance imaging scan of a gestational trophoblastic tumor.

titer on serial determinations after evacuation of a mole. These patients may have persistent trophoblastic disease and require additional therapy, as outlined later. A new pregnancy should be excluded by correlating the hCG level with the ultrasound findings prior to assuming malignant GTD; that is, once the hCG level rises to a level where a fetal pole should be identified, an ultrasound should exclude conception.

At one time, the ratio of β -hCG in serum to that in cerebrospinal fluid (CSF) was used to detect brain metastases in GTD. A serum:CSF β -hCG ratio of less than 60:1 was considered a positive predictor for brain metastases⁽⁴¹⁾. With the availability of MRI, this test is rarely used. CA-125 may also have a role as a marker for GTD. In at least one study of patients with hydatidiform mole, the CA-125 level was elevated; more significant was the association of the degree of CA-125 elevation with the development of persistent GTD⁽⁴⁵⁾.

The complete blood count usually reveals anemia and thrombocytopenia. Clotting times may be prolonged, and consumption of coagulation factors may be unusually high in patients with disseminated intravascular coagulation. Hepatic or renal impairments are rare. Thyroid function studies are mandated in patients with a clinical history or physical examination findings suggestive of hyperthyroidism.

PHANTOM HUMAN CHORIONIC GONADOTROPIN SYNDROME

Phantom hCG or phantom choriocarcinoma syndrome is also called pseudohypergonadotropinemia. It refers to persistent mild elevation of hCG when no true hCG or trophoblastic tissue is present. This may result in the patient being treated further by her physician during the follow-up period either after primary surgery for molar pregnancy or chemotherapy for metastatic disease. It is mentioned here because clinicians may encounter this problem during the follow-up period and should rule out this syndrome before deciding to label a patient as having persistent disease.

Human chorionic gonadotropin is a glycoprotein whose two subunits, α and β , are held together by charge and hydrophobic interactions. Over 40 different professional laboratory tests are available for assaying the level of serum hCG. Most of these work through the multiantibody “sandwich assay,” using the labeled-enzyme or chemoluminescent assay (radioimmunoassay) method developed in the 1950s. The mechanism by which heterophilic antibodies cause false-positive results relates to the nature of this immunometric assay. One antibody, commonly a mouse monoclonal immunoglobulin (IgG), immobilizes hCG by binding one site on the molecule. A second antibody, commonly

a polyclonal antibody labeled with an enzyme or chemiluminescent agent, marks the first antibody. Heterophilic antibodies usually bind the assay of IgG at sites common to humans and other species. They are bivalent and therefore link the capture and tracer antibodies, mimicking hCG immunoactivity. Binding of human antibodies to mouse IgG is the most common form of interference. The positivity of this test in the serum, however, is not correlated with positivity in the urine. These large heterophile antibodies are filtered out at the level of the glomerulus, and the urine hCG test is therefore negative in the setting of heterophile antibodies. Therefore, a simple urine hCG test can support or refute a “phantom hCG” test result. If both the urine test and the serum test results are positive, this likely represents true malignant GTD, and searching for occult disease is prudent. If the urine test is negative, assuming that no clear radiologic sites of disease are identified, different assay systems can then be used to confirm the first serum result, which may indicate heterophile antibodies and exclude true malignant GTD⁽⁴⁶⁾. It is recommended that the serum be tested by a reference laboratory in these cases.

Phantom hCG emphasizes the clinical dilemma that arises when patient care is based primarily on laboratory data. It is the clinician’s responsibility to interpret test results with caution. The prevalence of false-positive hCG results is not well recognized. It has been found to be 3.4% of healthy individuals.

STAGING AND PROGNOSIS

There are many staging and prognostic systems in GTD. Each of these systems attempts to define prognostic groups in order to identify patients most likely to become resistant to single-agent methotrexate or dactinomycin and direct a rational therapeutic strategy, thereby optimizing treatment and achieving the highest possible cure rate⁽²⁾. Patients are classified into different prognostic groups based on factors such as tumor histologic subtype, extent of disease, human gonadotropin titer, duration of disease, nature of the antecedent pregnancy, and extent of prior treatment. The staging system of the International Federation of Gynecology and Obstetrics (FIGO 2000) is the most commonly used system (Table 34-4). This staging system was developed from the WHO scoring system, shown in Table 34-5^(47, 48). Patients with a score of 0 to 6 have a low risk of developing resistance to single-agent therapy and may be appropriately treated with dactinomycin or methotrexate. Patients scoring greater than 6 have a higher risk of developing disease resistant to treatment with a single chemotherapy agent and are best treated with combination chemotherapy^(2, 48, 49).

Table 34-4 FIGO Staging of Gestational Trophoblastic Tumors

Stage I: GTT confined to the uterus	
Stage IA	Disease confined to the uterus with no risk factors
Stage IB	Disease confined to the uterus with one risk factor
Stage IC	Disease confined to the uterus with two risk factors
Stage II: GTT extends outside the uterus but is limited to the genital structures (ovary, tube, vagina, broad ligament)	
Stage IIA	Disease involving genital structures without risk factors
Stage IIB	Disease extends outside the uterus but is limited to the genital structures with one risk factor
Stage IIC	Disease extends outside of the uterus but is limited to the genital structures with two risk factors
Stage III: GTT extends to the lungs with or without known genital tract involvement	
Stage IIIA	Disease extends to the lungs with or without known genital tract involvement and no risk factors
Stage IIIB	Disease extends to the lungs with or without known genital tract involvement with one risk factor
Stage IIIC	Disease extends to the lungs with or without known genital tract involvement with two risk factors
Stage IV: All other metastatic sites	
Stage IVA	All other metastatic sites without risk factors
Stage IVB	All other metastatic sites with one risk factor
Stage IVC	All other metastatic sites with two risk factors

The FIGO 2000 system is not universally predictive of individual patient outcome. Patients with a score of 0 to 3 will almost all be cured with single-agent chemotherapy, but 70% of patients who score 5 to 6 will fail single-agent treatment and require combination chemotherapy. Because almost all failures can be cured by transitioning to combination

chemotherapy, single-agent therapy is still used initially for patients who score 5 to 6 to spare the 30% of responders the more toxic effects of combination chemotherapy⁽⁶⁾.

Certain other factors can be used to predict and identify early development of resistance to therapy. Pulsatility index, measured with Doppler ultrasonography,

Table 34-5 FIGO 2000 Prognostic Scoring for Gestational Trophoblastic Disease

FIGO (WHO) Risk Factor Scoring With FIGO Staging	0	1	2	4
Age (year)	<40	>40

Low risk ≤6, High risk ≥7.

This combination of the modified WHO risk factor scoring system with the FIGO Cancer Staging and Nomenclature Committee in September 2000 and ratified in June 2002 with the FIGO announcement.

Modified with permission from Kohorn EI: The new FIGO 2000 staging and risk factor scoring system for gestational trophoblastic disease: description and critical assessment, *Int J Gynecol Cancer* 2001 Jan-Feb;11(1):73-77.

can measure uterine vascularity and predict methotrexate-resistant disease⁽⁶⁾. Additionally, hCG regression nomograms and kinetics may predict early onset of resistant disease during treatment with a single agent, although this is not yet in common practice⁽⁵⁰⁾. Patients infected with human immunodeficiency virus who have CD4 counts less than 200 cells/ μ L do not tolerate chemotherapy and have poor outcomes with higher mortality⁽⁵¹⁾.

Although outcomes for patients treated with GTD are favorable, the mortality rate for patients primarily treated at a trophoblast center is lower than that in patients referred after failure of primary treatment, prompting the recommendation for early referral to a trophoblast center when possible^(3, 52).

MANAGEMENT

Using the FIGO 2000 scoring system, each patient is considered individually and treated by a multidisciplinary team. Figure 34-9 outlines the general diagnostic and therapeutic approaches used at the University of Texas MD Anderson Cancer Center.

Molar Pregnancy

Primary Treatment

Hydatidiform mole is curable. The treatment is mainly surgical⁽⁵³⁾, but optimal management is dependent on the desire to preserve reproductive capability. All patients are evaluated for any medical condition secondary to the mole and treated appropriately before surgery. Most patients are of reproductive age, wish to maintain fertility, and are treated with suction dilation and curettage, often with ultrasound guidance to remove all molar tissue and avoid uterine perforation^(1, 53). The procedure has less than a 1% incidence of mortality⁽¹⁵⁾. If the uterus is greater than 16 weeks in size, there is a risk of pulmonary embolization of molar tissue, and care in a referral center is warranted⁽²⁾. Depending on the trophoblastic elements, the amount of bleeding can vary. Oxytocin is often infused immediately prior to surgery to limit the volume of blood lost, although caution is necessary in patients with medical complications due to the risk of hyponatremia and fluid overload⁽⁵⁴⁾. Specimens from surgery are sent for pathologic evaluation. Labor induction and hysterectomy are not recommended due to the increased incidence of post-molar GTN requiring chemotherapy⁽³⁸⁾. Patients maintaining fertility should be counseled with regard to the possibility of another molar pregnancy and of malignant transformation. Patients with partial moles should be given anti-D immunoglobulin prophylaxis.

In the rare patient who has completed childbearing and no longer desires fertility, hysterectomy to remove the uterus with the mole intact is reasonable. The ovaries may be preserved, even in the setting of theca lutein cysts. After hysterectomy, patients must be followed with hCG levels.

Postsurgical Care and Indications for Chemotherapy

After primary surgical treatment, all patients undergo weekly serum β -hCG tests until the level returns to normal on three consecutive assays (ie, 3 consecutive weeks). Three consecutive normal β -hCG levels define complete remission.

Urine pregnancy tests alone are considered inadequate for monitoring. The level of β -hCG typically normalizes within 8 weeks, but this may take up to 14 to 16 weeks in 20% of patients. In patients with complete moles, the β -hCG should be checked monthly for 6 months. Patients with partial moles have less than 1 in 3,000 risk of subsequent GTD, but rates in the literature range up to 6%^(2, 3). Although international guidelines do not require follow-up serum hCG testing, this is still performed at our institution^(2, 6).

Contraception should be used for 6 months, but no increased risk of recurrent molar pregnancy has been demonstrated in the 6-month period⁽²⁾. Because luteinizing hormone (LH) interferes with the detection of β -hCG at low levels, the use of oral contraceptives may be useful, because they suppress endogenous LH. Historically, oral contraceptive use prior to normalization of hCG was linked to GTD, but modern oral contraceptives do not appear to pose this risk^(2, 6).

Eighty percent of patients need no further treatment^(4, 55). The other 20% who develop malignant sequelae are treated as appropriate for their status, as either low- or high-risk patients as defined by the FIGO 2000 criteria (see Table 34-5)⁽¹⁵⁾. These patients are considered to have malignant GTN rather than molar pregnancies. The initial pathologic results of the previous gestation were complete mole in 78%, partial mole in 9%, and choriocarcinoma in 8%⁽¹⁵⁾. Of these patients, 81% had low-risk disease, 18% had high-risk disease, and 1% had PSTT. Risk factors include a pre-evacuation hCG level >100,000 IU/L, excessive uterine growth, theca lutein cysts over 6 cm in diameter, and age over 40 years^(56, 57). These patients are identified through the following events^(2, 3, 49):

- Rising or plateaued β -hCG level for 2 weeks measured over three separate intervals
- Tissue diagnosis of choriocarcinoma
- Evidence of metastatic disease
- Elevation of β -hCG level after a normal result
- Postevacuation bleeding not due to retained tissues

An elevated but falling hCG 6 months after molar evacuation does not mandate chemotherapy because hCG levels eventually normalize in patients⁽⁵⁸⁾. However, a serum hCG level greater than 20,000 IU/L more than 4 weeks after evacuation prompts chemotherapy because of the risk of uterine perforation and hemorrhage^(1, 2). Patients who receive treatment for molar pregnancy are encouraged to use effective contraception with hormonal or barrier methods during the 6-month interval of β -hCG follow-up. Intrauterine devices are not used because of the potential for uterine perforation. It is essential to exclude a new pregnancy in a patient under surveillance, rather than assume GTD. This is done by correlating the rise in β -hCG levels and ultrasonic findings based on the hCG level.

Prophylactic Chemotherapy

Prophylactic adjuvant chemotherapy after molar evacuation is controversial and usually not advised. The postevacuation risk of developing GTN is 15% to 20% after complete mole and 0.5% to 1% after partial mole. In one study, administering dactinomycin intravenously for 5 days starting 3 days after molar evacuation reduced the risk of GTN to 3% to 8%⁽⁵⁹⁾. However, such prophylaxis exposes approximately 80% of women to unnecessary chemotherapy and its attendant side effects, as the hCG levels would have been expected to decline without chemotherapy. Additionally, surveillance is still required after chemotherapy, and unnecessary chemotherapy may induce drug resistance⁽⁶⁰⁾. Because the vast majority of patients with GTN are detected and cured with hCG surveillance and directed chemotherapy without prophylaxis, prophylactic chemotherapy has not improved survival. Thus, the benefit of prophylaxis is outweighed by the risk, except in unique circumstances where compliant patient follow-up is not possible^(2, 61).

A minority of patients who have undergone removal of a complete hydatidiform mole may develop the unusual complication of intermediate trophoblastic disease⁽¹⁹⁾. They usually present with vaginal bleeding and a slightly elevated β -hCG titer. Examination of the uterus may reveal multiple nodules involving the endometrium and myometrium. Surgical intervention is warranted because progressive disease tends to develop, and the disease does not readily respond to chemotherapy.

Malignant Gestational Trophoblastic Disease

For malignant GTD, the treatment depends on the cell type, stage, level of serum β -hCG, duration of the

disease, specific sites of metastases, and extent of prior treatment. Patients should be stratified for risk prior to initiating a treatment plan. The FIGO 2000 system incorporating the modified WHO scoring system is the most commonly used risk stratification system (see Table 34-4)⁽⁴⁷⁻⁴⁹⁾. A score of 0 to 6 indicates a low risk of developing resistance to single-agent chemotherapy; a score over 6 indicates a high risk of resistance to single-agent chemotherapy and mandates combination chemotherapy.

To assign a risk category and stage, patients must undergo history, physical, and directed imaging. Patients who are detected early by hCG monitoring are evaluated by history, examination, serum hCG, pelvic ultrasound (excludes pregnancy, measures uterine size, and excludes pelvic extension), and chest x-ray. If the chest x-ray suggests lung metastasis, a chest CT may be ordered, but only lesions visible on chest x-ray should be scored^(2, 49). If a patient is found to have lung metastasis, an MRI of the brain is obtained to exclude brain metastasis⁽⁶⁾. If a patient has choriocarcinoma or suspected GTN following a nonmolar pregnancy, imaging should include a CT of the chest and abdomen, MRI of the brain and pelvis, and a pelvic ultrasound to evaluate for metastases to the lung, liver, pelvis, and brain⁽²⁾. Positron emission tomography (PET)/CT may be useful in imaging patients with recurrent disease prior to consideration of surgical resection⁽⁶⁾. Lumbar puncture to measure the CSF:serum hCG ratio is of historical interest but is not routinely used since the advent of MRI.

Low-Risk Disease, Nonmetastatic

Hysterectomy is the treatment of choice for patients who do not wish to maintain fertility. Posthysterectomy chemotherapy may be considered but is not routine. The rationale behind chemotherapy is to reduce the likelihood of disseminating viable tumor cells at surgery and during the immediate postoperative period as well as to eliminate any occult metastases. Outcomes data are not convincing. Patients who wish to retain fertility should receive chemotherapy as primary treatment for low-risk disease. Each patient must be stratified for risk prior to initiating chemotherapy.

Acceptable chemotherapy regimens are listed in Table 34-6. Either methotrexate, with or without folinic acid rescue, or dactinomycin is acceptable with the schedules as outlined. The differences in inclusion criteria in studies comparing these regimens make determining superiority of one regimen over another difficult, although dactinomycin may result in superior outcomes. The only published randomized trial compared low-dose methotrexate (30 mg/m²) with dactinomycin and found dactinomycin to be

Table 34-6 Chemotherapy Regimes for Low-Risk^a Gestational Trophoblastic Disease

Drug	Administration	Cycle ^b
Methotrexate and folinic acid	1 mg/kg (up to 70 mg) IM or IV days 1, 3, 5, 7 0.1 mg/kg IM or IV days 2, 4, 6, 8	14 days
Methotrexate	0.4 mg/kg IM or IV daily for 5 days	14 days
Methotrexate	30 to 50 mg/m ² IM	7 days
Dactinomycin	10 µg/kg (max 0.5 mg) IV daily for 5 days	14 days
Dactinomycin	1.25 mg/m ²	14 days

^aTherapy based on WHO risk criteria.^bWithhold treatment for marrow recovery if necessary

superior⁽⁶²⁾. Advocates of methotrexate cite less toxicity, no hair loss, less nausea, less vomiting, and less myelosuppression. Advocates of dactinomycin cite the above trial and less frequent infusion schedule⁽²⁾. An ongoing trial conducted by the Gynecologic Oncology Group compares pulsed dactinomycin with intravenous methotrexate. Regardless, patient outcome for low-risk nonmetastatic GTN is cure.

Response to treatment is determined by monitoring serum β -hCG levels every 1 to 2 weeks during treatment⁽²⁾. Persistent elevation over three consecutive samples or an increase in titer of β -hCG over two consecutive samples over more than 2 weeks indicates disease resistant to first-line therapy and requires restaging⁽²⁾. Phantom hCG syndrome must be excluded in the setting of low-level persistent positive results. Assuming this represents a true result, if the tumor is still limited to the uterus and the patient is older than 40 years and/or has no wish to retain fertility, hysterectomy is offered. If the patient prefers to retain fertility and belongs to the low-risk category, she can be treated with other chemotherapy. Patients who are initially treated with methotrexate but fail with hCG levels less than 300 IU/L can often be cured with dactinomycin administered as a single agent. Patients with higher levels of hCG should be treated with combination EMA-CO chemotherapy (etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine)^(2,6). Despite a high rate of resistance to first-line chemotherapy, a cure rate of almost 100% is achieved with combination chemotherapy. In the rare instances of tumor resistance to combination chemotherapy in a patient who wishes

to retain fertility, localized resection should be offered after careful evaluation by perioperative MRI, ultrasonography, and/or arteriography.

Once the serum hCG has normalized, three additional treatments of chemotherapy past normal are administered to minimize the chance of recurrence⁽²⁾. A comparison of two versus three cycles of methotrexate past normalization of hCG level showed a doubling in recurrence rates in patients receiving only two consolidation courses, so it is important to administer three cycles past titer normalization⁽⁶³⁾.

Low-Risk Disease, Metastatic

More than 50 years ago, metastatic GTD was not curable. Since then, treatments have improved such that the cure rate now exceeds 90%⁽⁵⁾. This success is the result of a combination of factors:

- The discovery that these tumors are chemosensitive
- The ability to diagnose and monitor therapy by using β -hCG levels
- Identification of prognostic factors
- Use of combination therapy
- Referral of patients to specialized centers for treatment

Patients with metastatic low-risk disease as determined by the WHO prognostic scoring system have a high potential for cure with chemotherapy alone^(1,2). Single-agent chemotherapy with methotrexate or dactinomycin is indicated as in low risk nonmetastatic disease (see Table 34-6). Complete response occurs in 90% of patients with low-risk disease, with little short- or long-term toxicity⁽⁶⁴⁾. In patients who fail single-agent therapy with methotrexate and have hCG levels less than 300 IU/L, dactinomycin can still result in cure⁽⁶⁾. Patients who fail single-agent chemotherapy are still cured with combination regimens⁽⁶⁴⁾.

Patients in whom treatment does not produce a complete response may have undetected metastatic disease. Mutch et al reported that at least 40% of patients with a negative chest radiograph result will have a positive chest CT scan and may be at higher risk of resistance to single-agent therapy⁽⁶⁵⁾. The cure rate for patients with low-risk disease is essentially 100%^(2,6).

High-Risk Disease

High-risk disease is not likely to be cured by single-agent chemotherapy, and patients with high-risk disease are at the highest risk of treatment failure. These patients should be treated with

Table 34-7 Chemotherapy Regimes for Intermediate- and High-Risk^a Gestational Trophoblastic Disease

Drug Regimen		Administration
EMA-CO ^b (preferred regimen)		
Course I (EMA)		
Day 1	Etoposide	100 mg/m ² IV over 30 min
	Methotrexate	100 mg/m ² IV bolus
	Methotrexate ^c	200 mg/m ² IV as 12-h continuous infusion
	Dactinomycin	0.5 mg IV bolus
Day 2	Etoposide	100 mg/m ² IV over 30 min
	Folinic acid	15 mg IV/IM/PO every 6 h for four doses, beginning 24 h after start of methotrexate
	Dactinomycin	0.5 mg IV bolus
Course II (CO)		
Day 8	Cyclophosphamide	600 mg/m ² IV over 30 min
	Vincristine	1 mg/m ² (up to 2 mg) IV bolus

^aTherapy based on the WHO risk criteria.

^bRepeat each regimen in sequence every 14 days as toxicity permits.

^cIn case of CNS metastases, the dose of infused methotrexate is increased to 1000 mg/m² IV over 12 h after alkalization of the urine. Increase the number of folinic acid doses to eight given every 6 h. This regimen is called "high-dose methotrexate EMA-CO."

combination chemotherapy, most commonly EMA-CO (Table 34-7) (1,2,5). The ACE regimen (dactinomycin, cisplatin, and etoposide) has recently been reported to have outstanding efficacy but is not yet regarded as standard of care for upfront high-risk disease (66).

Historically, a combination of MAC (methotrexate, dactinomycin, and cyclophosphamide) was used, producing cure rates of 63% to 80% (67). In intermediate- or high-risk GTT, MAC is most effective when used as initial chemotherapy (65% survival) rather than second-line treatment (39% survival) following failed single-agent therapy (67).

An older regimen, CHAMOCA (cyclophosphamide, hydroxyurea, dactinomycin, methotrexate with leucovorin rescue, vincristine, cyclophosphamide, and doxorubicin), resulted in a remission rate of 82%, but this regimen was inferior to MAC in terms of toxicity and efficacy and is not used in current practice (68).

Because etoposide was identified to have activity against trophoblastic disease, Bagshawe developed the EMA-CO regimen and reported a survival rate of 83% in patients with high-risk choriocarcinoma (69). The efficacy of this combination has been confirmed and this remains the preferred regimen for high-risk GTT (70-72). It is generally well tolerated. Toxicity includes alopecia, mild anemia, neutropenia, and stomatitis. Reproductive function is preserved in 75% of patients. In patients with significant tumor volume, rapid tumor necrosis may result in hemorrhage, and consideration may be given to lower dose induction therapy. After normalization of hCG, three additional consolidation cycles (6 weeks) of EMA-CO are administered (2).

Metastases Requiring Special Care

In the setting of high-risk disease and bulky tumor in areas susceptible to massive hemorrhage or worsening organ failure, consideration may be given to induction chemotherapy followed by full-dose combination chemotherapy. Patients with massive pulmonary or liver metastases or brain metastases may benefit from a 25% dose reduction for the first two cycles, with monitoring in an intensive care unit setting until the disease shrinks enough to allow full-dose chemotherapy with less significant risk of hemorrhage. An alternative strategy is to use low-dose etoposide 100 mg/m² and cisplatin 20 mg/m² on days 1 and 2 every week up to three times prior to initiating standard EMA-CO. Additionally, consideration can be given to using EMA-EP (EMA with etoposide and cisplatin) rather than EMA-CO in patients with the worst prognosis, namely with liver and brain metastases.

Significant vaginal hemorrhage should prompt resuscitative transfusion but is expected to resolve within 3 to 4 days. Additional strategies for management may include embolization, hysterectomy, and arterial ligation. Nearly all patients experiencing hemorrhage can be expected to survive with appropriate resuscitation and management (73). Twenty-five percent of patients with high-risk disease do not attain complete remission, in which case salvage chemotherapy is administered.

Pulmonary Metastases

Pulmonary metastases can be extensive and may cause respiratory failure and death (74). Some factors that predict a worse outcome or early death from respiratory compromise include cyanosis, pulmonary hypertension, dyspnea, anemia, tachycardia, extensive (>50%) lung opacification, mediastinal involvement, bilateral pleural effusion, and a high WHO prognostic score (75,76). In patients with extensive pulmonary metastases, reduced doses of initial chemotherapy have been suggested to abate the risk of respiratory failure, although

this strategy does not protect completely against pulmonary failure and death^(75,76).

Central Nervous System Metastases

Like pulmonary metastases, CNS metastases pose a significant threat. Although clinically apparent in only 7% to 28% of patients with choriocarcinoma, CNS involvement is found in as many as 40% of patients on postmortem examination. Multimodality therapy seems to be optimal, yielding a remission rate of 50% (7 of 14 patients) with disease-free intervals of 12 to 120 months.

Athanassiou et al reported that 8.8% of 782 patients had CNS metastases⁽⁴¹⁾. The overall survival rate of patients who had CNS metastases at diagnosis was 80%. The overall survival of patients who developed CNS metastases after initial diagnosis and treatment was only 25%. Two other studies found similar outcomes and concluded that CNS prophylaxis may improve prognosis^(77,78). However, Gillespie et al showed no benefit of CNS prophylaxis in 69 patients with lung metastases⁽⁷⁹⁾. We do not advocate CNS prophylaxis in the absence of definite CNS disease.

Patients with known CNS disease benefit from chemotherapy and whole-brain irradiation. In a retrospective analysis of 70 patients, half died before therapy was initiated. Of the remaining patients, 24% of those given chemotherapy alone survived, but 50% of patients given concurrent chemotherapy plus whole-brain irradiation achieved long-term remission and none died of CNS disease⁽⁸⁰⁾.

When patients present with CNS metastases, primary treatment of the brain with surgical resection or radiotherapy prior to EMA-CO chemotherapy is indicated to decrease the risk of hemorrhage. Surgical resection is appropriate only for patients with solitary metastasis. Surgical decompression should be considered for patients who have symptoms of raised intracranial pressure⁽⁸¹⁾.

The optimal dose of radiation appears to be 30 Gy. Patients with less than 25 Gy had a lower cure rate⁽⁸⁰⁾. The local control rate was 91% if >22 Gy was administered but 24% if <22 Gy was administered⁽⁸²⁾. For CNS disease, it is prudent to administer 30 Gy over 10 fractions initiated simultaneously with the start of chemotherapy. Stereotactic radiotherapy or gamma-knife treatment has been advocated at the end of chemotherapy to treat any residual unresectable lesions as an alternative to whole-brain radiation, due to the toxicity and limited evidence of improvement with whole-brain irradiation⁽⁶⁾.

The EMA-CO chemotherapy regimen should be administered following surgery or radiation⁽⁸³⁾. The dose of methotrexate is escalated to 1,000 mg/m². Intrathecal methotrexate 12.5 mg may be given with the CO component of EMA-CO or with whole-brain

radiotherapy (20-30 Gy in two daily fractions) concurrent with chemotherapy^(6,84). Extracranial sites of metastases at the time of CNS metastasis are common. Overall survival in patients with CNS metastases is 67%⁽⁸³⁾.

Patients in First Remission

Patients in first remission thought to have a high risk of recurrence are observed closely with serum β -hCG levels and posttherapy baseline radiologic imaging. For patients who had lung metastases, a repeat high-resolution CT scan at the end of chemotherapy serves as a baseline for follow-up. Many patients who have had lung metastases have residual nodules in the lung field on CT scans or chest x-ray, signifying fibrous scar tissue. For patients who had brain metastases, an MRI of the head would be obtained. Likewise, for patients who had liver metastases, a CT scan of the liver would be obtained. If the uterus is in place and was a site of previous disease, consideration is also given to baseline MRI of the uterus. The rationale is that modest increases in the β -hCG level, signifying relapse, may be accompanied by subtle changes in "sterile" lesions noted on earlier images. This finding raises the issue of surgical resection of a chemotherapy-resistant site. If the imaging obtained after chemotherapy reveals suspicious nodules or masses and the β -hCG level is normal, a baseline PET-CT scan is sometimes obtained to serve as a baseline. If the β -hCG level rises during follow-up, a PET-CT scan would help identify active disease.

Salvage Therapy

One-quarter of patients with high-risk metastatic disease do not achieve complete remission with EMA-CO or experience relapse later. These patients require identification of chemotherapy-resistant sites for possible surgical resection and salvage therapy with alternative platinum-based regimens. These regimens may include EMA-EP (omitting day 2 etoposide and dactinomycin and alternating weekly with etoposide and cisplatin); TE/TP (paclitaxel and etoposide alternating weekly with paclitaxel and cisplatin); ACE (dactinomycin, cisplatin, and etoposide); VIP (etoposide, ifosfamide, and cisplatin); BEP (bleomycin, etoposide, and cisplatin); cisplatin, vincristine, and methotrexate; PVB (cisplatin, vinblastine, and bleomycin); PEBA (cisplatin, etoposide, bleomycin, and doxorubicin); and ICE (high-dose ifosfamide, carboplatin, and etoposide)^(2,5,66,85-95). Response rates range from 20% to 75%. The most commonly used regimens are EMA-EP, which is toxic but results in a cure rate greater than 75%, and TE/TP, which may be equally efficacious and less toxic⁽²⁾.

Cure can also be achieved with surgery in a subset of chemoresistant patients who have one to three disease sites after combination chemotherapy. In this setting, PET-CT may be useful to detect metastatic sites (^{6, 96}). Total or radical hysterectomy to remove the disease, with or without adnexectomy and lymphadenectomy, can be curative in 90% of patients with primary drug-resistant and relapsed GTN (^{97, 98}).

Patients who fail these approaches may be candidates for high-dose chemotherapy. Limited outcomes data exist, but reports suggest that high-dose chemotherapy alone combined with surgical resection may lead to salvage in one-third of patients. The most common regimen is CarbopEC-T (carboplatin, etoposide, cyclophosphamide, and paclitaxel) (^{2, 9}).

Placental Site Trophoblastic Tumor

Originally known as trophoblastic pseudotumor, these tumors have been designated as PSTT to better reflect their malignant potential. The median age at diagnosis is 33 years (range, 18-47 years). The most common presenting symptoms are irregular vaginal bleeding, amenorrhea, and a pelvic mass (¹⁷). The median interval from antecedent pregnancy is 3.4 years. These tumors present with lung metastases in 10% to 20% of cases, and 10% of patients develop metastases during the follow-up interval (¹⁷).

The FIGO scoring is not used to determine the treatment of PSTT (²). Hysterectomy is the preferred treatment for nonmetastatic disease, which is highly curable. Postoperative chemotherapy is indicated for patients with certain risk factors, including metastatic disease, mitotic index, hCG level, and time from antecedent pregnancy. The latter is the most prognostic factor (²). The long-term survival rate of patients presenting with PSTT within 4 years of antecedent pregnancy was 98%, compared with 100% mortality for patients presenting with PSTT more than 4 years after antecedent pregnancy, but these findings have been inconsistent (^{14, 17}).

The general strategy is to perform hysterectomy for patients with nonmetastatic disease who present less than 4 years after antecedent pregnancy. Premenopausal patients with limited disease may preserve their ovaries, and lymphadenectomy is of limited utility (¹⁷). Patients with metastatic disease at presentation receive EMA-EP (^{2, 14, 94, 99, 100}) and, upon response, undergo resection of residual disease sites and hysterectomy. Recurrent disease not amenable to surgical resection may require radiation or combination chemotherapy with EMA-CO (^{94, 99}). Patients who present more than 4 years after antecedent pregnancy have poor survival and should be considered for clinical trials or high-dose chemotherapy, even when the disease appears to be localized (^{1, 2, 7}). Patients with limited disease who

desire fertility may be considered for focal uterine resection with or without chemotherapy, but this is investigational (^{1, 2}).

Placental site trophoblastic tumor produces β -hCG inconsistently, so the serum β -hCG level is not uniformly helpful in diagnosis, treatment, or follow-up (^{17, 64}). Placental site trophoblastic tumor is less responsive to chemotherapy than choriocarcinoma, but chemotherapy remains effective in many patients, and the prognosis depends on the extent of disease at presentation (^{2, 17}). The overall mortality rate of PSTT is 16% to 21% (³). The median overall survival is 86 months; 88% of patients with early-stage disease and 11% of patients with advanced-stage disease were without evidence of disease 28 months after diagnosis (¹⁷).

Epithelioid Trophoblastic Tumor

This rare disease entity appears to be distinct from PSTT but is treated in a similar fashion. The International Society for the Study of Trophoblastic Disease database is collecting information on both of these tumor entities and will inform future treatment decisions (²).

CO-TWIN PREGNANCY

The estimated incidence of twin pregnancy consisting of a molar pregnancy and a normal fetus is 1 per 22,000 to 100,000 pregnancies. This has been described in both spontaneous and in vitro fertilization (IVF) gestations, although the incidence may be greater in women undergoing assisted reproduction. Gestational trophoblastic tumors in such cases have been either molar pregnancies or malignant neoplasms.

A patient with this rare condition poses a therapeutic dilemma. Although some have suggested termination for these pregnancies due to a low successful birth rate and an increased risk of GTN, recent studies have reported that 38% to 57% of women deliver a healthy baby, with a slight increase in maternal complications but no increase in malignant transformation of molar pregnancy (¹⁰¹). The decision on any therapy is made after consultation with the patient, a perinatologist, and a gynecologic oncologist, with careful assessment of the risk to the mother and the fetus.

FUTURE CHILDBEARING AND SURVIVORSHIP

Women who have undergone effective treatment for molar pregnancy have a risk of future molar pregnancy of 1% to 2% (¹⁰²). Strict contraception is required

during the surveillance period because pregnancy would obviate the usefulness of β -hCG as a tumor marker. Patients are advised to use effective hormonal or barrier contraception. Intrauterine devices are not employed as contraception for patients with intact uteri because of concerns of uterine perforation. In general, once a 6-month surveillance establishes disease-free status, conception is acceptable, although these women are always at higher risk for future molar disease and will require close observation during future pregnancies⁽¹⁰³⁾. Previous studies suggested a 12-month conception-free period, but 6 months confers the same protection and allows the patient to pursue fertility earlier without an increased risk of GTD relapse. The recommendation to avoid pregnancy relates to the importance of hCG surveillance and does not relate to the risk of recurrence, as GTN-related outcomes, miscarriage, and the incidence of birth defects appear to be unrelated to conception^(6,56).

Standard chemotherapy has minimal impact on subsequent ability to reproduce^(104,105). In one study, 83% of women who received prior chemotherapy subsequently conceived⁽⁶⁾. In general, no increase in adverse events such as first- or second-trimester abortions or stillbirths, prematurity, or need for cesarean section has been noted, except for one report documenting a slight increase in stillbirth in subsequent pregnancies after chemotherapy⁽¹⁰²⁾. Similarly, their offspring have no increased risk of anomalies⁽⁵⁶⁾. Patients are monitored closely throughout any subsequent pregnancy, especially in the first trimester, to confirm that gestation is normal⁽⁷⁹⁾. Patients who have difficulty with conception are considered for fertility treatment but are at increased risk of repeat molar pregnancy.

Combination chemotherapy with EMA-CO induces menopause an average of 3 to 5 years earlier than otherwise anticipated^(6,105). The previously identified increased risk of second primary cancers (eg, acute myelogenous leukemia and thyroid cancer) after chemotherapy for choriocarcinoma was not observed in recent studies⁽¹⁰⁶⁾. Issues of survivorship concern sexual dysfunction and reproductive quality of life and appear to be greater in socially disadvantaged patients^(2,107).

CONCLUSION

Gestational trophoblastic disease represents a wide spectrum of neoplastic disorders that arise from placental trophoblastic tissue after abnormal fertilization. Patients are classified into different prognostic groups based on factors such as tumor histologic subtype, extent of disease, human gonadotropin titer, duration of disease, nature of the antecedent pregnancy, and extent of prior treatment. Each patient should receive individualized management after careful prognostication

under the care of a multidisciplinary team. Surgery and chemotherapy each play an important role in effective management. Patients with GTD are followed long term with regular laboratory tests of complete blood count and β -hCG. Survivors of GTD are also followed for management of psychosocial problems that may be associated with GTD and their treatment.

INCIDENCE AND DIAGNOSIS

The American Cancer Society predicts that in 2015 there will be over 64,000 new cases of renal neoplasms in the United States and that 14,000 patients will die as a consequence of disease progression ⁽¹⁾. Renal cell carcinoma (RCC) is the most common histology found in kidney tumors, with clear cell RCC (ccRCC) being the most common histologic subtype (Fig. 35-1). Non-clear cell RCC (nccRCC) subtypes include chromophobe, papillary, oncocytoma, collecting duct carcinoma (CDC), renal medullary, translocation, and unclassified RCC.

Work by Chow et al ⁽¹⁾ found the worldwide incidence of RCC appearing to plateau after a steady increase over several decades. To examine the incidence in the United States, the group used the database of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program to track patients with a diagnosis of kidney cancer from 1977 to 2006. The rate of localized cancer detection has continued to increase, whereas the rates of regional, metastatic, and unstaged RCC have declined. In this work, the mortality rate associated with RCC appears to begin declining in the early 2000s across both gender and racial lines. Although the direct causal relationship for the decline in RCC mortality in this study is unclear, early detection in the era of computed tomography (CT) imaging may be contributing to this finding.

STAGING, EPIDEMIOLOGY, AND RISK FACTORS

The American Joint Commission on Cancer staging schema for RCC was updated in 2010. Major staging categories are as follows: stage 1: T1 tumors that are 7 cm in maximum diameter or less and are confined to the kidney; stage 2: T2 tumors that exceed 7 cm in diameter but are confined to the kidney; stage 3: T3 tumors that demonstrate extracapsular invasion into the perinephric adipose tissue or renal sinus or extend into the renal vein or inferior vena cava (stage 3 also includes tumors with regional lymph node metastasis); and stage 4: extension of the primary tumor into the ipsilateral adrenal gland or beyond Gerota's fascia or distant metastases ⁽²⁾.

The link between germline genetic mutations and the development of RCC is well established and applies to a small but biologically important subset of RCC cases ⁽³⁾. Although these genetic alterations certainly play an important role in the biology of RCC in both familial and sporadic cases, there are also some environmental factors that contribute to the risk of developing a renal neoplasm. Smoking has long been linked to an increase in the risk of developing RCC, in addition to its association with multiple other malignancies ⁽⁴⁾. As is the case with other malignancies, cessation of smoking can be associated with a diminution in the risk of developing RCC ⁽⁵⁾. Interestingly, this diminution in risk appears to be slower and requires

FIGURE 35-1 Photomicrographs of clear cell (conventional) renal cell carcinoma (RCC) with low-grade (A) and high-grade (B) nuclear features. Photomicrographs of a type 1 papillary RCC (C) showing papillae lined by short cuboidal cells and a type 2 papillary RCC (D) showing papillae lined by tall columnar cells, with eosinophilic cytoplasm and high-grade nuclear features. (Used with permission from Pheroze Tamboli, MD.)

a significantly longer time to reach baseline than that seen with other malignancies, such as lung cancer.

Obesity or increased body mass index (BMI) has also been linked to increased risk of developing RCC. Several studies have demonstrated a higher incidence of obesity or increased BMI in patients with RCC, suggesting an epidemiologic linkage⁽⁶⁾. As is the case in most retrospective epidemiologic studies, these observations are confounded by other associated variables, including diet, occupational history, and smoking. In a report by Kamat et al., overweight and obese patients had a more favorable prognosis following surgery than did patients with a lower BMI⁽⁷⁾. Additional possible risk factors identified retrospectively in epidemiologic studies include diabetes, hypertension, and treatment with diuretics; in addition, certain diets have been linked to higher or lower risk than the general population.

PROGNOSTIC FACTORS, PATHOLOGY, AND MOLECULAR MARKERS

The natural history is variable, depending on tumor genetic factors, the general medical condition of the patient, and factors such as angiogenesis and immune response. Patients who undergo nephrectomy for localized disease remain at risk of recurrence for many years and require appropriate counseling and surveillance.

The traditional measures of performance status, tumor stage, and tumor grade each demonstrate good correlation with clinical outcome⁽⁸⁾. Integration of these parameters and other clinical prognostic variables allows the classification of patients into groups with statistically significant differences in survival. There are a variety of clinical, pathologic, and molecular

Table 35-1 Prognostic Factors in Advanced Renal Cell Carcinoma

Patient- or Treatment-Related Factors	Laboratory Studies	Tumor-Related Factors	Molecular Markers
Performance status	Lactate dehydrogenase	Site and/or number of metastatic sites	<i>VHL</i> mutation or hypermethylation
Age, gender, race	Alkaline phosphatase	Disease-free interval	Carbonic anhydrase IX expression
Symptoms: weight loss, fatigue, pain, loss of appetite, fever	Calcium	Metastasis-free interval	Phospho-extracellular signal regulated kinase (pERK)
Overweight	Albumin	Tumor burden	Cytoplasmic mTOR staining
Prior nephrectomy	Liver dysfunction	Histologic type	<i>PTEN</i> deletion
Prior therapy	Anemia Neutrophilia	Sarcomatoid dedifferentiation	p53 overexpression
	Thrombocytosis	Ploidy	MMP-2 and MMP-9 overexpression <i>BAP1</i> and <i>PBRM1</i> mutation

features that have been proposed and studied as prognostic factors (Table 35-1) (^{9, 10}). As the genomic landscape continues to be more clearly defined in ccRCC and the genetic drivers of metastasis are identified, more refined putative biomarkers are needed to more effectively treat this heterogeneous disease (^{11, 12}).

Clinical Prognostic Variables

In 1999, Motzer et al identified five risk factors (elevated serum corrected calcium level, anemia, lactate dehydrogenase $>1.5\times$ the upper limit of normal [ULN], Karnofsky performance score [KPS] <80 , and primary tumor in place) that segregated patients into three risk groups (good, zero factors; intermediate, one to two factors; and poor, three or more factors) (¹³). In 2002, an updated version, now referred to as the Memorial Sloan-Kettering Cancer Center (MSKCC) risk criteria (also referred to as the “Motzer criteria”), was published with the original four risk factors, with the fifth being treatment of interferon within 1 year of diagnosis (¹⁴). For clinical trial purposes, the fifth factor is often considered time to initiation of systemic therapy within 1 year from initial diagnosis of RCC. With the introduction of targeted therapy, the International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) was formed, and a modified prognostic scoring system was put forth in 2009 and externally validated in 2013 (^{15, 16}). The IMDC prognostic scoring system (also referred to as the “Heng score”) has six risk factors (elevated serum corrected calcium level, anemia, KPS <80 , systemic treatment for metastatic disease within 1 year, absolute neutrophil count $>ULN$, and platelet count $>ULN$). Similar to the MSKCC scoring system, good risk is defined as zero risk factors, intermediate

risk as one to two risk factors, and poor risk as three or more risk factors. Although other systems have been proposed, the MSKCC and IMDC remain the most widely used (Table 35-2).

Non-clear cell histology has been associated with lower response to systemic therapy (¹⁷). In an attempt to improve on the MSKCC clinical prognostic model, we investigated the role of cytokines and angiogenic factors (CAFs) in serum of patients treated with interferon- α (IFN- α) and found elevated baseline levels of interleukin (IL)-5, IL-6, IL-12p40, and vascular endothelial growth factor A (VEGFA) to be independent risk factors associated with inferior survival. Incorporating the CAF model with the MSKCC clinical model improved the concordance index for predicting overall survival (OS). Patients with three or more of the four CAFs or with MSKCC poor-risk status had a median OS of 9 months, compared with a median OS of 32 months for patients with two or fewer CAFs (¹⁸). Similar efforts have been undertaken to develop serum and plasma-based prognostic and predictive biomarkers in individuals who received antiangiogenic therapy (^{19, 20}).

Pathology and Molecular Markers

There are several major histologic subtypes in RCC, including clear cell, papillary, and chromophobe RCC (see Fig. 35-1). Historically, patients with nccRCC variants except chromophobe do poorly once they develop metastatic disease, mainly due to the dearth of effective systemic therapy.

The *VHL* gene product regulates the hypoxia-induced pathway and is commonly mutated in ccRCC (¹¹). The hypoxia-induced pathway leads to the activation of survival genes that mediate glucose transport, proliferation,

Table 35-2 The Memorial Sloan-Kettering Cancer Center (MSKCC) Modified Risk Score for Metastatic Renal Cell Carcinoma and the International Metastatic Renal Cell Database Consortium (IMDC) Risk Score With Survival by Risk Stratification

MSKCC 2002 Factors (1 point each)	Risk Group (points)	Overall Survival (months)	IMDC or Heng Score (1 point each)	Risk Group (points)	Overall Survival (months)
Anemia	Good (0)	30	Anemia	Good (0)	43
Elevated calcium			Elevated calcium		
KPS <80	Intermediate (1-2)	14	KPS <80	Intermediate (1-2)	22.5
Metastatic Tx within 1 year of Dx			Metastatic Tx within 1 year		
LDH >1.5× ULN	Poor (3-5)	5	Platelet count >ULN	Poor (3-6)	7.8
			Neutrophil count >ULN		

Dx, diagnosis; KPS, Karnofsky performance score; LDH, lactate dehydrogenase; Tx, treatment; ULN, upper limit of normal.

angiogenesis, and pH regulation and is also implicated in the other tumor types. In a study of 187 patients undergoing nephrectomy for ccRCC in Japan, mutation or hypermethylation of the *VHL* gene was found in 58% of tumors, and was associated with significantly improved disease-free and cancer-specific survival in patients with organ-confined tumors ($n = 134$), but not in those with stage IV disease at the time of nephrectomy ($n = 53$)⁽²¹⁾. *VHL* loss occurs early in the development of clear cell carcinoma⁽¹²⁾, potentially identifying a subset of patients who do well after surgery.

In ccRCC, loss of the short arm of chromosome 3 was the most common genetic alteration identified in The Cancer Genome Atlas (TCGA) analysis. The most common genetic mutations related to this loss include *VHL*, *SETD2* (a histone methyltransferase), *BAP1* (histone deubiquitinase), and *PBRM1* (part of chromatin remodeling complex), and all lie on chromosome 3p⁽¹¹⁾. The University of Texas Southwestern group identified *BAP1* mutations to be associated with poor survival, with a median OS of 4.6 years from nephrectomy in patients who present with nonmetastatic disease compared with a median OS of 10.6 years in patients whose tumors harbor *PBRM1* mutations. The investigators validated these findings from tumor specimens included in the TCGA analysis⁽²²⁾.

MANAGEMENT OF NONMETASTATIC RENAL CELL CARCINOMA

With the introduction of improved cross-sectional imaging including CT and magnetic resonance imaging (MRI), the detection of renal masses has increased

substantially. The ability to characterize renal masses as benign or malignant appearing has also evolved with improved technology and the use of specific contrast-enhancing sequences. The management of small renal masses (<4 cm) will not be extensively covered in this chapter but includes options such as active surveillance, partial nephrectomy (PN), radical nephrectomy (RN), or thermal ablation depending on factors including patient comorbidities and surgical expertise⁽²³⁾. Current surgical approaches to both PN and RN include open, laparoscopic, and robotic-assisted techniques^(24,25). Loss of nephrons associated with RN compared to PN increases patient risk for development of chronic kidney disease (CKD)⁽²⁶⁾. In the general population, CKD is associated with increased risk of mortality and cardiovascular disease. Retrospectively, patients treated with RN were found to have higher all-cause mortality and an increased incidence of cardiovascular events⁽²⁷⁾.

With the introduction of robotic partial nephrectomy, the warm ischemia and suturing times are reduced compared to laparoscopic PN even among experienced laparoscopic surgeons⁽²⁸⁾. The management algorithm of potential tumors amenable to PN continues to evolve and should take into account the health of the contralateral kidney, familial cancer syndromes leading to multiple renal masses, proximity to the hilum and vascular structures, baseline kidney function, and surgeon experience and volume.

With larger, more locally advanced tumors requiring nephrectomy, the decision to perform a lymph node dissection remains an area of debate. In the European Organization for Research and Treatment of Cancer (EORTC) 30881 trial, 772 patients were randomized between lymph node resection or no resection during

nephrectomy procedure. The majority of patients had $\leq T2$ disease⁽²⁹⁾. The study found no difference in recurrence-free survival or OS. However, other series have found the presence of lymph node positivity to be directly correlated with increasing T stage. As a result, at the University of Texas MD Anderson Cancer Center (MDACC) when patients have radiographic evidence of lymph node involvement or T stage $\geq T3a$, a therapeutic or staging lymph node dissection is typically undertaken.

The decision to perform ipsilateral adrenalectomy as part of the standard RN procedure has evolved. In a retrospective review of the literature, O'Malley et al estimated a negative predictive value of 96% when cross-sectional imaging of the ipsilateral adrenal gland was compared to surgical pathology⁽³⁰⁾. Unless there is evidence of involvement either by direct extension, radiographic evidence of metastatic spread of disease, or concern for involvement during gross inspection during surgery, the ipsilateral adrenal gland is typically spared.

Locally advanced tumors staged as T3b or higher require considerable institutional and surgeon experience in the management of these patients and will not be covered here in detail.

METASTATIC DISEASE WITH CLEAR CELL HISTOLOGY

Role of Cytoreductive Nephrectomy in Metastatic Disease

Renal cell carcinoma remains a relatively rare malignancy where addressing the primary tumor in selected patients with metastatic disease leads to an improvement in OS^(31, 32). In a pooled analysis of the results of the Southwest Oncology Group (SWOG) 8949 and EORTC 30947 studies, improvement in OS favored the nephrectomy arm, with a median survival of 13.6 months versus 7.8 months for those randomized to the surgical arm⁽³³⁾. Because the initial studies compared patients treated with IFN- α with or without cytoreductive nephrectomy, the question of benefit of cytoreductive nephrectomy in the era of targeted therapy has reemerged. In a retrospective analysis, the IMDC found that patients treated in the targeted era appear to benefit from cytoreductive nephrectomy if they have three or fewer prognostic risk factors as outlined in Table 35-2, whereas those with four or more factors do not appear to benefit⁽³⁴⁾. Two ongoing prospective trials, SURTIME (NCT01099423) and CARMENA (NCT0093033), are attempting to address two questions regarding targeted therapy and cytoreductive nephrectomy. The SURTIME trial is investigating whether cytoreductive surgery is better performed

before or after first-line sunitinib. The CARMENA trial is an EORTC effort investigating whether cytoreductive nephrectomy is beneficial in patients treated with sunitinib. Based on the available data and our institutional experience, patients at MDACC with synchronous metastatic disease who have a good performance status, a good or intermediate prognosis based on MSKCC or IMDC score, ccRCC, and a sizable renal primary compared to metastatic disease burden are generally offered upfront cytoreductive nephrectomy.

Patients who present with metastatic disease and primary tumor in situ offer an ideal presurgical setting for clinical and translational research studies⁽³⁵⁾. Retrospectively, patients at MDACC treated with targeted agents prior to cytoreductive nephrectomy compared to upfront cytoreductive nephrectomy experienced similar rates of serious adverse events⁽³⁶⁾. With the ability to analyze treated tissue paired with time blood samples and clinical and radiographic parameters at defined intervals, presurgical clinical trials offer an opportunity to enhance our understanding of metastatic RCC and determinants of response and resistance to targeted and immunotherapeutic agents.

Role of Metastasectomy

In carefully selected patients, metastasectomy plays an important role in the multidisciplinary treatment of patients with metastatic RCC (mRCC). Retrospective series have found survival benefit in resecting oligometastatic disease from multiple sites. Interpretation of these results is always limited due to the highly selected and retrospective nature of these studies. However, appropriate patient selection, complete resection of disease, and metachronous single site or oligometastatic disease positively impact patient outcomes. In a pooled retrospective analysis from three centers including patients from MDACC, 22 patients who had received targeted therapy underwent consolidative metastasectomy with an acceptable postoperative complication rate. After 108 weeks of follow-up, 11 patients remained disease free, and the median time to resumption of targeted therapy was 55 weeks⁽³⁷⁾. An ongoing randomized phase II study (NCT01575548) is addressing the role of pazopanib versus placebo in patients with no evidence of disease after metastasectomy. Further treatment decisions are based on the timing of recurrence, sites of recurrence, and individual patient characteristics. At MDACC, we strongly believe a multidisciplinary approach at high-volume centers is required to optimally manage these patients.

An algorithm to select candidates for metastasectomy and for the approach to postmetastasectomy systemic treatment is shown in Fig. 35-2.

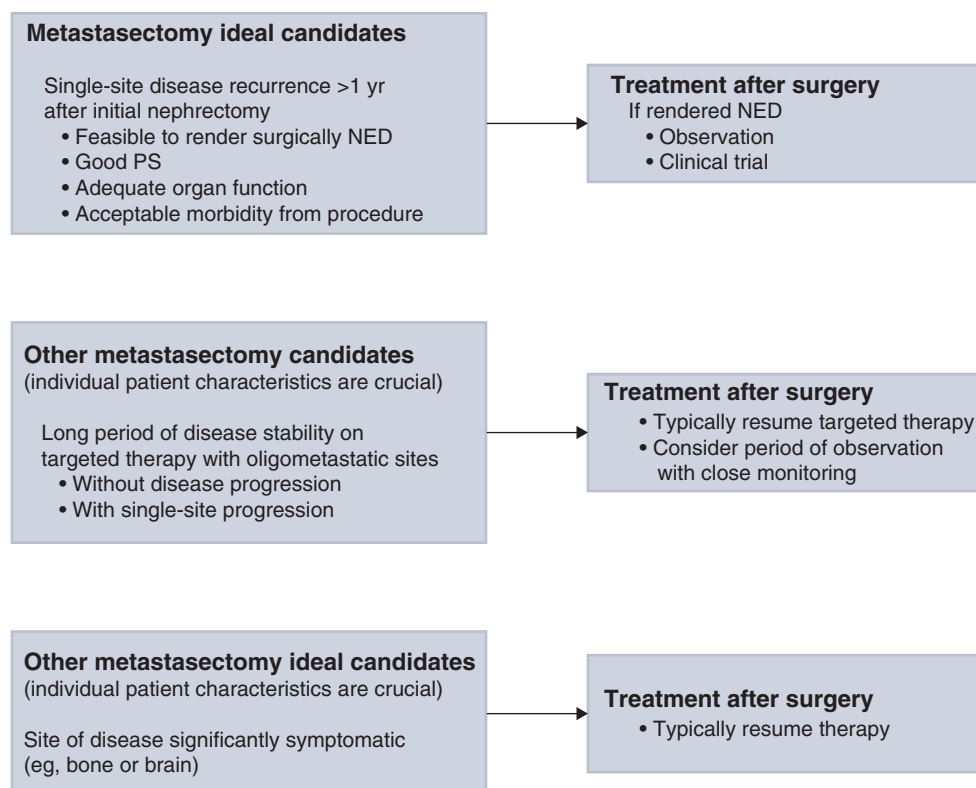

FIGURE 35-2 Metastasectomy candidates and treatment after procedure. NED, no evidence of disease; PS, performance status.

SYSTEMIC THERAPY

Cytokine Therapy

Until the introduction of targeted therapy (discussed in more detail in the later section on targeted therapy), metastatic resection and cytokine therapy remained the only viable treatment options in mRCC. Interferon- α and IL-2 have been extensively evaluated over the past three decades. In a randomized phase II study from MDACC, treatment with low-dose IFN- α -2b compared to intermediate-dose IFN- α -2b resulted in no significant differences in progression-free survival (PFS) or OS, but patients had an improved quality of life while on low-dose therapy⁽³⁸⁾. Sustained complete remissions with IFN- α are rare (1%-2%), and with the relatively low response rate of approximately 7%, IFN- α monotherapy never received US Food and Drug Administration (FDA) approval for treatment of mRCC and is no longer considered as a single agent for mRCC at MDACC.

High-dose IL-2 (HD IL-2) received FDA approval in the treatment of mRCC in 1992 based on the results of several phase II trials that found an overall response rate of 15% to 20% and a durable response in the majority of patients who achieved a complete response. A phase III trial comparing HD IL-2 with an outpatient low-dose IL-2 plus IFN- α regimen yielded

a higher response rate to HD IL-2 of 23% versus 10% but no statistically significant differences in PFS and OS. However, durable responses of greater than 3 years were seen in 7% of those treated with HD IL-2 versus 0% of patients in the other arm, supporting HD IL-2 as a viable standard-of-care option for patients who are candidates for this therapy⁽³⁹⁾. Although the management of toxicity related to the delivery of HD IL-2 is challenging, high-volume centers have published a toxic death rate of less than 1%, with response rates of roughly 15% to 20% and durable remissions in the range of 5% to 7%^(40,41). Given the ability to produce a sustained remission with likely cure in a small subset of patients, at MDACC, we offer frontline HD IL-2 therapy to patients with excellent performance status, previous nephrectomy, limited or no comorbidities, and low-volume metastatic disease burden, especially lung-only disease.

Targeted Therapy

Over the last decade, seven agents have been FDA approved for the treatment of mRCC. Of these agents, five are vascular endothelial growth factor (VEGF) pathway-blocking agents, with four being within the small-molecule tyrosine kinase inhibitor family and one, bevacizumab, being a monoclonal antibody

directed against VEGF on the cell surface. The remaining two agents are mammalian target of rapamycin (mTOR) inhibitors. These agents target both the tumor cells and the tumor microenvironment.

Vascular Endothelial Growth Factor, or Vascular Endothelial Growth Factor Receptor–Targeted Agents

The presence of a *VHL* mutation in up to 80% of patients with ccRCC and the resultant increased production of angiogenic factors has made this axis the most exploited treatment target. A number of agents that target either VEGF or its receptors (VEGFR) were FDA approved in the past 10 years (Table 35-3).

Bevacizumab is a humanized recombinant anti-VEGF antibody. Two large randomized phase III studies demonstrated an improved PFS in patients who

received a combination of bevacizumab plus IFN- α , when compared to IFN- α alone in patients with mRCC who had not received prior systemic therapy^(42, 43). The AVOREN study compared patients treated with the combination of bevacizumab plus IFN versus placebo plus IFN and found that the bevacizumab combination resulted in a superior median PFS of 10.2 months compared to 5.4 months. The Cancer and Leukemia Group B (CALGB) 90206 study yielded a median PFS of 8.5 months for the combination arm versus 5.2 months for IFN monotherapy, a difference that was statistically significant. Of note, the OS for both studies was numerically superior in the bevacizumab-containing arm but did not reach statistical significance. Bevacizumab plus IFN was FDA approved for advanced RCC in 2009.

Sorafenib is an orally bioavailable small-molecule inhibitor of VEGFR, platelet-derived growth factor receptor (PDGFR), and Raf and was FDA approved

Table 35-3 Phase III Studies Leading to Approval of Molecularly Targeted Agents in Renal Cell Carcinoma

Agent	Year FDA Approved	Trial Design	Setting	No. of Patients	MSKCC Risk (%)	Median PFS (months)	Median OS (months)
Sorafenib	2005	Sorafenib vs placebo	Cytokine failures ccRCC	903	Good: 50 Int: 49 Missing: 1	5.5 vs 2.8	19.3 vs 15.9 (NS)

ccRCC, clear cell renal cell carcinoma; FDA, US Food and Drug Administration; IFN, interferon; Int, intermediate; MSKCC, Memorial Sloan-Kettering Cancer Center; NS, not significant; OS, overall survival; PFS, progression-free survival.

in 2005 for the treatment of advanced RCC. In a randomized phase III trial, sorafenib yielded a significant improvement in PFS compared to placebo (median, 5.5 vs 2.8 months) in patients who had failed one prior therapy, with the majority having received prior cytokines⁽⁴⁴⁾. A phase II study compared sorafenib monotherapy to sorafenib plus IFN- α and found similar overall response rates, toxicity, and median PFS, leading further exploration of this combination to be abandoned⁽⁴⁵⁾.

Sunitinib is an oral inhibitor of VEGFR and PDGFR. When it was first tested in the cytokine-refractory population, a time to progression of 8.7 months was achieved⁽⁴⁶⁾, earning it provisional FDA approval in early 2006. A follow-up first-line phase III trial randomizing patients between sunitinib and IFN showed a median PFS of 11.0 months for sunitinib versus 5.0 months for IFN⁽⁴⁷⁾. Median OS of sunitinib-treated patients was 26.4 months versus 21.8 months for the IFN-treated group ($P = .051$), which although not statistically significant was likely due to crossover from IFN to sunitinib and salvage therapy after protocol⁽⁴⁸⁾. When a subgroup analysis of the individuals who did not receive any subsequent therapy was performed, it was found that those who received sunitinib had a median OS of 28 months versus 14 months for the IFN group.

Pazopanib is an oral small molecule with a lower half-maximal inhibitory concentration (IC_{50}) for VEGFR when compared to sorafenib and sunitinib⁽⁴⁹⁾. A randomized, phase III trial compared pazopanib to placebo in patients treated with a cytokine and previously untreated patients and demonstrated an overall PFS of 9.2 versus 4.2 months (hazard ratio, 0.46; 95% confidence interval, 0.34-0.62; $P < .0000001$)⁽⁵⁰⁾. Pazopanib was FDA approved in 2009 for the first-line treatment of advanced RCC. Pazopanib has not been evaluated prospectively after first-line targeted therapy. At MDACC, we retrospectively studied 93 patients who received targeted therapy preceding pazopanib and observed an overall response rate of 15%, a median PFS of 6.5 months, and a median OS of 18.1 months⁽⁵¹⁾. Adverse events were similar to those described in the large prospective trials with the agent.

Axitinib is a selective small-molecular inhibitor of the VEGFR-1, VEGFR-2, and VEGFR-3 signaling pathways⁽⁵²⁾. In a randomized phase III trial, axitinib was compared to sorafenib as second-line therapy after sunitinib, cytokines, bevacizumab plus IFN, or temsirolimus. The overall median PFS time was 6.7 versus 4.7 months in favor of axitinib⁽⁵³⁾. Median OS was not statistically different between the two groups (20.1 months for axitinib and 19.2 months for sorafenib)⁽⁵⁴⁾. The largest difference between the two arms was in patients previously treated with cytokines. Patients who developed hypertension with a diastolic blood pressure of greater than 90 mm Hg on trial had a

significantly improved survival in both treatment arms as compared to patients who remained normotensive. When axitinib was compared with sorafenib in the first-line setting, the median PFS was 10.1 months with axitinib and 6.5 months with sorafenib with overlapping confidence intervals. Despite the numerically longer PFS with axitinib, the difference did not reach the trial's prespecified threshold of statistical significance⁽⁵⁵⁾.

Mammalian Target of Rapamycin Inhibitors

Temsirolimus is an intravenous sirolimus ester that was tested in intermediate- and poor-risk patients after phase II data had suggested that this was the subgroup of patients most likely to benefit from temsirolimus⁽⁵⁶⁾. This first-line phase III trial randomized patients to temsirolimus, temsirolimus plus IFN, or IFN monotherapy. The median OS in the temsirolimus arm was 10.9 months versus 8.4 months for the combination arm and 7.3 months for IFN monotherapy⁽⁵⁷⁾. An elevated pretreatment serum lactate dehydrogenase was found to be both a predictive and prognostic biomarker in patients treated with temsirolimus compared to IFN (OS, 6.9 vs 4.2 months, $P < .002$)⁽⁵⁸⁾.

Everolimus is an orally bioavailable sirolimus ester that was evaluated in patients who had progressed on sorafenib, sunitinib, or both. This phase III trial (RECORD-1) randomized patients between everolimus 10 mg by mouth daily versus placebo in a 2:1 fashion. Median PFS was 4.0 months with everolimus versus 1.9 months with placebo⁽⁵⁹⁾.

Because everolimus and temsirolimus are mTORC1 inhibitors, agents capable of blocking both the mTORC1 and mTORC2 pathways have been developed. In a recent study comparing everolimus with GDC-0980, a pan PI3K and TORC1/2 inhibitor, the median PFS was 6.1 months with everolimus versus 3.7 months with the investigational agent, with a higher rate of adverse events in the investigational arm⁽⁶⁰⁾. The reasons for this surprising result are unclear at this time.

Side Effect Profiles

The major side effects of the targeted agents are summarized in [Table 35-4](#).

Blockade of VEGFRs or depletion of the VEGF ligand causes class effects, which include hypertension, fatigue, proteinuria, and a slightly increased risk of bleeding and thromboembolic events. All of the anti-VEGF agents will cause these side effects to varying degrees. Sorafenib, sunitinib, and pazopanib are also inhibitors of PDGF, Flt3, and a number of other

Table 35-4 Summary of Side Effects of Targeted Agents Approved in Renal Cell Carcinoma

X, XX, and XXX: Low (0%-25%), intermediate (25%-50%), and high incidence (>50%), all grades/grade 3 or higher.

receptor tyrosine kinases and thus will induce hand-foot syndrome, diarrhea, and dysgeusia. Sunitinib appears to be particularly prone to inducing hypothyroidism^(61, 62) and, in some cases, cardiomyopathy with decreased ejection fraction⁽⁶³⁾. The frequency of cardiac toxicity may be underappreciated. A single-institution experience from Stanford found that 33% of patients had evidence of cardiac toxicity even when excluding hypertension⁽⁶⁴⁾. The rate of heart failure induced by sunitinib at MDACC in the treatment of a variety of tumor types including mRCC was 2.7%⁽⁶⁵⁾. Emerging data suggest that scrupulous control of blood pressure in patients on sunitinib will decrease cardiac stress and resultant cardiac failure.

Other side effects include wound dehiscence and increased thromboembolic events. Our group reported perioperative complications in patients with mRCC and primary in situ who received antiangiogenic agents in the presurgical setting prior to cytoreductive nephrectomy. In a single-arm phase II trial⁽³⁵⁾, perioperative wound healing complications in patients who received 8 weeks of bevacizumab therapy were increased when compared to a set of matched controls. The retrospective study, which looked at 44 individuals who received sorafenib, sunitinib, or bevacizumab preoperatively, did not detect a significant elevation of any perioperative events⁽⁶⁶⁾.

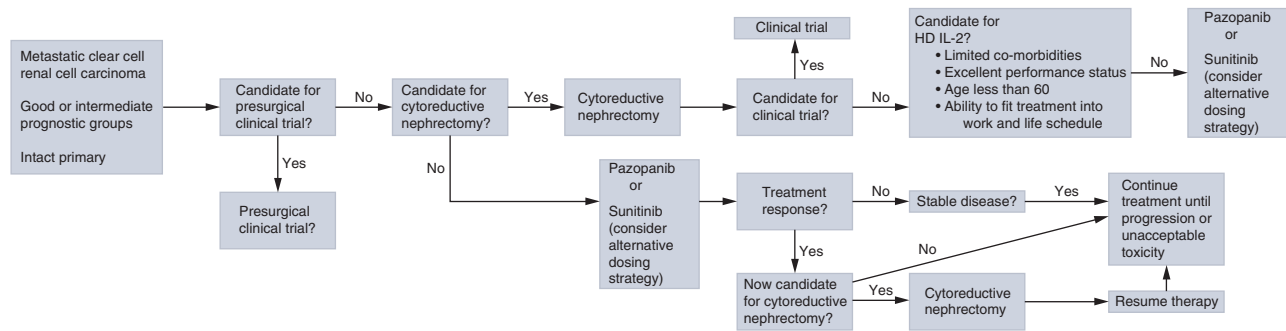

The mTOR inhibitors demonstrate several unique side effects, including hyperglycemia, hypertriglyceridemia, and noninfectious pneumonitis. However, these agents are not as likely to induce hypertension or hand-foot skin reaction.

Agent Selection and Side Effect Management

A number of different factors are important when choosing the best initial agent for patients with metastatic ccRCC. Clearly, evidence-based criteria for selection are vital, but as seen in [Fig. 35-3](#), there are several agents available for a particular treatment stage.

For example, if we are dealing with a patient who has undergone nephrectomy, has good-risk characteristics, and is younger than age 70 years, HD IL-2, sunitinib, bevacizumab plus IFN, and pazopanib are all reasonable options. In the COMPARZ trial, a noninferiority phase III trial with PFS as the primary end point, sunitinib and pazopanib were directly compared⁽⁶⁷⁾. The trial showed noninferiority of pazopanib. Importantly, the side effect profile and quality-of-life assessment favored pazopanib. Consequently, we prefer pazopanib over the standard dosing schedule of sunitinib and over bevacizumab plus IFN given the relative ease of patient administration. Although HD IL-2

is often offered, many patients are not interested to receive it because of the low likelihood of success and the formidable toxicity.

Table 35-4 provides a summary of some of the most common side effects seen with these agents. A review of these side effects may aid in treatment selection for specific patients. Some may have occupational considerations that make hand-foot skin reaction a particular problem. Others may have cardiac comorbidities that make an agent like sunitinib, with a known effect on cardiac output in a subset of patients, less favorable. Table 35-5 summarizes the standard dose-reduction algorithms used in clinical trials of these agents.

In addition to dose interruptions and dose reductions, a change in schedule may be beneficial for some patients. Our group and others have retrospectively compared cohorts of patients treated on the standard sunitinib schedule of 4 weeks on, 2 weeks off with

a schedule of 2 weeks on and 1 week off⁽⁶⁸⁾. The 2-week-on, 1-week-off schedule has a better toxicity profile and retrospectively has similar treatment efficacy compared with the standard approach⁽⁶⁹⁾. However, prospective comparison of the two treatment schedules has not been reported.

Symptom control is essential for patients receiving molecularly targeted agents. Table 35-6 outlines supportive care measures that can mitigate or prevent specific side effects. It is essential that the patient and health-care team maintain an ongoing dialogue during each cycle of therapy to ensure that patients proactively and appropriately manage these adverse events. Successful adverse event management will translate into higher drug compliance and a greater probability of achieving a successful outcome.

A retrospective review of patients treated with temsirolimus or everolimus at MDACC found a rate

Table 35-5 Dose Reduction Algorithm Used in Pivotal Trials of Approved Targeted Agents^a

Agent	Standard Dose	Dose Reduction Schema
Sorafenib	400 mg PO bid	Dose level 1: 400 mg PO daily
		Dose level 2: 400 mg PO every other day
		Alternate ^b : Dose reduction to 600 mg PO daily
Sunitinib	50 mg PO daily 4 weeks on, followed by 2 weeks off	Dose level 1: 37.5 mg PO daily, 4 weeks on, 2 weeks off
		Dose level 2: 25 mg PO daily, 4 weeks on, 2 weeks off
		Alternate ^b : Schedule change to 50 mg PO 14 days on and 7 days off
Temsirolimus	25 mg IV weekly	Dose level 1: 20 mg IV weekly
		Dose level 2: 15 mg IV weekly
Everolimus	10 mg PO daily	Dose level 1: 5 mg PO daily
		Dose level 2: 5 mg PO every other day
Bevacizumab plus IFN	Bevacizumab 10 mg/kg IV every 14 days; IFN 9 MU SC TIW	IFN: Dose level 1: 6 MU SC TIW Dose level 2: 3 MU SC TIW
		Bevacizumab: for proteinuria: If greater than 2 g/dL hold until below 500 mg/dL
Pazopanib	800 mg PO daily	600 mg/d (dose level 1); 400 mg/d (dose level 2)
Axitinib	5 mg PO bid	3 mg PO bid (dose level 1); 2 mg PO bid (dose level 2)

bid, twice a day; IFN, interferon; IV, intravenous; MU, million units; PO, oral; SC, subcutaneous; TIW, three times a week.

^aOnce patients are on therapy, there are several ways to mitigate side effects. The package inserts of each agent outline the standard algorithm for dose reduction. This table summarizes the standard dose reduction algorithms used in clinical trials of these agents.

^bNot prospectively validated but used empirically with good effect.

of noninfectious pneumonitis (NIP) of 6% with temsirolimus and 23% with everolimus (⁷⁰). We observed that patients who developed NIP had longer treatment duration and longer OS. Recent guidelines have been established to diagnose and treat NIP with the important caveats that patients with radiographic findings but lacking symptoms can continue therapy and patients with radiographic findings with mild to moderate cough can continue therapy with close monitoring (⁷¹). More severe symptoms require corticosteroids with a consideration of break or permanent discontinuation of mTOR inhibitor therapy depending on the severity of the event.

The decision for second-line and later therapy has become increasingly complex. Sequencing of VEGF-VEGF-directed therapy or VEGF-mTOR-directed therapy has been compared prospectively. In a randomized phase III trial of second-line therapy in patients who received first-line sunitinib, temsirolimus was compared to sorafenib. The trial's primary end point of detecting a superior PFS with temsirolimus was not met, with a median PFS of 4.1 months with temsirolimus and 3.7 months with sorafenib. Interestingly, the secondary end point of median OS favored the sorafenib arm (16.6 vs 12.3 months, $P = .01$). Although median OS was not the primary end point of the trial, the authors hypothesized that VEGF-VEGF sequencing may be more beneficial compared with the

so-called "sandwich approach" of VEGF-mTOR-VEGF sequence (⁷²). In the community, VEGF-mTOR-VEGF sequencing is the most common current treatment approach (⁷³). In the AXIS trial, axitinib was compared to sorafenib in the second-line setting (although first-line treatment could be cytokine-based treatment) and led to an improved PFS (⁵³). A phase II, single-arm, single-institution study found that after failure of frontline sunitinib or bevacizumab, pazopanib had activity, with a median PFS of 7.5 months (⁷⁴). As such, a reasonable treatment approach for patients with good- or intermediate-risk disease by Heng criteria who are deemed good candidates for targeted therapy and do not elect to pursue HD IL-2 therapy can receive pazopanib as first-line therapy and receive axitinib or everolimus as second-line therapy. Depending on performance status and comorbidities, the decision can be made to continue with an alternative VEGF-directed therapy with sorafenib or sunitinib or change to an mTOR-directed therapy at progression. Certainly, consideration of a clinical trial should be entertained in the frontline and later line settings.

Patients who fall into the poor prognostic group remain a considerable unmet need in the care of patients with mRCC. At this time, temsirolimus remains the only agent with category 1 evidence to support its use. Ongoing trials in this setting include the FLIPPER trial (NCT01521715), which is a phase IV trial evaluating

Table 35-6 Management Recommendations for Commonly Experienced Toxicities

Side Effect	Preventative Measures	Supportive Care Measures		
Diarrhea	In patients with prior history of diarrhea on agent, consider loperamide once daily in morning	Loperamide 1-2 tabs after diarrhea	Diphenoxylate plus atropine	1 scoop psyllium with 1 oz water daily
Hand-foot syndrome	Heavy emollients applied to hands and feet bid and prn	As in preventive measures, plus urea-based callus creams		
Fatigue	Regular physical activity	Consider modafenil or methylphenidate	Check thyroid function	Short naps Regular exercise Regularized diet
Hypertension		Maintain BP below 140/90 using: 1. Calcium channel blockers (amlodipine okay but not diltiazem) 2. Angiotensin-converting enzyme inhibitors 3. β -Blockers		
Hypothyroidism		Levothyroxine		
Dysgeusia	Salt and soda mouthwash 4 times a day	Avoidance of hot and spicy foods Salt and soda mouthwash	Carafate	
Mouth sores	Salt and soda mouthwash 4 times a day	Xylocaine-based mouthwash		
Hyperglycemia	Scrupulous glycemic control	Scrupulous glycemic control		
Rash (sorafenib)		Dose adjustment Aveeno baths		
Rash (temsirolimus and everolimus)		Topical steroids		
Noninfectious pneumonitis (temsirolimus and everolimus)		Corticosteroids		

bid, twice a day; BP, blood pressure; prn, as needed.

pazopanib in poor-risk mRCC, and a randomized phase II trial at MDACC comparing temsirolimus to pazopanib in the frontline setting (NCT01392183).

Combinations of Targeted Therapy

In an attempt to improve on the success of single-agent targeted therapy, combinations of VEGF and mTOR pathway blockade have been pursued. To date, combinations are associated with significant toxicity without

a positive impact on response rate, PFS, or OS, as compared with sequential single-agent targeted therapy. A phase III trial compared the standard of bevacizumab plus IFN- α versus bevacizumab plus temsirolimus (⁷⁵). The response rate, median PFS, and median OS were not found to be statistically different between the two treatment arms. As a result of early phase and later phase clinical trials to date, combinations of VEGF and mTOR inhibitors are unlikely to yield significant clinical benefit.

EMERGING THERAPIES

Vaccine Strategies

Given the rare durable responses to cytokine therapy, investigators have searched for vaccine-based strategies. At this time, no vaccine has proven successful in rigorous phase III testing. Currently, two phase III trials are ongoing. The first trial compares a multi-peptide vaccine, IMA-901, paired with sunitinib versus sunitinib alone (NCT01265901). The second trial, the ADAPT phase III trial, involves a dendritic cell-based RNA vaccine, AGS-003, plus standard therapy versus standard therapy alone (NCT01582672).

Immune Checkpoint Inhibitors

A class of agents known as the immune checkpoint inhibitors has been developed allowing the targeting of molecules on both T cells and tumor cells important in downregulating the immune system, allowing for a sustained antitumor response. Agents including the cytotoxic T lymphocyte-associated antigen 4 antibody (anti-CTLA-4; ipilimumab) ⁽⁷⁶⁾ and the programmed death receptor-1 antibody (anti-PD-1; nivolumab and MK-3475) ⁽⁷⁷⁾ and its ligand antibody (anti-PDL-1; MPDL3280A) ⁽⁷⁸⁾ have shown significant, sustained antitumor responses in mRCC ⁽⁷⁹⁾.

Table 35-7 shows the available clinical results for these agents. The VEGF pathway has been found pre-clinically to play an important role in tumor microenvironment immunosuppression ⁽⁸⁰⁾. At this time, 10 ongoing studies are evaluating a variety of immune checkpoint inhibitors alone, in combination with other checkpoint inhibitors, or in combination with anti-VEGF therapy. Table 35-8 outlines the registered trials with these agents as of December 2014.

NON-CLEAR CELL RENAL CELL CARCINOMA

The large majority of studies performed to date excluded nccRCC. The exception was the phase III temsirolimus study, where 20% of the 626 patients had non-clear cell histology. A post hoc analysis of papillary RCC showed outcomes similar to ccRCC after treatment with temsirolimus ⁽⁸¹⁾. At MDACC, we conducted a phase II single-arm study of sunitinib in advanced nccRCC histologies including patients who had up to two previous lines of treatment and reported a median PFS of 2.7 months and an overall response rate of 5% ⁽⁸²⁾. Our group recently presented the findings of the ESPN randomized phase II clinical trial comparing everolimus to sunitinib for frontline systemic therapy in patients with metastatic non-clear

Table 35-7 Results of Clinical Trials of Immune Checkpoint Inhibitors in Patients With Metastatic Clear Cell Renal Cell Carcinoma

Check Point Inhibitor	Phase of Trial, Malignancy	Dosing	Response Rate in mRCC	Toxicity: Grade 3 or Higher
Ipilimumab ⁽⁷⁷⁾	Phase II, mRCC, any number of previous treatments allowed All risk groups	Arm A: 3 mg/kg \times 1 then 1 mg/kg Arm B: 3 mg/kg	1/29 (3.4%) 5/40 (12.5%)	14% 43%, 2 deaths
Nivolumab (anti-PD-1) ⁽⁷⁸⁾ Abstract only	Phase II, mRCC, one prior VEGF, \leq 3 prior therapies All risk groups	Arm A: 0.3 mg/kg Arm B: 2 mg/kg Arm C: 10 mg/kg	20% 22% 20%	5% 17% 13%
Nivolumab (Nivo) plus ipilimumab (Ipi) ⁽⁷⁹⁾ Abstract only	Phase I, mRCC No or any prior treatments allowed Good-/intermediate-risk groups only	Arm A: Nivo 3 mg/Ipi 1 mg Arm B: Nivo 1 mg/Ipi 3 mg Arm C: Nivo 3 mg/Ipi 3 mg	6/21 (29%) 9/23 (39%) Not available	24% 61% Not available
MPDL3280A (anti-PD-L1) ⁽⁸⁰⁾ Abstract only	Phase I, mRCC expansion cohort 83% prior treatment ccRCC and nccRCC	Dosing arms 3 mg/kg 10 mg/kg 15 mg/kg 20 mg/kg	Overall RR, 13% PFS, 50% at 24 wk	43% (13% attributed to study drug)

ccRCC, clear cell renal cell carcinoma; mRCC, metastatic clear cell renal cell carcinoma; mRCC, metastatic renal cell carcinoma; nccRCC, non-clear cell renal cell carcinoma; PFS, progression-free survival; RR, response rate; VEGF, vascular endothelial growth factor.

Table 35-8 Registered Clinical Trials With Immune Checkpoint Inhibitors in Metastatic Renal Cell Carcinoma

Trial Name ± Sponsor	Drugs	Phase and setting	Identifying Number
CheckMate 025 Bristol-Meyer Squibb (BMS)	Nivolumab (anti-PD-1) vs everolimus	Phase III, mccRCC pretreated with anti-VEGF	NCT01668784, accrual complete
CheckMate 214 BMS	Nivolumab + ipilimumab (anti-CTLA-4) vs sunitinib	Phase III, mccRCC, untreated	NCT02231749
MD Anderson with BMS	Nivolumab vs nivolumab + bevacizumab vs nivolumab + ipilimumab	Phase I, presurgical, eligible for cytoreductive nephrectomy	NCT02210117
GlaxoSmithKline (GSK)	Pazopanib vs MK3475 (anti-PD-1) vs pazopanib + MK3475	Phase I/II, mccRCC, untreated	NCT02014636
Beth-Israel Deaconess	CT-011 (anti-PD-1) ± vaccine	Phase II, mRCC (any histology), any prior number of therapies	NCT02014636
Hoffman-La-Roche	MPDL3280A (anti-PDL-1) ± bevacizumab	Phase II, untreated mccRCC	NCT01984242
BMS	Anti-LAG-3 ± anti-PD-1	Phase I, solid tumors	NCT01968109
Pfizer and Merck, Sharp & Dohme	MK3475 + axitinib	Phase I, mccRCC	NCT02133742
Keynote-029 Merck, Sharp & Dohme Corp.	MK3475 + pegylated IFN-2α MK3475 + ipilimumab	Phase I/II, mRCC eligible only for phase I portion, melanoma eligible for all portions	NCT02089685
Merck, Sharp & Dohme Corp.	MK3475	Phase I, presurgical	NCT02212730

IFN, interferon; mccRCC, metastatic clear cell renal cell carcinoma; mRCC, metastatic renal cell carcinoma; VEGF, vascular endothelial growth factor;

cell histologies⁽⁸³⁾. The primary end point was PFS after first-line treatment. The trial was stopped early due to futility of satisfying the primary end point, with a median PFS of 4.1 months with everolimus compared to 6.1 months with sunitinib. Foretinib, a c-MET, RET, and VEGFR-2 inhibitor, was tested with two different dosing schedules in a phase II trial enrolling patients with papillary RCC⁽⁸⁴⁾. The study found an overall response rate of 13.5% and a median PFS of 9.5 months, and foretinib is no longer being developed in this setting. Of note, a subset of 10 patients with a germline *c-MET* mutation had a 50% response rate, and alternative c-MET inhibitors should be explored in this setting. An actuarial 45-patient trial evaluating erlotinib in papillary RCC showed a response rate of 11%, and an OS of 27 months⁽⁸⁵⁾. Unfortunately, choosing the right agent for this relatively heterogeneous group of patients is hampered by a lack of studies and relatively small patient numbers. With the paucity of available data for clinical treatment decisions, we recommend enrolling patients with non-clear cell histologies on clinical trials when available.

Sarcomatoid Renal Cell Carcinoma

Approximately 5% of all patients with RCC will demonstrate sarcomatoid dedifferentiation in their tumors⁽⁸⁶⁾. Varying percentages of sarcomatoid involvement can be seen, and in cases where there is a predominance of sarcomatoid cells, it is difficult to determine the underlying histologic background. In these extreme cases, epithelial tumor markers are still present on the tumor cells, distinguishing these tumors from sarcomas.

Presence of sarcomatoid features in the tumor portends a poor prognosis⁽⁸⁷⁾. The results of chemotherapy and immunotherapy have been largely disappointing in patients with metastatic disease. Therapy targeting VEGF has been retrospectively reviewed, and in a series of 43 patients from several institutions, this approach had limited utility, with a median PFS of 5.3 months and median OS of 11.7 months⁽⁸⁸⁾. At MDACC, we retrospectively reviewed 28 patients with mRCC who received the combination of gemcitabine, capecitabine, and bevacizumab, including 8 patients with sarcomatoid features, and reported a median PFS

of 5.9 months and a median OS of 10.4 months. These observations formed the basis of a prospective study at MDACC using this three-drug combination in patients with sarcomatoid histology. Preliminary findings from this study in the first 18 patients treated (out of a planned 40 patients) revealed time to treatment failure of 5.5 months and median OS of 12 months.

Collecting Duct Carcinoma

Tumors arising from the collecting duct epithelium are located in the medulla or center portion of the kidney, in contrast to RCC tumors, which arise from tubules in the cortex⁽⁸⁹⁾. The diagnosis of CDC is based on both clinical and histologic features. Sarcomatoid dedifferentiation is not uncommon, and patterns of metastasis are similar to those of a high-grade, rapidly progressive RCC. There is no established effective systemic therapy for metastatic CDC, although marginal benefit is occasionally seen with chemotherapy regimens developed for transitional cell carcinoma^(90, 91).

Medullary Carcinoma

Renal medullary carcinoma is a rare and virulent malignancy, afflicting patients with sickle cell hemoglobinopathies, usually sickle cell trait⁽⁹²⁾. It arises from the caliceal epithelium and can be morphologically distinguished from RCC and CDC. Some investigators have suggested that it is a dedifferentiated form of transitional cell carcinoma. Other kidney disorders associated with sickle cell hemoglobinopathies include unilateral hematuria, papillary necrosis, nephrotic syndrome, renal infarction, inability to concentrate urine, and pyelonephritis. These associated conditions may contribute to the development of renal medullary carcinoma. The majority of cases reported have a highly aggressive clinical course, presenting with metastatic disease and with a survival historically of about 4 months. It is refractory to most forms of systemic therapy⁽⁹³⁾, with some responses to cytotoxic chemotherapy.

Outcomes of patients with renal medullary carcinoma treated at four institutions found the median OS for all patients to be approximately 1 year from diagnosis⁽⁹⁴⁾. Of 16 patients who received targeted therapy, one response was noted. An updated effort from seven institutions that evaluated clinical outcomes for 39 patients with renal medullary carcinoma was presented in abstract form at the 2015 Genitourinary Cancer Symposium⁽⁹⁵⁾. Again, the median OS was 1 year, with the majority of patients presenting with advanced disease. Of seven patients who received presurgical treatment, one patient had a complete response, three had a partial response, and three had

stable disease. The patient with the complete response had a near-complete pathologic response at the time of nephrectomy and remains without evidence of disease 27 months after diagnosis. Continued efforts to gain insight into the biology of this devastating entity are ongoing. In our experience, initial systemic therapy with chemotherapy with or without the addition of bevacizumab is a reasonable initial approach.

Xp11.2 Translocation Carcinoma

Xp11.2 translocation carcinoma is a rare disease entity that is proportionally more common in children but can also occur in young adults⁽⁹⁶⁾. A strong female predominance is observed. The *TFE3* gene located at Xp11.2 has a number of potential translocation partners leading to fusion of a novel gene. A recent analysis of 16 patients with translocation RCC found significant genomic heterogeneity, with 17q gain, 9p loss, 3p loss, and 17p loss being the most common findings⁽⁹⁷⁾. Histologically, these tumors may resemble ccRCC or show mixed clear and papillary features. These histologic findings in a young adult should prompt further histologic and molecular characterization of the tumor. Staining for *TFE3* permits relatively specific identification of this disease entity, but if it is highly suspected, a break apart fluorescent in situ hybridization assay should be used to increase sensitivity^(98, 99). Response to standard immunotherapy or chemotherapy is poor, and patients have a relatively short OS. A retrospective review of 15 adult patients (12 females; median age, 40 years) with translocation carcinoma who were treated with targeted therapy at four centers in the United States showed an overall response rate of 20%, with a median PFS of 7.1 months and median OS of 14.3 months⁽¹⁰⁰⁾. A French study reported on 21 patients with adult translocation carcinoma treated with anti-VEGF agents or mTOR inhibitors. The authors reported objective responses, PFS, and OS results in the range of those previously reported for ccRCC⁽¹⁰¹⁾.

CONCLUSION

Figure 35-4 succinctly outlines the current approach at MDACC for diagnosing and treating patients with a renal mass. With rapidly improving understanding of the biology of RCC, better patient selection and surgical techniques, an enriched arsenal of targeted agents, and the promise of new immunotherapy agents in late-phase clinical testing, the future of treatment for patients with RCC appears bright. We need to continue to focus on patients in the poor-risk clinical prognostic categories with metastatic clear cell carcinoma

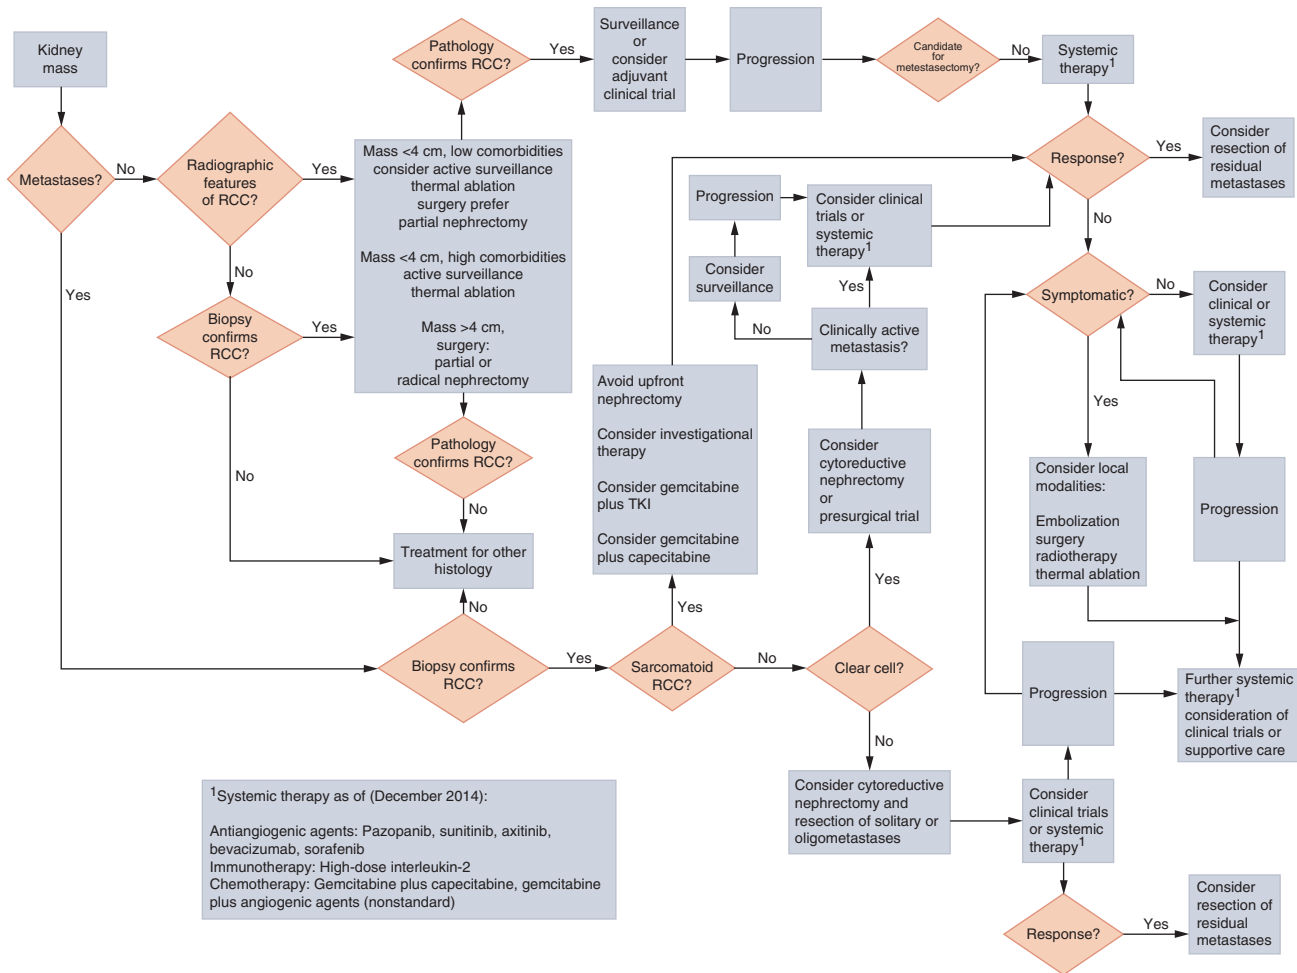

FIGURE 35-4 Management algorithm for patients diagnosed with a renal mass. RCC, renal cell carcinoma; TKI, tyrosine kinase inhibitor.

and patients with non-clear cell histologies because these represent major areas of unmet clinical need.

Bladder Cancer

Arlene O. Siefker-Radtke

Bogdan A. Czerniak

Colin P.N. Dinney

Commentary: David J. McConkey

Expectant optimism is now pervading the field of urothelial cancer as we anticipate that we will soon be soaring above the plateaus established with cisplatin-based chemotherapy in the 1980s and finally have new agents approved for the treatment of urothelial carcinoma. Immune checkpoint inhibitors, which are transforming the field of oncology, are showing evidence of clinical activity in early clinical trials in this disease (¹). In addition, there are several ongoing trials of targeted agents including fibroblast growth factor (FGF) receptor inhibitors and vascular endothelial growth factor (VEGF) inhibitors currently in clinical trials with the goal of obtaining US Food and Drug Administration (FDA) approval. Our fundamental understanding of the biology of urothelial cancer is changing as well, with molecular characterization suggesting that urothelial cancer is no longer only one disease (²). These nascent technologies suggest we will soon be able to personalize therapy for urothelial cancer and reliably predict which patients will benefit from specific chemotherapy and/or other targeted agents, transforming our current treatment of urothelial cancer.

OVERVIEW

The urinary tract conveys urine from the confluence of urinary tubules in the renal papillae to the outside world. This entire path is lined by a specialized epithelial surface known as the urothelium, which is composed primarily of transitional cells, and extends from the renal pelvis through the ureters, bladder, and

urethra. In males, it also lines the terminal prostatic ducts and prostatic urethra. Although tumors arising from the urothelium can involve any organ along this path, about 90% of these cancers arise in the urinary bladder.

EPIDEMIOLOGY

Urothelial cancer is the fifth most common cancer diagnosis in the United States and is strikingly related to cigarette smoking. In 2015, about 80,000 new cases were expected, with about 74,000 arising in the bladder. Altogether, these cases account for just over 18,000 deaths (³). These incidence figures are somewhat misleading, however, because it is a historical anomaly that only in the bladder are histologically bland hyperplastic lesions counted as cancers. In other sites, such lesions would be counted as benign or at most premalignant, and thus the incidence figures include many patients with lesions that do not meet the conventional definition of malignancy. Imagine what the incidence figures for colon cancer would be if every patient with a polyp was counted as a case of colon cancer! Many such lesions recur; however, few progress to true malignancy. Thus, it is critically important to separate risk models that are designed to predict recurrence from those that predict progression, which is far more biologically significant. Because of this anomaly of classification, the literature on “risk of bladder cancer,” both for incidence and recurrence, must be interpreted very carefully.

In contrast to most other carcinomas, the majority of patients with urothelial cancer (even after excluding the low-grade papillary “cancers”) have early-stage, potentially curable disease at presentation. Only about 20% of patients present with disease that invades into the muscle wall. Fewer than 5% of patients present with locally advanced (ie, clinically extravesical) disease, and another 5% or so present with clinically apparent metastatic disease. Once clinically metastatic, urothelial cancer is remarkably aggressive, exhibiting a natural history reminiscent of small cell carcinoma of the lungs: untreated, the survival is measured in weeks; it is markedly chemotherapy sensitive; responses are typically short lived; the brain is a typical “sanctuary” site of relapse after response to initial therapy; and cure of patients with distant metastases, although well documented, remains anecdotal.

The ready accessibility of urine and the fact that the urothelium itself can be accessed via minimally invasive cystoscopy makes urothelial cancer an important context for understanding the processes of carcinogenesis and clonal evolution and an important platform for the development of human gene therapy.

The current state of the art is rather sobering:

- Careful patient selection has made it possible for some patients to have organ preservation, but this strategy clearly results in some patients dying unnecessarily.
- Although the combination of chemotherapy and surgery does improve the cure fraction for patients with locally advanced disease, a disturbing fraction (30%-40% even at referral centers) of patients with invasive disease but no detectable involvement beyond the bladder at the time of diagnosis still succumb to the disease.
- There have been no substantive advances in systemic treatment since the introduction of methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC) in the early 1980s, and indeed, reported outcomes for patients with metastatic urothelial cancer are getting worse as marginally effective systemic therapies (such as gemcitabine and carboplatin) are now widely used.

However, there is optimism for the following reasons:

- Recent developments in immunology with checkpoint inhibitors suggest their utility in urothelial cancer.
- The molecular characterization of urothelial cancer may help us choose which patients are most likely to benefit from a specific therapy, leading to a personalized approach to care.

CLASSICAL EPIDEMIOLOGY

Malignant transformation of the urothelium parallels observations with other epithelial tumors ⁽⁴⁾, in that it is distinctly uncommon before age 40 and has a peak incidence in the seventh decade. The male-to-female ratio is about 3:1, reflecting, in part, differences in exposure to smoking and industrial toxins. Malignant transformation is the result of a multistep process in which multiple genes are implicated. The appearance of clinical cancer typically follows carcinogenic exposure by decades. Fluid intake is inversely associated with risk ⁽⁵⁾, supporting the concept that contact time of excreted carcinogens with the urothelial surface contributes to carcinogenesis.

There is a striking correlation of urothelial cancer incidence with exposure to certain environmental toxins. About half of all cases are related to smoking. Industrial exposures, especially to petrochemicals, account for another 10% to 15%. Many occupations with “chemical” exposures have been linked to an excess risk of urothelial cancer. An association with aniline dye exposure was noted more than a century ago, and many aromatic amines (prototypically β -naphthyl amine) have now been shown to be potent urothelial carcinogens. Cigarette smoke is rich in both aromatic amines and the highly reactive bladder toxin acrolein. Another source of acrolein, which is strongly linked to urothelial carcinogenesis, is the metabolism of cyclophosphamide and ifosfamide. In one report, prolonged exposure to oral cyclophosphamide (as was a common intervention for some forms of cancer and for autoimmune disease in the 1970s) increased the risk of bladder cancer by a factor of nine ⁽⁶⁾. Also noteworthy are exposures to the analgesic phenacetin and to the plant toxin–related “Balkan nephropathy” in which the risk of upper tract tumors is increased ^(7,8).

As is generally true for epithelial carcinogenesis, chronic irritation and inflammation have also been associated with malignant transformation. This is seen prototypically in settings such as staghorn calculus and other cases of chronic urolithiasis, chronic bladder catheterization (a particularly distressing complication of spinal cord injury ⁽⁹⁾) or congenital malformations), and classically, chronic schistosomiasis in the Middle East. Urothelial cancers that arise in the context of chronic irritation typically show squamous differentiation.

Molecular Epidemiology

Assessment of genomic variations, as well as functional assessment of certain metabolic pathways, is now routinely integrated with classical aspects of cancer risk assessment. As might have been anticipated from the classical epidemiologic studies of

environmental exposures, it has now been confirmed that polymorphisms of various genes involved in xenobiotic metabolism are correlated with the risk of developing bladder cancer. However, these pathways are complex, and the impact of genetic changes is of course context dependent. A classic example of this is provided by *N*-acetyltransferase 2 (NAT-2)-mediated *N*-acetylation, which constitutes a detoxification step for some carcinogens but can be an activation step for others^(10, 11). A meta-analysis suggests a possible role for some of these variants in risk of bladder cancer and clearly demonstrates an interaction with smoking status⁽¹²⁾, as would be expected on the hypothesis that these genes are important for the response to smoking-induced DNA damage⁽¹³⁾.

Telomere length, which also contributes to the maintenance of genetic integrity, may also be relevant to urothelial carcinogenesis because patients with bladder cancer have been found to have shortened telomeres or telomerase abnormalities^(14, 15).

TUMOR BIOLOGY

Carcinogenesis

A dual track concept has been proposed in urothelial cancer carcinogenesis (Fig. 36-1)⁽¹⁶⁾. The majority of urothelial cancers, approximately 80% to 85%, arise from a hyperplastic epithelium and most commonly present as low-grade papillary tumors. Although these tumors tend to recur, they are much less likely to evolve into a more aggressive form of urothelial cancer. Earlier studies suggested that preservation of E-cadherin expression is classic in these tumors and associated with a low risk of recurrence⁽¹⁷⁾, with additional studies suggesting that ratios of E-cadherin to matrix metalloproteinase-9, which is a surrogate for epithelial to mesenchymal transformation (EMT), are inversely correlated with outcome^(18, 19). Additional proliferative drivers including FGF receptor (FGFR)-3 have been observed in a much higher frequency in

FIGURE 36-1 Dual track pathway of urothelial cancer. CIS, carcinoma in situ; TCC, transitional cell carcinoma. (Reproduced with permission from Dinney CP, McConkey DJ, Millikan RE, et al: Focus on bladder cancer, *Cancer Cell* 2004 Aug;6(2):111-116.)

these superficial papillary urothelial cancers of low malignant potential⁽²⁰⁾.

Because the bladder is readily accessible, with most patients presenting before life-threatening progression is apparent, bladder cancer is well suited for studying the details of the molecular pathogenesis of transformation, invasion, and metastasis. Molecular genetics investigations have revealed that numerous loci are lost and have confirmed that clonal expansion is an early event; that is, morphologically normal urothelium in bladders harboring urothelial tumors is genetically altered, and multifocal disease generally represents multifocal expansion of a preexisting clonal lesion⁽²¹⁾. Thus, the classical notion of “field carcinogenesis” is amply confirmed by these molecular genetic studies. These studies demonstrate that early carcinogenesis involves relatively few key loci that provide the fertile context for more generalized chromosomal instability that is apparent in grossly established invasive tumors.

Following along the dual track concept of bladder carcinogenesis, the nonpapillary pathway is associated with early genetic instability (see Fig. 36-1). These flat, infiltrative tumors typically behave more aggressively and invade the muscularis propria with a much higher probability of impacting survival. Loss of the retinoblastoma gene (*RB*) or any inactivation of *RB* function is clearly associated with an adverse prognosis in these tumors⁽²²⁾. The *p53* gene is also frequently mutated in these tumors⁽²³⁾ and appears to interact with *RB*⁽²⁴⁾. Abnormal *p53* immunohistochemical staining is highly correlated with a nonfunctional mutation associated adverse prognosis⁽²⁵⁾.

Tumors from the nonpapillary pathway typically have mesenchymal features associated with their invasive nature. However, recent studies suggest that the EMT concept is indeed more complex as some epithelial markers, including TP63 expression, have been associated with adverse outcome in the setting of invasive disease^(26, 27). TP63 expression has been noted to be at high levels within the basal layer of the urothelium, which typically contains the stem cell compartments. In addition, most *p63* isoforms are felt to act as dominant negatives, potentially suppressing *p53*-dependent transactivation⁽²⁸⁾. Recent studies using gene expression profiling continue to suggest a strong role for *p63* controlling basal gene expression in these lethal basal tumors⁽²⁾.

Recently, three distinct subtypes of urothelial cancer have been identified using gene expression profiling (GEP) (Fig. 36-2)^(2, 29). Basal urothelial carcinomas, which have immunohistochemical markers associated with the basal layer, are often characterized by TP63 activation and rapid proliferation with more aggressive disease and may be prognostic for poor outcomes. The angiogenic signature is expressed in the basal subtype. Luminal urothelial carcinomas, which share

immunohistochemical markers associated with the umbrella cell layer, show evidence of PPAR γ activation. Enrichment of *FGFR3* mutations has been noted in this group of tumors. A third group of *p53*-like urothelial cancers show a high degree of resistance to typical chemotherapy agents and are associated with a stromal infiltrate. A recent series of patient treated on clinical trial suggests a high incidence of bone metastasis in this subtype (in press, *Eur. Urol.*). Furthermore, data from this clinical trial suggest that clinical outcomes are improved when the basal subtype tumors are treated with neoadjuvant chemotherapy, suggesting this is a potential predictive marker for clinical outcomes. Therefore, subtyping strategies may aid in the development of personalized treatment for urothelial cancer and appropriate selection of patients for systemic chemotherapy and specific targeting agents.

Novel Therapeutic Targets

The use of immune checkpoint inhibitors appears to be transforming the world of cancer, including the field of urothelial cancer. Early results from clinical trials suggest that response rates with programmed cell death (PD)-1 inhibitors maybe as high as 20% to 40%⁽¹⁾. Combined checkpoint inhibition using PD1 inhibitors in combination with cytotoxic T lymphocyte-associated antigen 4 (CTLA4) antibodies potentially may yield improved responses, although trials are still accruing in this group of patients. Expression of PD ligand 1 (PDL1) either on the tumor cell or on the lymphocyte infiltrate has been proposed as one method of determining which patients are most likely respond to checkpoint inhibition. Because the response rates in PDL1 negative disease maybe anywhere from 15% to 20% and PDL1 expression is dynamic and may be influenced by chemotherapy and intravesical agents including bacillus Calmette-Guérin (BCG), the clinical utility of this biomarker remains problematic. Approval of a checkpoint inhibitor in the treatment of urothelial cancer is an event that is highly anticipated and will likely be the first novel agent approved for urothelial cancer in more than 20 years.

The FGFR inhibitors are also showing promise, with early phase I studies suggesting response rates as high as 40% to 50% in patients with *FGFR3* mutations or translocations. Although FGFR mutations and translocations are predicted to occur in less than 20% of muscle-invasive bladder cancers, approvals of such agents may also play a role in earlier stage disease where the presence of these mutations maybe as high as 50%. Trials are currently accruing in the second-line setting in hopes of obtaining FDA approval.

Angiogenesis inhibitors still remain of interest in the treatment of urothelial cancer. Early studies suggested that overexpression of VEGF was associated with

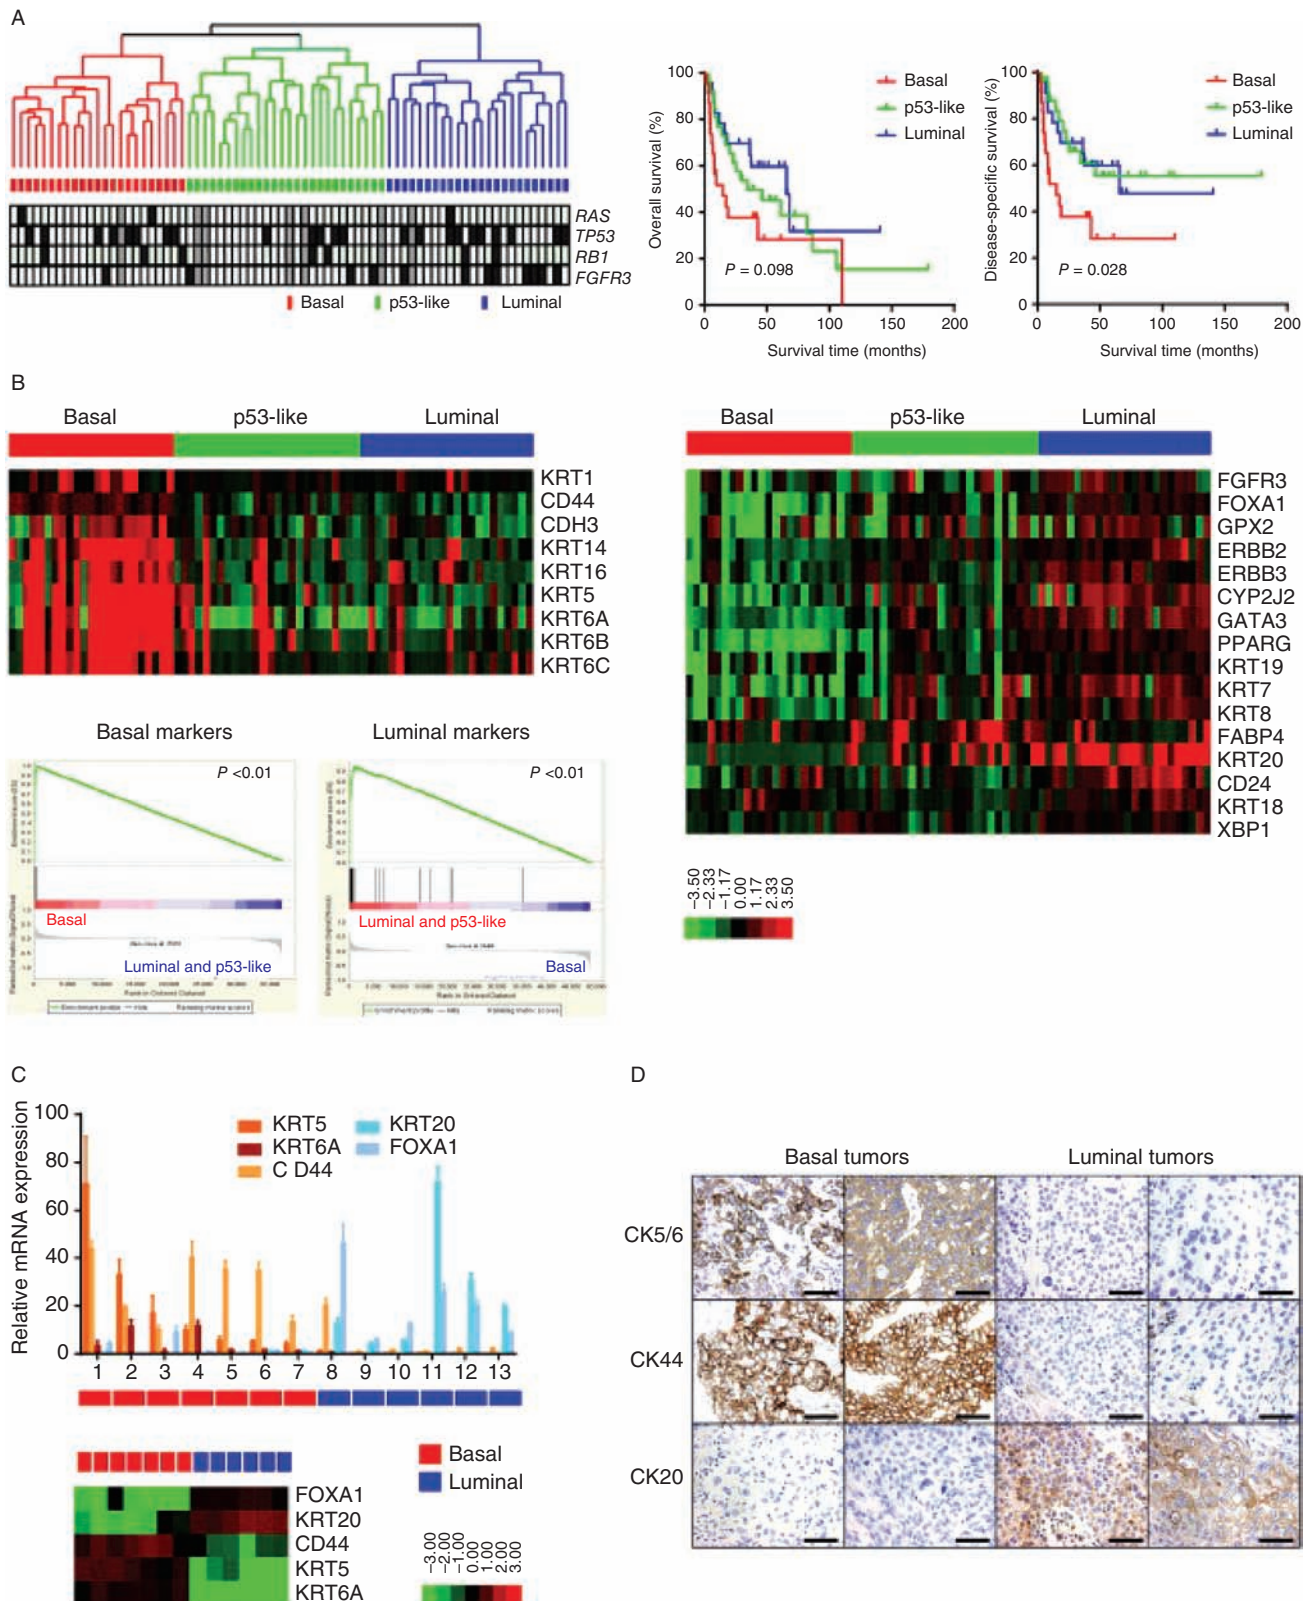

FIGURE 36-2 Molecular characterization of bladder cancer suggesting three intrinsic subtypes: basal, luminal, and p53-like. (Reproduced with permission from Choi W, Porten S, Kim S, et al: Identification of distinct basal and luminal subtypes of muscle-invasive bladder cancer with different sensitivities to frontline chemotherapy, *Cancer Cell* 2014 Feb 10;25(2):152-165.)

adverse outcomes and poor prognosis in patients treated with neoadjuvant chemotherapy⁽¹⁸⁾. One mouse model suggested that these effects could be enhanced when angiogenesis inhibitors are combined with taxanes⁽³⁰⁾. Preliminary results of a randomized phase II trial of docetaxel plus or minus the VEGF inhibitor ramucirumab suggested an improvement in progression-free survival for the combination as a second-line therapy for metastatic urothelial carcinoma⁽³¹⁾. A frontline trial of gemcitabine with cisplatin plus or minus bevacizumab is still completing accrual. Phase II results were promising, with an objective response rate of 72% and a median overall survival (OS) of 19.1 months⁽³²⁾. In the neoadjuvant setting, a trial of dose-dense M-VAC with bevacizumab showed pT0N0 rates of 39%, with 5-year OS and disease-specific survival rates of 63% and 64%, respectively⁽³³⁾. Using GEP to molecularly characterize the tumors from this trial, we found that the 5-year survival for the basal subtype was 91% (in press, *Eur. Urol.*). Because the angiogenic signature is enriched in the basal subtype, one would hypothesize that to promote personalized medicine in urothelial cancer, future studies should focus on enrichment of basal tumors on clinical trials of antiangiogenic therapies.

Histology

In the United States, approximately 90% of all urothelial malignancies are within the histologic spectrum of transitional cell carcinoma (TCC), which, in our view, merges without obvious demarcation with the sarcomatoid and small cell variants at the extreme of dedifferentiation. Most of the remainder exhibit squamous histology (especially prominent in the more distal urethra) or glandular differentiation (ie, adenocarcinoma). The finding of adenocarcinoma apart from the context of bladder exstrophy or a urachal tumor (see below) should prompt consideration of metastatic disease from some other primary site because bona fide primary adenocarcinomas originating from the urothelium are distinctly uncommon.

As noted earlier, primarily hyperplastic lesions, biologically akin to polyps in the gastrointestinal tract, account for a large portion of incident cases. In 1999, the World Health Organization (WHO) put forward a new classification of noninvasive papillary urothelial tumors in recognition of the fact that the malignant potential of these lesions varies widely⁽³⁴⁾. The WHO terminology for these lesions, which together account for more than half of all new cases of urothelial neoplasia, is as follows:

Papillary urothelial neoplasm of low malignant potential. This lesion is characterized by orderly progression of morphology within the urothelium and

no cellular atypia. Recurrence is seen in about 25% of cases, but progression is rare.

Noninvasive papillary urothelial carcinoma, low grade. This lesion shows some architectural variation and mild atypia. Such lesions commonly recur (in 50% or more of cases), but progression is seen in only 5% to 10%. It is classified by the WHO as a borderline tumor.

Noninvasive papillary urothelial carcinoma, high grade. This lesion shows predominantly disorganized architecture and moderate to marked cytologic atypia. Such lesions do not invade below the basement membrane, but they have substantial biologic potential, with progression to invasive, potentially life-threatening disease in up to 65% of cases. These are classified by the WHO as malignant. Note that in the WHO system, grades are collapsed to a two-tier system of low grade and high grade. In general, this would map to the older three-tier system as follows: grade 1 = low grade and grades 2 and 3 = high grade.

In contrast to these papillary cancers, some urothelial cancers exhibit dysplasia and chromosomal instability early on and constitute a “second pathway” of carcinogenesis^(16,35,36), and most of the cases with lethal potential are in this class (see Fig. 36-1). In contrast to the classic “mulberry” appearance, the nonpapillary lesions have a grossly flat or infiltrative appearance at cystoscopy. In older literature, such cancers have been known as *flat*, *sessile*, *solid*, or *tentacular*. Currently, the preferred nomenclature is simply *nonpapillary*, although *flat* persists in the American Joint Committee on Cancer (AJCC) *Cancer Staging Manual* (seventh edition). These morphologic differences were noted long before an understanding of the genetic changes associated with cancer was appreciated. As expected for such distinct phenotypes, the characteristic genetic lesions have been found to be distinct.

In addition to papillary and nonpapillary variants, a *micropapillary* pattern is increasingly recognized⁽³⁷⁻⁴⁰⁾. The term *micropapillary* originally came from the recognition of morphologic resemblance to an aggressive variant of ovarian cancer. Indeed, this general histologic pattern has been reported in many epithelial malignancies and invariably identifies a more aggressive subset, as was first reported for bladder cancer in 1994. Thus, the biologic potential of urothelial neoplasia extends from relatively nonthreatening in papillary lesions, to potentially life-threatening in nonpapillary lesions, to remarkably aggressive micropapillary lesions, all of which are recognizable as TCC.

Depending on the series, about 30% (or more) of muscle-invasive urothelial cancers are found to have focal areas of squamous or glandular morphology when examined in detail. It is not clear that such “mixed” tumors have a different prognosis than “pure”

TCC, and we do not consider this a meaningful subset at University of Texas MD Anderson Cancer Center (MDACC). Certainly, tumors with only focal areas of squamous or glandular differentiation do not exhibit the distinctive natural history of pure squamous cancers or pure adenocarcinomas. Primary nonepithelial cancers (eg, sarcomas, lymphomas, melanomas) are exceedingly uncommon in the bladder. When they do occur, they do not appear to have a distinctive natural history or clinical management from what would be expected of similar tumors arising in more typical sites.

Urothelial cancers can dedifferentiate to include spindle (“sarcomatoid”), small cell, and plasmacytoid variants. In these cases, the clinical expression of the overall disease process is dominated by the aggressive component, even if most of the primary cancer is well within the typical morphologic spectrum of TCC.

Small cell carcinoma of the urothelium is a remarkably aggressive malignancy and exhibits a similar propensity for spread to the brain as small cell carcinoma arising in other sites. Even in the setting of clinically localized disease, the prognosis with local therapy alone remains poor, reflecting the early development of micrometastases. We strongly favor management of patients with cT2 or lower disease that is based on neoadjuvant chemotherapy, followed by surgical consolidation^(41,42). In our hands, this provides about 70% cure^(42,43). Patients with locally advanced disease have a high incidence (8 of 16 patients in our series) of relapse in the brain⁽⁴³⁾, and thus, we feel these patients are candidates for prophylactic cranial irradiation. Patients with metastatic disease at presentation continue to have nearly a 100% response rate, with a 100% relapse rate and a median survival of only 11 months⁽⁴³⁾.

Plasmacytoid urothelial cancer is a rare histology with limited series reported to date⁽⁴⁴⁾. These tumors typically appear mesenchymal with downregulation of E-cadherin^(45,46) and consist of poorly cohesive tumor cells with perinuclear clearing reminiscent of plasma cells^(46,47). They also tend to be highly proliferative with abundant mitosis and staining for Ki-67. These tumors tend to have a unique spread pattern, often appearing as a linitis plastica with diffuse thickening of the bladder and rectum. Although plasmacytoid tumors appear to be sensitive to chemotherapy, even in the neoadjuvant setting with adequate downstaging to pathologic T0 disease, there are few long-term survivors⁽⁴⁴⁾. These tumors have also been shown to have a high incidence of recurrence in the peritoneum (>50% of patients)⁽⁴⁴⁾.

Cancers arising in a urachal remnant, although not strictly “bladder cancers” in the sense of this chapter, merit a comment. These cancers typically involve the dome of the bladder and histologically are enteric-type adenocarcinomas. They are thought to reflect malignant transformation of an enteric epithelial rest

within the urachal remnant, producing a cancer readily recognized as a mucinous adenocarcinoma⁽⁴⁸⁾. An early MDACC series suggested that the risk of relapse was increased when an en bloc resection was not performed and in the setting of positive margins, lymph node involvement, and tumor involving the peritoneal surface⁽⁴⁹⁾. The Memorial Sloan-Kettering Cancer Center experience in 50 patients demonstrated long-term survival in 26 (93%) of 28 patients with pathologically localized disease, in 9 (69%) of 13 patients with extension through the bladder or urachal cavity, and in none of 9 patients with peritoneal involvement initially⁽⁵⁰⁾. Similarly, the Mayo Clinic experience⁽⁵¹⁾ in 49 patients demonstrated apparent cure in the majority of patients with confined disease and relapse in the majority of patients with nonconfined disease, with the latter group having a median survival of only 16 months⁽⁵²⁾. All investigators have emphasized the importance of an attempt at margin-negative, en bloc resection if at all possible.

Urachal cancers have a tendency to recur locally, often with peritoneal carcinomatosis, and the typical metastatic sites are (about equally) the lungs and liver. Although dramatic responses are infrequent, the use of modern combination regimens with activity in enteric adenocarcinoma is associated with about a 40% objective response rate. Thus, in essentially every clinical respect, urachal cancer behaves like colon cancer and, based on the available data, should be treated accordingly. Median survival from the recognition of metastases was 24 months in our retrospective series of 26 patients with metastatic disease, although some patients with grossly metastatic disease have been long-term survivors⁽⁴⁹⁾.

DIAGNOSIS, STAGING, AND PROGNOSIS

Presentation

About 80% of patients present with hematuria, usually painless. The “typical” patient is a smoker in his late 60s. Such patients frequently suffer from pulmonary disease and cardiovascular disease, magnifying the morbidity of both chemotherapy and surgery. They are also at high risk for other smoking-related malignancies. A high percentage of patients have diminished renal function as a result of hypertension and obstructive nephropathy. Thus, the use of nephrotoxic chemotherapy is especially challenging in this population. Hospitalization and meticulous attention to detail are typically required to safely deliver multiple cycles of cisplatin- or ifosfamide-based therapy.

Irritative voiding symptoms, including frequency, dysuria, and dribbling, are important points in the

medical history because the presence of irritative symptoms raises the possibility of extensive carcinoma in situ (CIS) or large, infiltrative tumors that may be far more extensive than is revealed by the initial cystoscopy. Obstructive symptoms (nocturia, double voiding, overflow incontinence, low anterior abdominal pain) are often encountered from tumors of the bladder neck or prostatic urethra. Tumors in these locations are far less likely to be anatomically confined (ie, curable with surgery) than are similarly muscle-invasive bladder cancers that are well away from these areas where the detrusor muscle is discontinuous.

In evaluating patients presenting with hematuria, it is mandatory to evaluate the upper urinary tracts. Even if a bladder tumor is confirmed on initial cystoscopy, excretory urography is still appropriate because synchronous or metachronous tumors of the upper tracts typically are not associated with specific symptoms.

Recently, several urine tests for cancer-associated antigens have been promulgated for diagnosis. None of these tests is yet sensitive and specific enough to replace cystoscopy and biopsy. The role of these tests for widespread screening is also not defined. Likewise, the role of urine cytology in initial diagnosis is unsettled. The yield is highly dependent on sample collection technique and the skill of the cytopathologist. As with many epithelial cancers, it is likely that DNA-based tests will eventually be widely used to find pathognomonic genetic alterations in urine and thus revolutionize the detection and clinical follow-up of bladder cancer. The role of some form of surveillance in high-risk populations (such as petrochemical workers) remains controversial. The relatively low positive and negative predictive value of cytology, even when applied to a high-risk group, makes such screening difficult to justify.

Stage and Prognostic Classification

Excepting the extremes of histology (eg, small cell), the dominant prognostic clinical variable is anatomic stage at diagnosis. Classically, this is defined by depth of invasion. The currently used staging system is summarized in Fig. 36-3. This system is, of course, historically rooted in pathologic findings related to cystectomy specimens. As a result, it is not well suited for *clinical* staging. For example, the distinction between deep muscle invasion (T2b) and more superficial muscle invasion (T2a) cannot be reliably made by cystoscopic biopsy, and indeed the differentiation of muscle fibers in the lamina propria from muscularis propria (ie, the distinction between deep cT1 and cT2) is often problematic. As with most solid tumors, one must be extraordinarily careful regarding staging information, especially when comparing surgical and radiotherapy series, which necessarily rely on different primary information.

FIGURE 36-3 Current scheme for tumor (T) staging of urothelial cancer. EUA, examination under anesthesia.

Unfortunately the AJCC staging system does not account for available information about tumor biology. Although “staging” has come to be understood as “prognostic assessment” for most cancers, urologic oncology lags behind in laying aside the historical notion of stage as essentially an anatomic concept. As noted earlier, the biology of papillary cancers is fundamentally different from that of nonpapillary cancers. Other biologic characteristics such as location of tumor within the bladder, the presence or absence of lymphovascular invasion, and the presence or absence of specific markers are known to influence prognosis, and thus, there is a significant need to fully evaluate and standardize how such features are reported.

A suggested refinement to the currently dominant AJCC system relates to the subdivision of cT1. Several ways of doing this have been suggested, including measuring the depth of invasion (with a break point at 1.5 mm) or determining whether muscle fibers consistent with muscularis mucosa are invaded (T1b) or not (T1a). Although many subspecialty pathologists have found such a subdivision to be strongly prognostic⁽⁵³⁾, it is not yet widely reported, and there are questions about both intra- and interobserver variability^(54, 55). We tend to think of the commonly reported “extensive involvement” of lamina propria as a useful way of identifying higher risk cT1 disease. What is clear is that there is significant variability of prognosis among patients with cT1 disease, and better ways of refining this group remain a worthy goal for clinical investigators.

Although there is no official system for *clinical* staging, there are several important factors that largely define prognosis that can be reasonably well assessed by clinical evaluation:

- The presence or absence of muscle invasion (ie, T1 vs \geq T2). This is fairly reliably established by transurethral resection (TUR), especially if the surgeon provides deep enough samples that contain muscularis propria.
- The presence or absence of a definable mass (ie, assessable in three dimensions) by examination

under anesthesia (EUA) following a complete TUR. This is the clinical definition of cT3b disease and is of critical prognostic importance. The role of cross-sectional imaging criteria for cT3b disease is controversial. We do not believe that routinely available studies can make this distinction reliably at the present time. The EUA is an essential component of the evaluation of a patient with muscle-invasive bladder cancer⁽⁵⁶⁾ and is most informative when it is done following drainage of the bladder once the TUR has been completed. A proper EUA provides important staging information complementing data obtained by imaging modalities such as computed tomography (CT) scan or magnetic resonance imaging (MRI). The presence of induration indicates deep muscle invasion, whereas the palpation of a discreet, mobile, three-dimensional mass implies gross invasion into extravesical tissue and carries a significant risk (30%-40%) of occult lymph node metastasis. At EUA, it is possible to identify masses extending directly into the prostate in men or into the vagina in women. These findings are also associated with a high risk of occult lymph node metastasis. The finding of a mass by EUA that extends and is fixed to the pelvic sidewall (ie, cT4b) indicates an unresectable cancer. These patients have a similar prognosis to those with overt distant metastases.

- The presence or absence of nodal disease, as assessed clinically by CT or MRI imaging of the pelvis. Patients with radiographically detectable adenopathy should have a biopsy prior to surgery. If positive, primary chemotherapy is appropriate, because distant recurrence dominates the clinical course in these patients. That being said, we certainly advocate surgical consolidation with cystectomy and pelvic node dissection in patients with no clinical evidence of disease after chemotherapy.
- The presence or absence of lymphovascular invasion (LVI) on the TUR biopsy specimen is also a powerful prognostic feature. Although it must be admitted that TUR samples are often difficult to assess secondary to crush and cautery artifact, the unequivocal finding of tumor cells in vascular spaces identifies a group of patients with a high risk of occult nodal involvement. In fact, LVI is associated with a risk of pN+ status of about 35%, comparable to the risk associated with a large cT3b tumor. (It should be noted that tumors in the dome are both difficult to completely resect by TUR and more difficult to evaluate by EUA, and thus, clinical staging is even less reliable in this subset.)

Other clinical factors that routinely “stay in the model” when investigators construct Cox proportional hazard models for the prognosis of urothelial cancer patients treated with cystectomy are age, gender

(females consistently do worse), and time from diagnosis to definitive therapy.

From a medical oncology perspective, the most important issue is how to recognize which patients will benefit from the addition of systemic chemotherapy to definitive surgery. The current management guidelines for bladder cancer as promulgated by the National Comprehensive Cancer Network (NCCN)⁽⁵⁴⁾ suggest the use of neoadjuvant chemotherapy for patients with cT2 disease. In our view, this is a wonderful example of how evidence-based medicine can pave the way for uncritical and even irrational management guidelines.

In evaluating this recommendation, it should first be noted that cT2 cancers could easily be pT0 (ie, no residual disease in cystectomy specimen after initial TUR), pTis, pTa, pT1, pT2a, pT2b, or pT3a without constituting a clinical staging error. However, it is abundantly clear that the burden of residual disease (ie, the burden of disease found at cystectomy) after TUR is strongly related to the risk of disease relapse and death. In a series of 208 patients, Isbarn et al recently demonstrated that those with residual invasive disease (ie, pT1 and pT2) were cured about 70% of the time, whereas all 55 patients with no residual invasive disease (pTa, pTis, or pT0) were cured⁽⁵⁷⁾.

To further highlight the enormous heterogeneity of patients with cT2 cancers, consider that we know of many features that have a dramatic influence on prognosis:

1. Cancers arising at the bladder neck are notoriously difficult to adequately stage and monitor and have a higher rate of occult nodal involvement.
2. Cancers presenting with hydronephrosis from tumors in the region of the ureterovesical junctions have a very high rate of pT3b extension, occult nodal involvement, and inferior outcome. This was first reported in the 1980s and has been amply confirmed. In a recent study of 241 patients with cT2 disease treated by cystectomy⁽⁵⁸⁾, the 5-year cause-specific survival (a good surrogate for cure) was 63% for those without this feature versus 12% for those with hydronephrosis. This remained prognostically significant after accounting for pathologic stage. Similar results were obtained by Bartsch et al⁽⁵⁹⁾, who observed survival rates of 68% versus 30%, again remaining significant after accounting for pathologic stage.
3. As noted earlier, cancers exhibiting micropapillary, sarcomatoid, plasmacytoid, and small cell histology have a much more aggressive biology and inferior stage-for-stage outcome with cystectomy.
4. Large nonpapillary tumors (cut points range from 3-5 cm) that are muscle invasive over a broad front are much worse (ie, much more likely to be

upstaged at cystectomy) than those with focal muscle invasion.

5. Cancers showing LVI, especially when appreciated in the TUR specimen, are associated with about a 30% rate of occult nodal involvement⁽⁶⁰⁾.
6. Cancers with an abnormal immunophenotype for *p53* and *RB* gene products have a decreased probability of cure with cystectomy, and the prognosis is especially unfavorable when both are altered. In a large study of patients with cT2 disease, the cure rate for patients with both genes showing wild-type expression was 80%, whereas only 20% of patients with both genes altered were cured⁽²²⁾.
7. Cancers with prominent neovascularity in the tumor (ie, microvessel density as revealed by CD34 staining or other methods) or strong expression of VEGF are consistently associated with a higher risk of recurrent disease after cystectomy^(18, 61).
8. Cancers with an invasive or mesenchymal phenotype characterized, for example, by high expression of matrix metalloprotease-9 and/or low expression of E-cadherin are consistently associated with an increased risk of recurrent and metastatic disease⁽⁶²⁾.
9. In addition to these tumor characteristics, it is now well established that circulating levels of tumor markers are independent predictors of outcome. This has been demonstrated for human chorionic gonadotropin (hCG), CA19-9, and CA-125⁽⁶³⁻⁶⁵⁾.

It is apparent that based on information that can be gathered preoperatively, it is possible to substantially refine the clinical risk of a patient with cT2 bladder cancer. Vickers et al⁽⁶⁶⁾ have provided a compelling numerical analysis of just how powerful the application of a multivariate model to decision making can be and how this consistently outperforms the simple-minded notion that all patients with cT2 cancer should get chemotherapy.

In addition to these clinical features that can be ascertained preoperatively, there are surgical factors that impact outcome. For example, we know that outcome is dependent on the experience of both the surgeon and the center where surgery is performed^(67, 68) and that cure is consistently related to extent of pelvic node dissection⁽⁶⁹⁾, and of course, patients with involved surgical margins nearly always relapse.

CLINICAL MANAGEMENT

Management of Superficial Disease (cTa, cTis)

The management of low-grade papillary disease is by TUR, and because these lesions recur but rarely progress, there is generally no thought of cystectomy except

in the rare case that the bladder surface is a carpet of lesions. In such a case, just as with overwhelming colon polyposis, radical surgery prior to progression to more threatening disease is appropriate.

High-grade noninvasive cancers present a difficult dilemma for the urologist, who must balance the risk of recurrent, invasive disease (which occurs despite therapy and surveillance in at least 20% of patients) with the risk of overtreating patients not destined to have a threatening cancer. As noted earlier, there is currently much interest in finding markers that will stratify the risk of progression and allow optimized management. The presence of CIS increases the probability of both recurrence and progression. Typically, patients with either high-grade Ta disease or CIS (or both) are now treated with both TUR and BCG.

Intravesical BCG was introduced in 1976, and since the first controlled trial establishing the efficacy of BCG was reported by Lamm et al in 1980⁽⁷⁰⁾, it has had a remarkable impact on the clinical management of bladder cancer. Although standard criteria for therapy are still evolving, BCG has been shown in randomized trials to be superior to intravesical chemotherapy and TUR alone and will delay recurrence and progression, decreasing the need for immediate cystectomy. It is important to note that complete responses to BCG are required for significant alteration of the natural history of the disease⁽⁷¹⁾. Partial responses should prompt referral for experimental therapy or consideration of early cystectomy. Especially in the context of any invasive component, BCG therapy will be associated with progression to potentially life-threatening disease in a substantial fraction, and thus, persistent treatment with BCG in the context of less than complete response is a major cause of potentially avoidable mortality from bladder cancer. In our experience, urologists are likely to emphasize the advantages of avoiding cystectomy but place less emphasis on the dangers of progression to the point that a cystectomy will no longer be curative. The decision to delay cystectomy in the face of less than an initial complete response to BCG is responsible for many deaths from disease that was not caught early enough, despite close surveillance⁽⁷²⁾.

The other feature of BCG therapy of particular interest from a medical oncology perspective (because it relates to assessment of the need for perioperative systemic therapy) is the increasing incidence of cancers in the distal ureter and prostatic urethra. In each case, these lesions are a challenge for cystoscopic surveillance. Particularly for ureteral lesions, minimal progression can be associated with a sharply increasing risk of life-threatening disease. Therapy with BCG can clear the bladder proper, while urothelial carcinogenesis and progression continue just millimeters away. Patients treated with BCG (especially those with CIS)

who have negative cystoscopy but positive cytology are at substantial risk of having such disease, and it is often fatal if definitive management is delayed (⁷³).

Management of Minimally Invasive Disease (cT1)

Patients with cancers that are invasive into the lamina propria (cT1) are at high risk of developing muscle-invasive disease. In general, patients with an invasive or high-grade component recognized on the initial TUR should have a re-excision approximately 4 weeks later (⁷⁴). A second TUR provides another opportunity to sample muscle and thus more definitively establish the status of muscle invasion, which is a key prognostic feature. In addition, the re-resection establishes which patients have or do not have persistent disease. Those with persistent disease have a prognosis similar to cT2 patients and should be informed of the risk associated with bladder-preserving therapy. Conversely, a complete TUR, as demonstrated by a negative re-resection, may be adequate therapy for many patients with cT1 disease, especially if there is no CIS present and noninvolved muscle has been sampled. In this context, it is especially important to have a highly sensitive test for CIS. Although not yet standard, there is substantial interest in looking at tissue fluorescence to enhance conventional cystoscopy (⁷⁵). In the United States, most patients with cT1 disease receive BCG, and the caveats about BCG use as noted earlier apply even more strongly to this group. It is also important to recognize that tumors that overlie the ureteral orifices or involve the bladder neck are sometimes difficult to confirm as only T1 lesions and require a lower threshold for definitive surgery.

Men with a positive cytology and no obvious tumor within the bladder should undergo transurethral biopsy of the prostate at 5 and 7 o'clock at the verumontanum in addition to random bladder biopsies. Prostate recurrence is detected in approximately 10% to 15% of patients within 5 years of treatment of their bladder tumor and in 20% to 40% by 10 years.

At MDACC, patients with persistent T1 disease despite resection and intravesical therapy are generally cautioned against second-line therapy and guided toward radical cystectomy. Esrig et al have provided a useful perspective on this situation (⁷⁶).

Management of Clinically Localized, Muscle-Invasive Disease (cT2)

In the United States, cystectomy is the standard therapy for muscle-invasive bladder cancer. In older surgical series, cystectomy was curative in about half of these patients. More contemporary series typically report cure in the range of 80%, but this is based on

pathologic stage. Thus, although it is true that in experienced centers 80% to 85% of patients undergoing cystectomy for cancers that are found to be pathologically confined to the muscular wall of the bladder (ie, pT2b or less, N0) will be cured, it is not absolutely clear that the old figure of about 50% cure for *clinical stage* T2 patients is now obsolete, although modern series do seem better (⁷⁷). At the very least, the finding of muscle invasion signals a potentially life-threatening problem; in fact, this seems to constitute an oncologic urgency. In a study of 214 patients treated with cystectomy at the University of Michigan (⁷⁸), a cut point of 93 days from recognition of muscle invasion to surgery was associated with statistically inferior cause-specific survival and OS. Specifically, about 60% of patients with timely surgery were long-term survivors versus about 40% of those with delay, even though there was no clinical or pathologic stage migration.

In view of available knowledge of prognostic features reviewed earlier, it is clearly inappropriate in the current era to speak of muscle-invasive bladder cancer as though it were a single disease state with a well-defined prognosis and a single best management. We know that there are many patients with cT2 bladder cancer with such a favorable prognosis that no available systemic therapy would be expected to improve outcome over that achieved with radical cystectomy and template pelvic node dissection (⁷⁹). Likewise, we know that some patients at high risk will benefit from currently available chemotherapy in addition to surgery. The challenge for clinicians, and especially for clinical investigators, is to better define those at each end of this spectrum and then continue to work on subdivision of the remaining patients where we currently do not know how to define the role of systemic chemotherapy. This issue of identifying the appropriate patients for systemic chemotherapy is the single most important question related to bladder cancer from a medical oncology perspective. There is no longer any question that perioperative chemotherapy can improve outcome for some patients; likewise, it is all too obvious that it can do much harm. Thus, as always, the central question for the medical oncologist is: How are we to balance risk and benefit for each patient?

Based on our understanding of the impact of currently available therapy, it is our sense that patients with a $\geq 70\%$ chance of cure should not be offered chemotherapy as it currently exists. Conversely, when the probability of surgical cure falls to about $\leq 40\%$, then it seems clear that chemotherapy should be offered. In between these extremes, the decision is a highly personal issue of risk abatement versus burden of therapy. As a practical implementation of this intuitive sense that 40% cure probability is about the right threshold for chemotherapy plus surgery, we offer chemotherapy to patients with any of the following: direct

invasion of the prostate or vagina (ie, cT4a disease), a three-dimensional mass on EUA (ie, cT3b disease), LVI on TUR material, bladder neck involvement, and hydronephrosis or an excessive delay (ie, >4 months) between the finding of muscle-invasive disease and definitive management. We look forward to implementing more refined prognostic tools in our own practice.

Primary Radiotherapy

In our view, radiotherapy is inferior to surgery as a local modality for bladder cancer. Available data clearly demonstrate that long-term control can be achieved in about 40% of patients with small primary tumors amenable to complete resection, not associated with CIS, not arising at the bladder neck or ureterovesical junction, and without hydronephrosis⁽⁸⁰⁾. This is precisely the subset that has about an 80% cure with surgery, and to claim that the available results are comparable to surgical series is not justified⁽⁸¹⁾. Clearly some patients could decide that the risks are acceptable and rationally choose radiotherapy, but this must not be presented as an option associated with a comparable outcome to surgery. When chosen as an option, we would recommend the use of concomitant radiosensitizing chemotherapy⁽⁸²⁾.

Management of Locally Advanced, Resectable Disease (High-Risk cT2, cT3, cT4A)

Since the publication of the Southwest Oncology Group (SWOG) intergroup trial of neoadjuvant chemotherapy⁽⁸³⁾, many guidelines, including the NCCN guidelines, advocate for neoadjuvant chemotherapy as the standard of care for patients with muscle-invasive urothelial carcinoma. Because, in our experience, the cure fraction for patients with muscle-invasive disease only with surgery is approximately 85% and the use of systemic chemotherapy can be toxic in this often frail and elderly patient population, we have advocated for a more refined approach relying on the probability of recurrence as a guide for the use of neoadjuvant treatment. Tumors that are clinically beyond the bladder wall (ie, those with a three-dimensional mass at exam under anesthesia) after thorough TUR of intravesical tumor carry a worse prognosis with a surgical cure rate of about 35%. Many patients with cT2 disease and high-risk features have a similar chance for surgical cure. The presence of LVI is associated with a high risk of nodal involvement, even in the setting of clinically negative lymph nodes on CT scan.

Patients with prostatic stromal involvement (from the bladder, *not* from TCC of prostatic ducts) or extension into the vaginal wall (ie, anatomic clinical stage

cT4a) have a surgical cure rate in the range of 5% to 20%. A recent retrospective multicenter study of 583 patients with pT4 disease (all obviously deemed resectable on clinical grounds) found a cause-specific survival rate of about 30%⁽⁸⁴⁾. Univariate analysis confirmed female gender, LVI, nodal involvement, positive surgical margins, and pT4b substage to be associated with inferior outcome. None of these patients received neoadjuvant therapy. Collectively, these groups have what we term *locally advanced but resectable* disease, and at MDACC, they are treated primarily with chemotherapy, followed by surgical consolidation as appropriate. Although this is a patient cohort with truly threatening disease, it is also true that this is the population for whom combined application of best systemic therapy and best surgical therapy has the greatest patient benefit. In the MDACC experience^(85, 86), the benchmark outcome in this cohort is cure in about 60% of patients (by intent to treat), with about 40% having no residual invasive cancer in the resected specimen following chemotherapy (so-called “p-zero” status), which we and others⁽⁸³⁾ have noted to be a reliable indicator of long-term disease-free survival.

Recently, several centers have reported on the use of dose-dense M-VAC in the neoadjuvant setting for urothelial carcinoma⁽⁸⁷⁻⁸⁹⁾. The use of the dose-dense strategy has had multiple benefits including a faster time to surgery, with chemotherapy given on a 2-week schedule, and an improved tolerance for chemotherapy. In one study, 93% of patients completed at least three cycles of neoadjuvant chemotherapy⁽⁸⁷⁾. Pathologic T0 rates have been quite promising, on the order of 39%⁽⁸⁷⁻⁸⁹⁾, with long-term survival at one center suggesting a cure fraction of approximately 63%⁽⁸⁷⁾. Molecular characterization of urothelial tumors from the MDACC trial suggests that the basal subtype may be predictive for benefit from neoadjuvant chemotherapy⁽⁹⁰⁾. Further efforts in subtyping bladder cancer may yield a prognostic test available for community use that would allow us to discriminate which patients are most likely to benefit from a neoadjuvant approach.

Management of Locally Advanced, Unresectable Disease (cT4B, cN+)

This group of patients has a dismal prognosis. In our experience, patients presenting with large tumors that are clinically fixed to the rectum, pelvic sidewall, or pubic symphysis actually have a worse prognosis than patients with extrapelvic nodes or lung-only metastases. These patients are considered unresectable and are treated with chemotherapy initially, and then reassessed for the possibility of surgical consolidation in light of the quality of response and their fitness for surgery after chemotherapy⁽⁹¹⁾.

Investigators from Memorial Sloan-Kettering Cancer Center ⁽⁹²⁾ and MDACC ⁽⁹³⁾ have published their experience with this strategy. These data suggest that response to systemic therapy is the dominant prognostic feature and that surgical consolidation is both feasible and associated with long-term survival. This experience also confirmed that patients with significant residual disease after chemotherapy did not benefit from surgery and that, overall, the prognosis is still poor. Still, a 22% to 40% survival rate among initially unresectable bladder cancer patients is much better than what could be expected of any single modality.

Radiotherapy has not been useful as a single modality with these large cancers. As with surgery, there probably is a role for radiotherapy in the consolidation of patients who show an excellent response to primary chemotherapy. It is worth emphasizing that sensitivity to chemotherapy and radiotherapy does tend to be parallel in the context of urothelial cancer. We have never seen a chemotherapy-refractory cancer respond to radiation, and we have seen some excellent long-term results from use of radiotherapy to consolidate an initially unresectable mass after an excellent response to combination chemotherapy.

Management of Distant Metastatic Disease

Bladder cancer typically spreads first to regional nodes and then disseminates with about equal frequency to the lungs, liver, and bone. Late in the course, subcutaneous and brain metastases are common. Brain involvement is especially likely in patients who have elevated serum levels of β -hCG or variant histology, including small cell.

Even with strictly palliative goals in mind, most patients with metastatic bladder cancer should be treated with multicomponent chemotherapy, pitched at their level of physiologic tolerance. Metastatic urothelial cancer remains a clinical situation in which toxic side effects are typically encountered if chemotherapy is given in a way that has any chance of substantially altering the natural history of the disease. Unfortunately, “kinder, gentler” therapy is likely to be of little benefit. Metastatic urothelial cancer is an aggressive malignancy, with an untreated natural history from the time it causes symptoms to death of approximately 3 to 4 months. Quality of life is essentially completely dependent on the efficacy of therapy. Even extraordinarily toxic regimens can be truly palliative in light of how rapidly (and morbidly) the disease progresses.

Since the mid-1980s, the use of cisplatin-based combination chemotherapy has been standard. In the modern era with a bit of lead time bias compared to practice in the early 1980s, such treatment results in median survival of about 16 months, with

few survivors beyond 3 years. This is the benchmark where therapy has plateaued for more than a decade.

Of course, some patients with distant metastatic disease still have disease restricted to one (or a few) anatomic areas, and one might imagine that local therapy would have a role in such a setting. However, in contrast to the situation with renal cell carcinoma for example, surgery is almost never an appropriate initial intervention for metastatic urothelial cancer. Almost always, the disease is not really localized, and one finds rapid progression in the postoperative setting. Thus, even in cases of anatomically threatening lesions such as threatened cord compression, we generally advocate primary chemotherapy to get the disease under some control that will then permit safe surgical intervention. Nonetheless, it is only natural to ask if there is a role for surgical consolidation after a good response to chemotherapy for (highly) selected patients with metastatic urothelial cancer. The MDACC experience with this strategy has been published in the setting of retroperitoneal lymph node metastases ⁽⁹¹⁾ and in a very small, select subset of patients with visceral metastases ⁽⁹⁴⁾. Selection criteria for this approach have not yet matured. In the absence of more data, we have adopted the following guidelines. For patients with pelvic or retroperitoneal nodal involvement (below the renal vessels), we typically offer an extended node dissection to patients with a complete radiographic response to initial chemotherapy. Because judging the completeness of response in a lymph node is problematic, we include in our working definition a negative biopsy for any node that is large enough for CT-guided biopsy. For patients with visceral involvement, we typically treat to maximum response and observe. Only when patients progress in the initially involved area (with no progression elsewhere) and then go on to have a significant response to a second course of chemotherapy do we consider surgical removal of residual metastatic disease. Just as with patients with germ cell cancers, failure of markers to normalize is nearly an absolute contraindication to surgical consolidation.

The exception to this is the rare patient with a long interval from initial management to the onset of resectable, oligometastatic visceral disease. In this setting, we typically give systemic therapy and then excise the lesions. Note that in our view surgery without some chemotherapy is essentially never appropriate because these cancers have a high propensity of seeding surgical wounds. Even in the face of cord compression, chemotherapy followed by surgery is usually the preferred management.

Patients relapsing after cystectomy essentially always have systemic disease, but a substantial fraction have clinically detectable involvement confined to local and/or regional nodes. We know that some of

these patients will have an excellent response to chemotherapy and, with surgical consolidation, will be long-term survivors. Thus, although it has not been rigorously shown to produce a better overall outcome, surveillance by periodic CT is usually performed. Relapse is stereotypically circumscribed between 9 and 18 months, by which time about 85% of those destined to relapse will have done so, and this is when we advocate surveillance.

In our experience, CIS of the distal ureter is the pathologic feature most closely associated with upper tract recurrence⁽⁹⁵⁾. In fact, 15% of those with post-cystectomy tumor within the distal intramural ureter developed an upper tract recurrence. Intraoperative ureteral margin status by itself was of little consequence. Patients with TCC involving the prostatic urethra also had a higher incidence of upper tract recurrence following cystectomy, in keeping with the field-change hypothesis of urothelial carcinogenesis. Upper tract surveillance of these patients can be accomplished with urine cytology and upper tract imaging. Traditionally, the intravenous pyelogram was the primary imaging tool for surveillance of the upper tract because it provides visualization of filling defects and can detect obstruction. More recently, CT urography has been found to be a more sensitive surveillance tool following cystectomy because it can identify not only local and distant recurrences but also early upper tract recurrences.

SYSTEMIC THERAPY FOR UROTHELIAL CANCER

Currently, *combination therapy is standard* in the treatment of metastatic TCC. The development of M-VAC at Memorial Sloan-Kettering Cancer Center⁽⁹⁶⁾ was an important achievement. Subsequent landmark trials have confirmed that M-VAC is superior to single-agent cisplatin⁽⁹⁷⁾; the combination of cyclophosphamide, doxorubicin, and cisplatin⁽⁹⁸⁾; the combination of 5-fluorouracil, interferon- α , and cisplatin⁽⁹⁹⁾; and the combination of docetaxel and cisplatin⁽⁹⁹⁾. In fact, there are at least nine randomized trials involving M-VAC, and to date, the only challenger to even suggest improved clinical outcome was a trial of a dose-dense variant of M-VAC given with granulocyte colony-stimulating factor support versus classic M-VAC⁽¹⁰⁰⁾. The dose-dense version was associated with markedly less mucositis, and the cycles are only 14 days (compared to 28 in the classic schedule), and thus, dose-dense M-VAC has supplanted classic M-VAC. With overall response rates in the 50% to 60% range and up to a 30% clinical complete response rate, there is no doubt that dose-dense M-VAC provides meaningful

palliation for most patients and can significantly change the natural history of the disease for a few.

Nonetheless, for most oncologists, M-VAC has overstayed its welcome. Despite having been the standard of care for 20 years, it is nearly completely abandoned because of significant toxicity and the availability of regimens of similar efficacy that are slightly less toxic. Although we freely acknowledge the considerable shortcomings of M-VAC, it is distressing to us to see phase II studies of newer doublets consistently show survival results inferior to the well-established benchmark established by M-VAC and to see widespread use of these regimens. Although one might argue that this is acceptable in the metastatic setting, where a shorter OS might be associated with “more good days” if one uses a less toxic treatment, we see no rationale for the widespread use of inferior regimens in the setting of perioperative therapy for locally advanced disease. In that context, improvement of cure fraction has been demonstrated for M-VAC, but not established for other regimens. Thus, in the absence of a clinical trial, the dose-dense version of M-VAC is the standard frontline therapy at MDACC when chemotherapy is given with curative intent.

In the setting of metastatic disease, for which the goals are clearly palliative, the doublet of gemcitabine and cisplatin has become a standard option. Gemcitabine-cisplatin was compared to M-VAC in a large international phase III trial⁽¹⁰¹⁾. The doublet was shown to be similar with respect to median survival and was associated with significantly less mucositis and neutropenic fever. Gemcitabine-cisplatin did cause more thrombocytopenia, however. As expected for two regimens with comparable efficacy, quality-of-life measures were not different between the two treatments, despite the favorable treatment-related side effect profile of gemcitabine-cisplatin. In our view, this is not a surprising finding, but rather reinforces the notion that the burden of morbidity in patients with metastatic bladder cancer is far more likely to be due to the disease, rather than secondary to the treatment.

Gemcitabine, the taxanes^(102, 103), and ifosfamide^(86, 104, 105) all have activity in urothelial cancer, and there have been many new doublets and triplets investigated over the past 10 years. From this experience, it is clear that all regimens substituting carboplatin for cisplatin show inferior results, or even increased toxicity, as was seen with the triplet combination of gemcitabine, paclitaxel, and carboplatin⁽¹⁰⁶⁾.

Urothelial cancer is a disease of the elderly. The lifetime accumulation of risk factors predisposing patients to bladder cancer often leads to other comorbid conditions such as coronary artery disease and chronic obstructive pulmonary disease. These diseases, in addition to other conditions found in an aging population,

such as diabetes and hypertension, often contribute to poor renal function or a performance status unable to tolerate aggressive cisplatin- or ifosfamide-based therapy.

Ureteral obstruction is also a frequent factor contributing to diminished renal function, and nephrostomy tubes are an indispensable tool in the treatment of advanced bladder cancer. Nephrostomy tubes are much preferred over ureteral stents in patients undergoing chemotherapy for locally advanced bladder cancer. This is because chemotherapy often engenders periods of neutropenia that can lead to chronic infection associated with foreign bodies. Nephrostomies are much more easily changed out than stents. Furthermore, stents are far more irritating and likely to bleed during periods of thrombocytopenia. It is not uncommon to have stents clog from bleeding, and this is much less problematic with nephrostomies. Finally, nephrostomies will reliably decompress the kidneys, even if the cancer grows, whereas stents can be collapsed by tumor and even by desmoplastic reaction to therapy.

Relatively effective chemotherapy for patients with impaired renal function is now fairly easy to come by. Vinblastine, gemcitabine, taxanes, and doxorubicin can all be given safely in the context of renal insufficiency. At the present time, we favor a triplet of gemcitabine (900 mg/m² given over 90 minutes), paclitaxel (100 mg/m²), and doxorubicin (30 mg/m²) repeated every 14 days for patients with poor renal function. This regimen is reliably deliverable and has useful clinical activity ⁽¹⁰⁷⁾.

FUTURE PROSPECTS

The ready availability of the bladder surface makes bladder cancer an ideal clinical model for the development of gene therapy. Investigators at MDACC have reported that adenoviral-mediated gene expression (in this case of interferon- α -2b) within the bladder can be achieved using the detergent Syn3 ⁽¹⁰⁸⁾. A phase I trial has been completed, and further work with this and other intravesical gene transfer therapies is ongoing.

The efficacy of BCG strongly suggests that immune recognition and reaction to bladder cancer antigens is a clinical strategy that could be further developed. Moreover, tumor-infiltrating CD8-expressing T cells are predictive of survival in patients with urothelial carcinoma ⁽¹⁰⁹⁾. Clinical trials are currently in the planning stages to evaluate the impact of the immune checkpoint inhibitors in patients with superficial disease who have failed BCG.

Further building upon the immunologic platform are studies of immune checkpoint inhibitors in patients with metastatic disease. The PD1 and PDL1 inhibitors are currently in late-phase clinical trials.

With early reported response rates of 20% to 40% ⁽¹⁾, their approval as the first targeted agents in metastatic urothelial cancer is eagerly anticipated. Future trials combining these agents with other therapies targeting the immune system, including CTLA4 antibodies, are currently ongoing.

Current optimism is high that we are now entering the era of personalized medicine for urothelial cancer. In addition to agents targeting mutations, including *FGFR3*, we are gaining an understanding of the underlying biology of urothelial cancer. The molecular characterization of urothelial cancer is expected to provide the framework of underlying biology and help us predict which patients are candidates for chemotherapy. One might predict that the basal subtype, which is sensitive to chemotherapy, may also benefit from angiogenesis inhibition. The luminal subtype, which is enriched for *FGFR3* mutations and downstream markers of FGFR activation, may be more susceptible to FGFR inhibition. Recently, *ERBB2* expression, which appears associated with subtype, may predict which of the luminal tumors are more likely to respond to systemic chemotherapy. Finally, further study of the p53-like subtype will help us in finding agents in chemotherapy-resistant disease. The presence of stroma in these tumors may correlate with the higher incidence of bone metastases and guide us toward therapies that impact the stromal environment.

Commentary: Molecular Markers for Risk Stratification and Personalized Therapy in Urothelial Tumors

As the authors of this chapter appropriately emphasize, the clinical management of bladder cancer appears to be on the verge of a remarkable transformation. Several large-scale cancer genomics projects (including the first phase of The Cancer Genome Atlas's bladder cancer project) have provided the first detailed molecular "parts lists" of the disease, and the information suggests clear implications for prognostication and precision therapy. Converging with these basic biological breakthroughs are the exciting, game-changing results of ongoing clinical trials with immune checkpoint inhibitors, which provide the first examples of targeted therapies that are active against tumors that are resistant to the current frontline therapies. This chapter provides an excellent and comprehensive description of the current state of the science with insightful predictions regarding where the field is heading in the near future.

David J. McConkey

Thus, urothelial cancer is no longer just one disease. Novel agents and selection strategies have now come to this disease, with an energy and optimism that we are moving from cytotoxic strategies to immunologic and targeted interventions that will be embraced by physicians and enhance the lives of our patients. The era of personalized medicine is indeed upon us.

Prostate Cancer

Mehmet A. Bilen
Christopher J. Logothetis
Paul G. Corn

Over the past decade, insight into the biological basis of prostate cancer development and progression has influenced our approach to treating patients with the disease. While research efforts have historically focused on the prostate cancer epithelial cell, there is growing evidence that interactions between the host tissue microenvironment and the cancer epithelial cell are critical for tumorigenesis. Understanding the bidirectional cancer cell–host interaction now dominates prostate cancer research.

Prostate cancers have recognizable clinical features that allow anticipation of their clinical behavior. Fortunately, the progression from localized, androgen-dependent disease to castration-resistant disease with bone-forming metastases occurs in only a minority of patients. To conceptualize the clinical heterogeneity displayed along this continuum, patients have historically been assigned to different “clinical states” (eg, metastatic castrate vs noncastrate) to help structure treatment recommendations and therapy development^(1, 2). However, this approach has been limited by the fact that patients within each state display wide biological heterogeneity and response to therapy. To address this, improved classification of the disease based on the underlying molecular mechanisms of progression is necessary. This effort will create a “marker-driven” strategy to more reliably predict prostate cancer progression, permit optimal selection of specific therapies for individual patients, and apply therapy to only those patients who need it. This strategy will favorably improve the outcome of selected patients threatened by their disease while avoiding unnecessary morbidity to the majority who are not.

EPIDEMIOLOGY AND CLINICAL FEATURES

Prostate cancer is a major health-care challenge in the United States⁽³⁾. It is the second most common cancer in men (behind skin cancer) and the second leading cause of cancer death (behind lung cancer). There are a number of unique clinical features of prostate cancer that distinguish it from other solid tumor types:

1. Despite the high prevalence of prostate cancer, the majority of patients diagnosed with the disease eventually die from other causes. This is in striking contrast to lung cancer, where the majority of patients diagnosed with the disease die from it.
2. Cancer of the prostate often has a prolonged natural history. This is evidenced by a high incidence of occult malignancy in autopsy series of men who die from nonprostate cancer causes and in clinically normal prostates of men undergoing cystoprostatectomy for bladder cancer. Therefore, over the course of a normal lifetime, most men will develop “clinically occult” prostate cancer that will never produce symptoms, require treatment, or cause death.
3. The incidence of detected carcinoma increases with age.
4. Androgens are a major driving force in normal prostate development and are implicated in tumorigenesis.
5. Prostate cancer is typically multifocal, commonly presenting as synchronous carcinomas arising in

multiple locations, and the malignant potential is determined by the sum of the primary and secondary grades (Gleason score). Thus, biologic heterogeneity is an inherent property of each tumor.

6. Clinical prostate cancer is more prevalent in Western than Eastern societies, although incidence rates increase for men from China and Japan who immigrate to the United States. This observation implicates environmental factors (diet, lifestyle, etc) in prostate cancer development.
7. Prostate cancers have a predictable rate and pattern of progression, with bone-forming metastases dominating the clinical progression in the majority of patients with advanced disease. This observation supports the view that the bone-epithelial interaction is central to the progression of prostate cancer.

Aging

It has long been recognized that prostate cancer is a disease of the elderly, and epidemiologic data demonstrate that rates of prostate cancer incidence and mortality increase with age (⁴). While prostate-specific antigen (PSA) screening has led to an earlier average age at diagnosis, mortality is still largely seen in patients 70 years of age or older. As the longevity of populations increases worldwide, the burden of prostate cancer creates a significant health-care challenge. This has generated a sense of urgency among physicians to refine our ability to predict cancer virulence and apply therapy to those patients who need it.

Endocrine

Androgens are central to the normal growth, differentiation, and function of the prostate gland, although

the role of androgen receptor (AR) signaling in prostate carcinogenesis and progression has not been fully elucidated. Even in the clinically castrate state (serum testosterone <50 ng/mL), there is growing evidence that prostate cancer cells continue to rely on AR signaling for proliferation (⁵). One of the principal mechanisms for this involves a gradual shift from endocrine sources of androgens (ie, from the testes and adrenal glands) to paracrine/autocrine/intracrine (ie, intratumoral) sources during prostate cancer progression (Fig. 37-1). This occurs through the peripheral conversion of adrenal steroid precursors (eg, dehydroepiandrosterone and androstenedione) in prostate and bone tissues expressing CYP17 enzymes (⁶). Other mechanisms accounting for castrate resistance include intratumoral amplification of AR, mutations of AR, changes in levels of AR cofactors, and ligand-independent activation of AR (Fig. 37-1).

Diet and Obesity

Several lines of clinical and experimental evidence support a central role for diet, caloric intake, and obesity in the development of prostate cancer with lethal potential. Obesity, defined as body mass index (BMI) above 30, is manifested by overgrowth of white adipose tissue (WAT). Obesity has been associated with incidence, progression, and mortality of prostate cancer (^{7,8}). The mechanism for the association between obesity and prostate cancer progression is poorly understood. Current models suggest that predetermined genetic traits associated with both obesity and cancers are influenced by lifestyle components such as diet and physical activity. However, epidemiological studies show that cancer can be accelerated in obese patients irrespective of their lifestyle. Thus, it has been

FIGURE 37-1 Androgen sources switch from endocrine to paracrine/autocrine during disease progression. PCa, prostate cancer.

proposed that WAT itself may have a direct effect on cancer progression.

Mechanisms linking obesity and aggressive prostate cancer include signaling through insulin-like growth factor 1 (IGF-1) and adipokines (⁹). The insulin/IGF-1 axis has been widely implicated in obesity-induced tumorigenesis, including prostate cancer (¹⁰). Primary human prostate cancer commonly expresses the insulin receptor, suggesting insulin may stimulate tumor growth (¹¹). Both excess body weight and a high plasma concentration of C-peptide are associated with increased prostate cancer–specific mortality (¹²). In addition, the antidiabetic agent metformin has been shown to reduce all-cause and prostate cancer–specific mortality among diabetic men (¹³).

Beyond changes in insulin, obesity alters levels of adipokines (such as leptin, adiponectin) due to chronic subclinical inflammation. Leptin is associated with in vitro protumor effect in human prostate cancer cell lines (¹⁴), but epidemiologic studies have failed to consistently establish an association with prostate cancer risk and mortality (¹⁵). In contrast to leptin, adiponectin serum levels are reduced in obesity and have largely antitumor effects (¹⁶).

Race and Ethnicity

African Americans have a higher frequency of death from prostate cancer compared to Caucasian and Hispanic Americans. This has variably been attributed to differences in steroid metabolism, genetics, environmental effects, or social factors (^{17,18}). There is a reduced incidence of prostate cancer among Chinese and Japanese Americans, but their incidence is higher than that reported in native Chinese or Japanese persons. Of interest is the fact that northern European men have a higher frequency of prostate cancer than men from southern Europe. A similar finding has been reported in the United States, suggesting that the incidence of prostate cancer is inversely related to sun exposure.

These findings have epidemiologically linked prostate cancer to vitamin D metabolism.

Genetic Predisposition

As with breast and colon cancer, familial clustering of prostate cancer has been reported. Unlike with breast and colon cancer, however, specific genetic lesions have not been identified to merit the routine use of genetic screening for prostate cancer. The search for “prostate cancer genes” has identified candidate genetic events implicated in tumorigenesis, but these findings have been more useful in understanding the underlying etiology of prostate cancer than in screening. For example, a major hereditary prostate cancer susceptibility locus resides at 1q24, although the responsible gene(s) remains under investigation (^{19,20}). More recently, men carrying *BRCA1/BRCA2* (breast cancer 1 and 2) mutations have been shown to be at increased risk of developing prostate cancer (^{21,22}). In addition, it has been suggested that BRCA-associated prostate cancer cases may be more virulent than non-familial cases (^{23,24}). However, it remains unclear how this information will influence management decisions for individual patients.

RELEVANT HISTOMORPHOLOGY OF PROSTATE CANCER

Most epithelial cancers arise from the prostatic acinus, with fewer than 10% having a pure ductal origin (this is the opposite of the pattern seen in cancers of the pancreas and breast, where ductal cancers are far more common than those arising in the acinar portion of the secretory unit). The majority show glandular differentiation (ie, adenocarcinoma) (Fig. 37-2A). Importantly, mucin is essentially never seen in prostate cancer. Historically, numerous grading systems have been devised, using all of the typical morphologic criteria

FIGURE 37-2 A. Architecture of prostate adenocarcinoma. B. Architecture of prostate ductal carcinoma. C. Architecture of prostate small cell carcinoma.

by which pathologists can sometimes infer biologic potential. While more than 20 systems have been put forward, prostate cancers are now almost universally graded according to the system of Gleason.

Gleason Grading System

The Gleason system is unique among pathologic grading systems because it is a composite classification based on a combination of architectural and cellular features often considered in the grading of other epithelial cancers. As originally described, the Gleason system includes two components:

1. There are five patterns, or grades, ranging from normal architecture to arrays of cells without any glandular organization at all. At our institution, because unequivocal criteria for malignancy already correspond to Gleason grade 2 and the Gleason grade 1 category is rarely reported, prostate cancers are assigned Gleason grades ranging from 3 through 5.
2. The Gleason score is obtained by assigning one Gleason grade to the most dominant (ie, “primary”) pattern and another to the next most common (ie, “secondary”) pattern. By convention, such data are expressed as a sum, with the primary pattern listed first. Thus, the Gleason score can range from 2 (ie, 1 + 1) to 10 (5 + 5). At MD Anderson, these scores range from 6 to 10, reflecting our decision not to assign a Gleason grade of 1.

A major advantage of the Gleason grading system is its reproducibility and ability to distinguish different cancer phenotypes that influence clinical management. The system is most useful for tumors falling at one the extremes (eg, Gleason 6 or less versus Gleason 8 to 10). However, a major disadvantage of the system is that it does not provide a refined view of Gleason 7 tumors, the most commonly reported type. Gleason 7 cancers (ie, 3 + 4 or 4 + 3) represent a clinically heterogeneous group with variable biologic potential and clinical outcome⁽²⁵⁾. Despite efforts to improve stratification of Gleason 7 tumors, it is clear the Gleason system is inherently limited by light microscopic methodology to evaluate morphology. Thus, most investigators are now looking to incorporate molecular characterization of tumors into the current grading system.

Assessment of Prostate Biopsies and Prostatectomy Specimens

Gleason grading is a validated system to prognosticate untreated prostate cancers sampled at initial diagnosis. However, the common practice of applying Gleason grading to treated cancers may be misleading. At MD Anderson, for example, pathology reports of

specimens obtained after hormone ablation typically indicate “hormonal treatment effect” rather than a Gleason grade per se. Thus, Gleason scores from serial biopsies obtained pre- and posttherapy from the same patient should be interpreted with careful regard to treatment effects. To address this problem, our group has proposed a novel “posttherapy” histologic classification to introduce uniformity in analysis of treated tissue specimens⁽²⁶⁾. If prospectively validated, this system should prove useful in prognosticating preoperatively treated prostate cancers.

An additional confounding variable is tissue sampling. We recognize that there is intratumoral heterogeneity of grade within individual prostate cancers. Thus, it logically follows that the extent and areas of sampling will affect the accuracy of grading and staging. The development of techniques to obtain prostate tissue samples with ultrasound guidance and limited patient morbidity has had a major effect on stage and grade assignment. We increasingly find that the completeness of tissue sampling as measured by the number and distribution of transrectal biopsies greatly influences the adequacy of tumor staging and grading. Biopsy algorithms have been developed to ensure adequate number and distribution of the biopsies⁽²⁷⁾.

Many of the challenges attributed to the sampling errors that occur with needle biopsies can be overcome with proper handling of the prostate following surgery. Assigning a primary and secondary Gleason score is straightforward in a properly processed specimen. This requires great attention to detail in assessing whether the cancer has invaded beyond the prostate capsule (extracapsular) or beyond the margin of resection (margin positive). Effective communication between the surgeon and pathologist is essential to properly identify the extent and site of surgical margin involvement. As the therapeutic benefit of postoperative radiation therapy is better appreciated, the importance of these aspects has proportionally increased.

Molecular Genetics of Prostate Cancer

In prostate cancer, gene fusions between *TMPRSS2* (21q22.3), an androgen-regulated gene, and *ERG*, from the ETS family of transcription factors (21q22.2), are common⁽²⁸⁾. However, the functional and prognostic significance of *TMPRSS2-ERG* remain poorly understood. Currently, detection and measurement of *TMPRSS2-ERG* are not performed in standard clinical practice.

Additional studies have sought to refine the diagnostic classification of prostate cancer through molecular methods. Unfortunately, no consensus yet exists about the usefulness of molecular phenotypic (or genotypic) characterization in prostate cancer. Using immunohistochemistry, we do know that expression of specific proteins in human specimens has been linked to the

clinical course of the disease. For example, loss of functional PTEN, mutations in p53, and increased expression of Bcl-2 are some of the widely reported gain- and loss-of-function changes that have been correlated with prostate cancer progression and mechanistically linked to castration-resistant growth^(29, 30). Despite this link to biology and correlation with clinical outcome, the methods provide insufficient additional clinical information to justify their routine use.

Prostate Cancer Variants

The two most prominent morphologic subtypes are ductal and small cell/anaplastic variants.

Ductal Cancers

The ductal variant of prostate cancer in its pure form is unusual. More often, ductal and acinar components are mixed, and the relative contribution of the ductal variant to the clinical phenotype of the cancer is unclear. Our impression of the behavior of ductal cancers of the prostate is based on those tumors that are either dominant or pure ductal in origin (Fig. 37-2B). The clinical features that lead us to suspect its presence include the lack of proportional rises in serum PSA concentrations with invasion of the base of the bladder (occasionally mistaken for urothelial cancer), soft tissue distribution of metastases, or lytic bone metastases. For localized disease, patients with pure ductal adenocarcinoma have a better clinical outcome after radical prostatectomy than patients with mixed ductal adenocarcinoma⁽³¹⁾. However, metastatic cancers as more aggressive and demonstrate a higher probability of developing visceral metastases than pure acinar adenocarcinomas.

Small Cell/Anaplastic Cancers

Small cell carcinoma of the prostate is clinically distinguishable from prostate adenocarcinoma in predictable ways. It is castration resistant, is highly metastatic, produces little or no PSA, and causes lytic rather than blastic bone metastases. In addition, in comparison to adenocarcinoma, small cell prostate cancer more frequently metastasizes to lymph nodes and visceral organs (eg, liver or lung). It can arise de novo or more commonly as a delayed manifestation of progression in patients with a history of high-grade adenocarcinomas following therapy (hormone ablation, radiation therapy, or chemotherapy). The classic clinical presentation is a patient with a precipitously enlarging prostate associated with obstructive symptoms and very little (to no) PSA production. Interestingly, the evolution to a neuroendocrine phenotype is often associated with expression of carcinoembryonic antigen (CEA). For many patients, the CEA will be a much more useful monitoring tool than PSA.

In our experience, small cell carcinomas are also frequently detected in metastatic sites. Our approach is to biopsy sites with unusual features (lytic as opposed to blastic metastases or soft tissue metastases), particularly in those patients whose PSA concentration is judged to be lower than would be expected for the volume of cancer. Requests are made to pathology to analyze the tissue for neuroendocrine markers (chromogranin, synaptophysin, etc). Although standard criteria for establishing a diagnosis have not emerged, most of these cancers will show “salt-and-pepper” chromatin, express synaptophysin and chromogranin, and display a high nuclear/cytoplasm ratio (Fig. 37-2C). However, the diagnosis of small cell carcinoma does not require proof of neuroendocrine differentiation.

For this reason, we have added the term *anaplastic* to our nomenclature to describe aggressive tumors presenting clinically as “neuroendocrine-like” but lacking neuroendocrine markers. Until more precise genotype-phenotype associations are elucidated, we recognize that tumors displaying the clinical phenotype described may display heterogeneity with respect to neuroendocrine differentiation. Small cell/anaplastic carcinomas are highly responsive to etoposide and cisplatin-based chemotherapy but are generally incurable⁽³²⁻³⁴⁾.

Candidate Premalignant Lesions

Prostatic Intraepithelial Neoplasia

The search for premalignant lesions of the prostate has resulted in the identification of two candidate morphologic lesions⁽³⁵⁾. The first and most promising premalignant lesion is prostatic intraepithelial neoplasia (PIN). Grades I and II PIN are observed but have not been reliably associated with cancer or linked with confidence to prostate cancer development or progression. Thus, the reporting of grades I and II PIN has fallen into disfavor at MD Anderson and at most leading institutions. Grade III PIN has been linked to the presence of cancer in many studies, but it does not justify a therapeutic intervention (eg, prostatectomy). Rather, its presence leads to the recommendation of a more thorough biopsy to search for coexistent cancer or a repeat biopsy within 6 to 12 months. Grade III PIN is frequently linked to the presence of established cancer in other regions of the prostate, and as a consequence it rarely serves as a useful early predictive marker. Therein lies the difficulty of performing prevention studies targeting PIN. Most MD Anderson clinicians share the view that a report of multifocal PIN III is nearly identical to a report of low-grade prostate cancer, but with the important caveat that there is insufficient evidence to justify routine intervention (surgery or radiation).

The second potential premalignant lesion is proliferative inflammatory atrophy (PIA)⁽³⁶⁾. Histologically,

these lesions are characterized by inflammatory infiltrates associated with atrophic epithelium. Compared with normal epithelium, there is an increased fraction of proliferating epithelial cells within PIAs. These lesions are thought to provide a mechanistic link between chronic infection or inflammation and the predisposition to develop prostate cancer. However, in contrast to PINs, adenocarcinomas rarely arise from PIAs, and PIAs are often observed in prostate biopsies that have no evidence of cancer. Thus, it remains unclear if PIAs are truly precursor lesions for prostate cancer. Ongoing studies seek to address this.

Staging

It is difficult to precisely assess the extent of prostate cancer on clinical criteria alone. The major benchmark of local extent that influences treatment—organ confined versus non-organ confined—is essentially impossible to distinguish by rectal examination and is not easily appreciated by any imaging modality. Furthermore, PSA levels do not accurately inform about extraprostatic extension of disease. Thus, it is common to employ an array of modalities, including transrectal ultrasound, computed tomography, conventional magnetic resonance imaging (MRI), MRI with an endorectal receiver coil, complex biopsy strategies designed to sample the seminal vesicles and extraprostatic space, and even pelvic lymph node sampling, to determine disease extent. Clearly, each of these modalities offers a different level of sensitivity for detecting lesions and can vary markedly in efficacy. In the final analysis, the concept of clinical stage is meaningless without proper context. One must ask, What is the clinical stage by a particular set of diagnostic tests?

The Case for Prostate Cancer Screening

With the advent of PSA screening, there has been a dramatic increase in the number of younger men detected with localized disease. Along with improved outcomes for local therapy (surgery or radiation), it logically follows that PSA screening has contributed to the improved survival rates for men diagnosed with localized prostate cancer. However, the benefits of PSA screening remain controversial for clinicians and a source of confusion for patients. For clinicians, there has been a lack of level 1 evidence supporting the use of PSA screening. The two large randomized screening trials (with greater than 250,000 patients) has not helped clarify the issue because one trial did not show a survival benefit (the PLCO Cancer Screening Trial in the United States), while the other one did (the ERSPC trial in Europe) ^(37, 38). While confounding factors to each study limit a definitive conclusion about PSA screening, the enormous expense and time required may discourage future PSA screening trials. Available evidence favors

Table 37-1 Rationale for Prostate Cancer Screening

• Reduction in prostate cancer mortality coincides with the introduction of routine PSA screening.
• Patients whose cancers are detected with PSA screening have early-stage disease.
• Long-term disease-free survival is linked to treatment of early-stage disease.
• Randomized trials demonstrate a survival advantage for early surgical intervention for early-stage disease.

clinician discussion of the pros and cons of PSA screening with average-risk men aged 55 to 69 years. Other strategies to mitigate the potential harms of screening include considering biennial screening, a higher PSA threshold for biopsy, and conservative therapy for men receiving a new diagnosis of prostate cancer.

Although the US Preventive Services Task Force no longer recommends routine screening ⁽³⁹⁾, in our practice, we recommend annual PSA and digital rectal examination (DRE) for all healthy men starting at age 50 or age 40 for those at high risk (eg, those men with a family history or African Americans). Early inclusion of the patient in the decision-making process is essential to optimize patient care given the ambiguities regarding the cost effectiveness and clinical value of widespread screening for prostate cancer. The rationale for routine screening that justifies routine application is outlined in [Table 37-1](#).

The Case for Chemoprevention

Given the high prevalence of prostate cancer and the significant burden of therapy for patients, there is great interest in preventing the disease altogether or preventing lethal progression of the disease. Inhibitors of 5α-reductase enzymes (types 1 and 2 enzymes convert testosterone to dihydrotestosterone, the predominant and more potent agonist of AR signaling in prostate tissues) have demonstrated potential in this regard. Two randomized, placebo-controlled clinical trials utilizing finasteride (a type II inhibitor) and dutasteride (a type I/II inhibitor) have demonstrated a reduction in prostate cancer in healthy men who had no evidence for prostate cancer at enrollment but did have risk for developing disease (based on age and PSA) ^(40, 41). A third clinical trial evaluated the ability of dutasteride to prevent prostate cancer progression in patients with low-grade, low-risk, localized prostate cancer at study entry (REDEEM), and dutasteride could provide a favorable addition to active surveillance for men with low-risk prostate cancer ⁽⁴²⁾. While we have not adapted chemoprevention as standard of care, we are encouraging patients with low-risk prostate cancer

to participate in preoperative trials that offer short-duration 5 α -reductase inhibition prior to radical prostatectomy. Our goal is to elucidate molecular signatures that (1) predict response (or resistance) to 5 α -reductase inhibition, (2) characterize therapy-specific effects on epithelial-stromal compartments, and (3) refine existing risk stratification schemas.

PATIENT MANAGEMENT BY DISEASE STATE

Clinically Localized Disease at Presentation

As a result of widespread screening of men by PSA and DRE, the majority of patients are seen with clinically localized disease at diagnosis. Unfortunately, it is not always obvious how to match the individual patient with the most appropriate management. In an abstract sense, patients with clinically localized prostate cancer fall into one of four theoretical categories:

- *Those not destined to have any clinical manifestations of their disease.* These patients are actually harmed by any intervention, including further surveillance.
- *Those destined to have a clinical manifestation of cancer but will not die of it.* These patients might benefit from definitive therapy (such as prostatectomy or radiation) but would likely benefit equally from less-morbid intervention (eg, minimally invasive surgery).
- *Those destined to have life-threatening disease for whom definitive therapy will be curative.* Patients who can be cured, or for whom there will be a substantial alteration of the natural history of their disease, constitute the group that will unequivocally benefit from definitive local therapy.
- *Those destined to have life-threatening disease for whom the opportunity to cure by means of local therapy either never existed or passed.* For these patients, however, control of the primary could still be an important component of an overall treatment strategy that considers the probability of local versus distant progression, comorbidity, and other factors.

The common practice of urologists and radiation therapists is to assume that nearly every patient falls into the third category, and thus they recommend definitive therapy for the vast majority of newly diagnosed cases of localized prostate cancer. Unfortunately, available evidence suggests that less than half of patients are in category 3, so it is not surprising that understanding the role of definitive therapy in eliminating prostate cancer morbidity and mortality has been both difficult and controversial. In fact, these

issues underscore the fact that overtreatment of “clinically insignificant” prostate cancers certainly occurs. The significant cost and morbidity associated with local treatment also adds to the difficulty of managing these patients (whether the patient ultimately benefited from the therapy or not).

In patients with newly diagnosed localized disease, current prognostic and predictive models rely on data derived from large prostatectomy series conducted at major academic centers. For example, investigators at Johns Hopkins initially published a predictive model relating the rate of finding disease that is not confined to the prostate (by assessing the surgical specimen) as a function of three readily available preoperative clinical parameters: PSA, Gleason score from the core biopsy, and the clinical stage based on DRE (^{43, 44}). The correlation of these features with pathologically organ-confined disease, summarized in the famous “Partin tables,” provided sobering evidence that commonly encountered subsets of patients had a surprisingly high risk of disease that was not confined to the prostate. Of course, not all patients with pathologically organ-confined disease relapse, and not all patients with pathologically organ-confined cancers are cured. Thus, the importance of this particular surrogate outcome was and remains uncertain. Nevertheless, the effect of the Partin tables on clinical practice has been profound. They have driven the application of prostatectomy to patients with smaller and smaller volumes of cancer. It is clear that although more patients are remaining free of disease after prostatectomy, this comes paradoxically at the cost of operating on many patients who may not have needed surgery or not operating on many patients who would have benefited from good local control even if the surgery were not curative.

Additional models have been developed to predict outcomes following radical prostatectomy or radiation therapy. Based on the work of D’Amico, a combination of pretherapy PSA, Gleason score, and clinical stage can be used to stratify patients into low (T1-T2a and Gleason score 2-6 and PSA <10 ng/mL); intermediate (T2b-T2c or Gleason score 7 or PSA 10-20 ng/mL); high (T3a or Gleason score 8-10 or PSA >20 ng/mL); and locally advanced (T3b-T4) groups that predict risk for both biochemical recurrence and survival following definitive local therapy (radical prostatectomy or radiation) (⁴⁵). Similarly, Kattan et al developed post-operative nomograms for predicting prostate cancer recurrence after radical prostatectomy (⁴⁶). These tools not only help guide recommendations for individual patients, but also help stratify patients for clinical trials. For example, low-risk patients can be directed toward “active surveillance” trials, while high-risk patients can be direct toward adjuvant/neoadjuvant trials. The rationale for the use of predictive nomograms is outlined in [Table 37-2](#).

Table 37-2 Rationale for Use of Predictive Nomograms

• Gleason grade, clinical stage, and initial PSA are predictive of surgical stage, risk of subsequent relapse, and risk of cancer-specific mortality.
• Improving the ability to predict outcome will inform both physicians and patients about the risk/benefits of local therapy.
• Fewer patients will undergo unnecessary or futile surgery.

Despite the efforts detailed previously, tumors with identical morphology and clinicopathologic characteristics often display biologic heterogeneity (ie, some “low-risk” tumors rapidly progress, while some “high-risk” tumors are relatively indolent). Thus, more refined models are needed. Recent efforts have sought to incorporate genetic tests to enhance current clinicopathologic risk stratification for patients newly diagnosed with localized prostate cancer. For example, PROLARIS (Myriad Genetics, Inc.) directly measures expression of 46 different genes in formalin-fixed paraffin-embedded tissue obtained by biopsy or prostatectomy⁽⁴⁷⁻⁴⁹⁾, including 31 cell cycle progression (CCP) genes and 15 housekeeper genes that correlate with proliferation of prostate cancer. Low expression is associated with a low risk of disease progression, whereas high expression is more indicative of higher risk of disease progression, suggesting either close monitoring or additional therapy for the latter group of patients.

Other investigational approaches to improve risk stratification include assessing suspicious nodes or small-volume extracapsular extension by MRI or positron emission tomography, staging biopsies of seminal vesicles and extraprostatic tissue, and incorporation of molecular signatures. Within our group, a significant effort is under way to relate the expression of genes that may affect apoptotic threshold, invasion, angiogenesis, and AR signaling to biologic potential and ultimately clinical outcome of localized tumors. These data suggest that both loss of tumor suppressor pathways (eg, p53) and gain of oncogene/antiapoptotic pathways (eg, Bcl-2) contributes to prostate cancer progression. In addition to these and other “epithelial” events, the importance of the host-epithelial interaction in prostate cancer progression has been supported by evidence that pathways involved in paracrine regulation of normal stromal-epithelial interactions have also been implicated in prostate cancer progression⁽⁵⁰⁻⁵²⁾.

Therapy

Localized Low-Stage Prostate Cancer

In patients with localized low-stage disease (generally including low- and intermediate-risk groups based on

the D’Amico risk stratification groups), the options offered include active surveillance, surgery, radiation, or presurgical clinical trials. Educating the patient about his treatment options is critical to make the best decision for each individual. Patients who are undecided or request more information about treatments and side effects are seen in our multidisciplinary clinic.

Critical evaluation of the relative merits of different therapies for localized low-stage prostate cancer is difficult. This is because patients in this category have a greater than 80% chance of 10-year progression-free survival following local therapy⁽⁵³⁻⁵⁵⁾. Prostate cancer has a long natural history, and 10-year data for patients with low-risk prostate cancer remain immature with respect to cause-specific and disease-free survival. The contribution of delayed hormonal therapy and the appreciation that not all patients with a delayed PSA recurrence after local therapy are threatened by their disease have made comparisons between different treatment modalities difficult. As a consequence, the modification of older therapies or the application of new ones (such as brachytherapy, cryoablation, or proton beam therapy) is often judged by their complication profile and the rate of PSA-free survival with a relatively short follow-up. While seemingly logical, interpreting potential benefit from “new and improved” therapies is challenged by the impact of “stage migration” on outcomes. Stage migration refers to the fact that, as a consequence of awareness and PSA screening, younger patients with lower-stage cancer are diagnosed with increasing frequency. This trend of earlier therapy in younger patients with earlier-stage disease likely has an effect on the analysis of therapy efficacy and morbidity for low-stage cancer. Therefore, the practice of deriving conclusions from the comparison of nonrandomized study groups in low-stage prostate cancer is a dubious exercise.

In fact, in localized, low-stage prostate cancer, the principal therapeutic dilemma is whether to intervene at all. Increasingly, many investigators are recognizing that not all patients diagnosed with prostate cancer by histologic criteria have a disease that has lethal potential⁽⁵⁶⁾. Hence, many clinicians have explored a strategy of observation followed by delayed therapy if required. This strategy has historically been called “watchful waiting,” but in recent years we have adopted the term *active surveillance*. This is because the definition of watchful waiting is ambiguous and includes the practice of not following or evaluating patients after diagnosis until they present with a prostate cancer–associated symptom(s). In contrast, active surveillance implies regular follow-ups with PSA evaluation, DRE, and repeat biopsies as indicated to inform the need for local therapy. Active surveillance acknowledges the reality that many patients with prostate cancer survive despite diagnosis and therapy,

as opposed to benefiting directly from the intervention. At MD Anderson, the rationale for offering active surveillance is the idea that carefully monitored patients will require therapy with curative intent only if accompanied by objective evidence that their cancer has become life threatening. In this way, patients with truly indolent disease can be spared the morbidities of local therapy, while patients who show progression over time to potentially lethal disease will preserve the opportunity for curative therapy.

Active Surveillance With Deferred Treatment

Two categories of patients with low-stage disease are generally considered for active surveillance: (1) men who have a higher probability of dying from a comorbid illness (such as coronary artery disease) than from prostate cancer and (2) men whose cancer poses some risk for lethality but choose active surveillance because of concerns about consequences of therapy (eg, impotence or incontinence). The rationale for active surveillance is outlined in [Table 37-3](#).

There are two central challenges of the active surveillance strategy. The first is that we do not yet have a validated method to anticipate progression of the disease to avoid “closing the window” on curative therapy. The second is that we lack methods to ensure reliable selection of all patients in whom the disease will be unlikely to spread while excluding all patients who will have lethal progression of the disease despite its initial morphologic appearance as low stage. Thus, this strategy, while supported by compelling logic, must be regarded as unproven. This is particularly true for those patients with a life expectancy of 15 years or more. As a patient’s life span shortens due to comorbid conditions, the unproven nature of this strategy has less predicted impact on outcome. Thus, outside a clinical trial, active surveillance in our practice is routinely reserved for patients with low-stage disease and an expected survival of less than 10 years due to comorbidities.

Active surveillance for category 1 patients is not codified, and follow-up strategies (such as annual PSA checks) are designed by mutual agreement between the physician and patient. Select elderly patients whose cancer diagnosis was precipitated by an ill-advised

PSA screening test may choose no further follow-up. In contrast, active surveillance for category 2 patients involves close observation with quarterly PSA checks and annual prostate biopsies. Often, these patients elect to undergo local therapy as the physical and emotional burden of close observation becomes more obvious. Despite the intensity of follow-up, the ability to anticipate progression of disease based on true biologic evidence as opposed to apparent progression caused by the randomness of the biopsies remains a major problem. These problems will be clarified with prospective studies accruing at several institutions.

Treatment of Low-Stage Disease With Available Therapy

Although there is much debate about the relative merits of radiation therapy and surgery for patients with localized low-stage prostate cancer, the inescapable conclusion is that both treatment groups have excellent survival, and the principal issues influencing choice are related to therapy-associated morbidity. Interestingly, competition between radiation therapy and surgery has resulted in the reduction of morbidity to both therapies. The morbidity of radiation therapy—while retaining its effectiveness—has been greatly reduced, as has morbidity related to improvements in surgical techniques. Thus, for low-stage prostate cancer, the principal therapeutic recommendation is to treat those patients who have a greater than 15-year expected life expectancy. The primary recommendation is surgery or radiation therapy, with a bias toward surgery for those patients with an expected longevity of more than 20 years and a bias toward radiation therapy for those patients with an expected longevity of 15 years or less ([Table 37-4](#)).

Table 37-4 Rationale for Selection of Local Treatment Modality

- There are no clinical trials showing a therapeutic advantage of surgery over radiation therapy for localized disease.
- Either approach is associated with some risk of significant morbidity (initial impotence rates are higher with surgery).
- There is a reduction in impotence rates over time with radiation.
- Surgery provides better assessment of risk for future relapse by allowing molecular-pathologic analysis of the radical prostatectomy specimen.
- Radiation is ideally suited for patients who are physically unfit for surgery or those who have disease extending beyond the bounds of traditional surgical fields.
- Surgery improves symptom-free and overall survival in patients with localized disease.

Table 37-3 Rationale for Active Surveillance

- A significant portion of newly diagnosed patients will not develop clinical progression.
- Complications of local therapy exceed benefits in some patients.
- Close monitoring of selected patients with serial PSA measurements may avoid or delay initiation of potentially morbid or unnecessary therapy.

Presurgical Trials for Low-Stage Disease

Presurgical trials facilitate the development of novel therapies and treatment strategies in prostate cancer by providing proof of “target engagement” by the drug(s) and modulation of the tumor phenotype in a therapeutically favorable manner⁽⁵⁷⁾. The principal goal of a *preoperative* clinical trial is to identify short-term molecular and pathologic tissue surrogates that establish target engagement and modulation of key signaling pathways by the drug(s). Because surgery is performed before cytoreduction or significant changes in the tumor phenotype are expected (as opposed to *neoadjuvant* trials), preoperative trials provide only limited inferences about the therapeutic potential of the drug(s) being tested. However, data from preoperative trials help identify the most promising therapeutic candidates worthy of further study. Preoperative studies of low-stage prostate cancer seek to identify molecular markers that characterize response to therapy and predict tumor biology.

High-Risk and Locally Advanced Prostate Cancer

As a general principle of oncology, high-risk and locally advanced tumors (based on the D’Amico risk stratification groups) are best treated with a combination of systemic therapy and aggressive local therapy. This strategy addresses occult disseminated disease while preventing local complications of the primary tumor. Despite the widely recognized poor outcomes for patients with seminal vesicle or regional node involvement, the application of optimum local control with systemic therapy has only recently become accepted⁽⁵⁸⁾.

Current multimodal therapies include radiation plus hormones and neoadjuvant therapy plus surgery. It is now well established that the addition of hormones to radiation therapy is superior to radiation therapy or hormones alone for patients with high-risk and locally advanced tumors⁽⁵⁹⁾. The duration and sequence of the combination are important in maximizing therapy benefit from the combination. Several lines of evidence suggest that initiating the androgen ablation 2 months prior to the radiation therapy is more effective than combined therapy from the outset or sequential therapy with radiation followed by androgen ablation. The available data demonstrate an increase in survival with a 3-year period of androgen ablation. However, the optimal duration of androgen ablation in the context of locally advanced prostate cancer treated with radiation remains an area of investigation.

It also appears that improved local control represents another strategy to improve overall survival (OS) in patients with T3N0M0 (TNM, tumor-node-metastasis) tumors. Randomized controlled trials have demonstrated that adjuvant radiation therapy

following radical prostatectomy for T3N0M0 tumors significantly reduces the risk of metastases and improves OS⁽⁶⁰⁾. These data support the hypothesis that untreated residual disease at the primary site can act as a source for metastatic progression.

Neoadjuvant Trials in High-Risk and Locally Advanced Prostate Cancer

At MD Anderson, we recognize two different categories of patients with high-risk or locally advanced disease: (1) those we believe can be effectively treated with hormones and radiation therapy and (2) those we believe will not be effectively treated with this approach because of the extent of their disease, adverse histologic features of the tumor, or the relative youth and expected long survival of the patient. Patients in the second category are candidates for a novel preoperative therapy given prior to prostatectomy. The rationale for neoadjuvant therapy in this setting is based on progress made in other cancer types and is described as follows: (1) In high-risk and locally advanced disease, the posttherapy pathology specimen will inform both prognosis and future treatment decisions, and (2) controlling the primary tumor is an essential part of an integrated strategy for patients with high-risk and locally advanced disease (although this strategy is not always curative)⁽⁶¹⁾. We are using neoadjuvant trial designs with increasing frequency to develop novel agents (eg, angiogenesis inhibitors) in prostate cancer. Analysis of the prostatectomy specimen permits detailed analysis of molecular (eg, apoptosis) and pathologic surrogates for therapy benefit (eg, achievement of Pathologic 0 stage-P0). We believe the preoperative model will significantly enhance our ability to identify the most promising agents worthy of development in a time-efficient manner.

A promising combined modality approach has recently been reported utilizing maximal androgen blockade of both endocrine (using luteinizing hormone-releasing hormone agonists) and paracrine/autocrine/intracrine (using abiraterone, a CYP17 inhibitor) testosterone sources. Two recent phase 2 studies demonstrated that combination leuprolide/abiraterone was clinically superior to leuprolide alone with respect to PSA responses and cytoreduction^(62, 63). A subset of patients in both trials achieved P0 (or near P0) in the surgical specimen, a relatively common phenomenon in neoadjuvant trials of other epithelial cancers (eg, breast and bladder) but essentially unprecedented in prostate cancer.

Castration-Resistant Locally Advanced Prostate Cancer

Castration-resistant prostate cancer (CRPC) is an “umbrella” term that encompasses a spectrum of

disease states ranging from rising PSA alone to rising PSA associated with osseous or soft tissue metastases (!). Furthermore, patients receiving combined androgen blockade are typically screened for an antiandrogen withdrawal response before being considered castration resistant. Patients with CRPC and PSA-only recurrence are discussed in the next section.

For patients with castration-resistant locally advanced prostate cancer, clinical progression presents significant clinical symptoms (pain, hematuria, bladder outlet and bowel obstruction), but optimal management remains a difficult therapeutic problem. The critical decision is whether to offer consolidative therapy. For patients without metastatic disease, we offer neoadjuvant chemotherapy followed by surgery for consolidation. If not used as primary therapy, salvage radiation therapy is another rational strategy, particularly for patients who are not candidates for salvage surgery.

For patients with both castration-resistant locally advanced and metastatic disease, these approaches are more controversial. Nonetheless, we recognize that these patients experience significant morbidity from local tumor progression that is comparable to patients without metastases. Thus, for select candidates, we still offer consolidative therapy. As an example, consider the case of a patient who presented with metastatic prostate cancer at diagnosis and was successfully treated with androgen ablation for 10 years. He then developed castration-resistant progression and presented with invasion of his primary tumor into the bladder (Fig. 37-3). To relieve painful voiding symptoms attributed to the bladder invasion, induction chemotherapy followed by salvage cystoprostatectomy was performed. At 3 years follow-up, the patient continued to have evidence of active metastases but was

FIGURE 37-3 Recurrent prostate cancer invading the base of the bladder.

Table 37-5 Rationale for Salvage Surgery

- Patients can avoid significant morbidity associated with local progression.
- Improved local control may contribute to longer overall survival.
- Patients who develop a delayed local relapse after treatment with primary radiation therapy may still have surgically curable disease.

free of cancer-associated local symptoms. While this patient benefited longer than most, striking relief of intractable symptoms is common using this approach. The clinical rationale to apply chemotherapy followed by salvage surgery is summarized in Table 37-5.

Rising Prostate-Specific Antigen After Definitive Local Therapy

The utility of PSA measurements is greatest in monitoring cancer progression and effects of therapy in patients with radiographic evidence of disease. In contrast, the significance of PSA in patients without detectable disease is less clear. Although available evidence suggests that patients with a measurable PSA following prostatectomy will eventually develop a recurrence given sufficient time, these recurrences are not uniformly fatal. Furthermore, in patients treated with radiation therapy, interpretation of PSA post-therapy is very different compared to patients treated with surgery.

Significance of Prostate-Specific Antigen Following Prostatectomy

The serum PSA concentration should be undetectable using standard commercial assays within 6 weeks of prostatectomy. Persistent PSA following surgery usually indicates persistent cancer secondary to inadequate surgery, persistent cancer despite adequate surgery, or the presence of occult metastases. The experience from Johns Hopkins suggests that, given sufficient time, patients with early PSA recurrence (≤ 2 years) or short PSA doubling time (< 10 months) will develop metastatic disease within 15 years of surgery (⁶⁴⁻⁶⁶). In contrast, patients with late PSA recurrence or a longer PSA doubling time are more likely to have a recurrence confined to the prostatic fossa. Patients who have a striking discordance between the predicted behavior of the cancer (eg, low stage) and early elevations of postoperative serum PSA may have had inadequate surgery and are considered for adjuvant radiation therapy. In patients who undergo nerve-sparing prostatectomy, consideration must also be given to the possibility that normal prostate gland left behind at surgery is producing PSA.

Significance of Prostate-Specific Antigen Following Radiation Therapy

In contrast to surgery, serum PSA concentrations are not expected to become undetectable following curative therapy. In addition, the phenomenon of a PSA “bounce” is well described following radiation of the primary tumor ⁽⁶⁷⁾. The PSA bounce is a modest, self-limited rise in PSA concentration without evidence of cancer progression. It typically occurs within the first 18 months following completion of radiation and can last for as long as 3 months before reaching a plateau and then declining. The central clinical dilemma with PSA bounces is that their presence can only be determined with confidence in retrospect. Thus, clinicians need to be aware of this phenomenon and show restraint in introducing therapy to patients displaying delayed PSA elevation after radiation without evidence for metastases.

Management of the Patient With Prostate-Specific Antigen–Only Recurrence

The scenario of the patient with prostate-specific antigen–only recurrence poses a therapeutic dilemma for physicians and considerable anxiety for patients. As experience with this disease state matures, it is becoming clear that PSA-only recurrences do not uniformly portend morbidity/mortality from the disease. Our general approach is to offer hormone ablative therapy (commonly using an intermittent strategy) during the androgen-dependent phase of the disease ⁽⁶⁸⁾. Notably, we never use chemotherapy for PSA-only recurrences that occur in the setting of CRPC. Instead, we advocate placing these patients on clinical trials testing novel compounds.

Currently, we are conducting a clinical trial at our institution (NCT01786265) that is testing whether more potent inhibition of androgen synthesis will help. The goal of this clinical research study is to determine whether inhibition of paracrine/autocrine/intracrine androgens (using abiraterone) in addition to endocrine androgens (using leuprolide) will improve efficacy in this patient group. A key data point will be *PSA-free survival*, defined as duration of time “off” therapy with an undetectable PSA and return of testosterone levels.

Metastatic Cancer

Metastatic Androgen-Dependent Disease

For patients with visible disease in the bone or lymph nodes, the standard approach is continuous androgen ablation. The clinical rationale for the use of androgen ablation is summarized in Table 37-6. For patients with de novo metastatic disease and primary tumors in place, we are currently conducting a clinical trial (NCT01751438) to test best systemic therapy versus best systemic therapy plus definitive treatment

Table 37-6 Clinical Rationale for Androgen Ablation

1. Androgen ablation enhances local therapy:
• Concurrent androgen ablation and radiation therapy increase survival in selected patients.
• Early use of androgen ablation in patients noted to be node positive following radical prostatectomy increases overall survival.
2. Timing of androgen ablation:
• The decision to introduce androgen ablation among patients with a rising PSA following local therapy should be based on assessment of risk for recurrence and cancer-associated mortality.
• Androgen ablation therapy reduces the duration of time patients experience symptomatic progression.
• Symptoms are reliably relieved and should be initiated in the presence of symptomatic progression.
3. Types of androgen ablation:
• Surgical castration and LHRH agonists or antagonists are considered to be equally effective.
• Combined androgen ablation is not convincingly superior to serial use of an LHRH agonist followed by an antiandrogen on progression. However, antiandrogen therapy should precede the use of an LHRH agonist in the setting of threatening disease to avoid a “surge.”
4. Secondary hormonal therapy:
• Experimental and clinical data demonstrate that some prostate cancers growing in a castrate environment still rely on androgen signaling for continued growth.
5. Management of complications associated with androgen ablation:
• Patients on sustained androgen ablation should be monitored for bone complications and considered for bisphosphonate therapy to reduce the risk of osteopenia.
• Supplementation with calcium (500 mg) and vitamin D (400 IU) is recommended.
• Antidepressants should be considered for androgen ablation–associated depression.

(radiation or surgery) of the prostate. The goal of this clinical research study is to learn if control of the primary tumor improves the clinical outcome in patients with metastatic disease. The safety of this combined modality treatment combination will also be studied.

The role of cytotoxic chemotherapy in patients with androgen-dependent disease remains controversial. Most recently, data from the CHAARTED trial comparing “up-front” chemotherapy plus androgen deprivation therapy (ADT) to ADT alone in men with metastatic prostate cancer was reported. The results showed that, in men with high-volume disease (defined as visceral metastasis and/or ≥4 bone metastases), median OS was 49.2 months with docetaxel plus ADT compared with 32.2 months with ADT, a difference of

17 months⁽⁶⁹⁾. Although the final manuscript is pending publication at this point, this study suggests that patients with high-volume, androgen-dependent disease may benefit from up-front docetaxel.

However, in contrast to those data, other large phase 3 studies of similar design have been negative^(70, 71). The GETUG-AFU 15 trial recently reported no differences in OS between patients with noncastrate metastatic disease receiving ADT plus docetaxel versus ADT alone (median OS was 58.9 months in the group given ADT plus docetaxel and 54.2 months in the group given ADT)⁽⁷¹⁾. It is likely that differences in patient populations (eg, volume of disease at baseline) and treatments postprogression explain the disparate results between these trials. At our institution, while our clinical experience strongly supports the notion that some patients with metastatic disease will benefit from early application of cytotoxic chemotherapy (eg, patients with small cell/anaplastic features), we offer it on a case-by-case basis rather than routinely.

Castration-Resistant Progression

Second-Line Hormonal Therapies

During castrate-resistant progression, there is a gradual “switch” in sources of androgens that sustain tumor growth from endocrine to intratumoral (paracrine/autocrine/intracrine). Second-line hormonal therapies that block these alternative sources have long been of interest as cancer therapeutics. For example, considerable advances have been made in developing small molecule inhibitors that block CYP17, a key enzyme involved in androgen biosynthesis expressed in testes, adrenal glands, and tumor tissues⁽⁷²⁾. Ketoconazole is an antifungal agent with weak and nonspecific CYP17 inhibitory properties that has been available for decades. While ketoconazole is active in prostate cancer, its application has been limited due to extremely poor tolerance. In contrast, several new agents, including abiraterone, have proven more successful. Abiraterone is a potent irreversible inhibitor of CYP17, and two large randomized phase 3 studies have demonstrated clinical benefit in both chemotherapy-naïve and docetaxel-treated patients with metastatic castration-resistant prostate cancer (mCRPC)^(73, 74).

Enzalutamide (Xtandi; Medivation/Astellas) is a small molecule that directly binds the AR to competitively inhibit endogenous androgen binding and antagonize AR function. It has a higher affinity for the AR than first-generation nonsteroidal antiandrogens (eg, bicalutamide). Randomized phase 3 studies have demonstrated that enzalutamide is clinically beneficial in both chemotherapy-naïve and docetaxel-treated patients with mCRPC⁽⁷⁵⁾. Because enzalutamide can potentially address molecular resistance mechanisms to abiraterone monotherapy and vice versa, studies

of combination abiraterone and enzalutamide are also under way. More specifically, resistance to abiraterone is associated with increased nuclear AR copy number (theoretically blocked with enzalutamide), and resistance to enzalutamide is associated with increased microenvironment testosterone levels (theoretically blocked with abiraterone)^(76, 77). Preliminary analysis suggested that a higher percentage of patients experience favorable PSA response profiles than seen with either agent alone, and the combination appears to be well tolerated⁽⁷⁸⁾.

Although abiraterone and enzalutamide represent breakthroughs in the treatment of mCRPC, approximately 20% to 40% of patients have no response to these agents (primary refractory). Furthermore, among patients who initially have a response to enzalutamide or abiraterone, virtually all eventually acquire secondary resistance. For example, the emergence of mutations (such as a single F876L amino acid substitution) in the AR can confer resistance to enzalutamide. Recently, Antonarakis et al reported detection of AR-V7 in circulating tumor cells from patients with CRPC may be associated with resistance to enzalutamide and abiraterone⁽⁷⁹⁾.

Chemotherapy

Prostate cancer has now entered the realm of the other adult common solid tumors in that chemotherapy is routinely applied to patients with castration-resistant locally advanced or metastatic disease. For more than a decade, patients have been treated with docetaxel-based regimens. However, while these therapies improve quality of life, prolongation in survival is modest. Faced with these challenges, the approach at MD Anderson has been to delay cytotoxic therapy until second-line hormonal (or experimental options) have been explored. Of course, patients with rapidly progressive disease causing (or expecting to cause) symptoms are offered chemotherapy sooner rather than later, particularly when additional hormonal manipulations are predicted to fail (eg, in patients with small cell/anaplastic tumors). The rationale for the use of chemotherapy is outlined in [Table 37-7](#).

Table 37-7 Rationale for the Use of Chemotherapy

- | |
|---|
| • Chemotherapy palliates or prevents symptoms associated with progression of disease. |
| • Docetaxel-based regimens result in modest improvements in survival in patients with metastatic castration-resistant cancer. |
| • Other active agents in prostate cancer (eg, mitoxantrone and prednisone) can be used as second-line therapy. |

Given the limitations of docetaxel-based chemotherapy, there has been a global research initiative to improve on it, principally by combining docetaxel with other agents. However, these efforts have met with little success. For example, antiangiogenic drugs such as sunitinib and avastin did not improve OS compared with placebo in docetaxel-refractory mCRPC^(80, 81). Similarly, bone microenvironment targeting agents such as zibotentan, atrasentan, and dasatinib were each tested in phase III trials and all failed to improve on standard docetaxel⁽⁸²⁻⁸⁴⁾. Interestingly, each of these agents showed promise in phase II studies, and some (eg, avastin and sunitinib) did result in improvements in median progression-free survival. These results suggest that a subset of patients did benefit and that moving forward, clinical trial designs that incorporate predictive biomarkers to enrich for patients most likely to respond will be necessary to develop novel treatment strategies.

Optimizing Therapy Benefit Using Different Cytotoxic Agents in Metastatic Castration-Resistant Prostate Cancer

The concept that patients can respond to another taxane after progressing on docetaxel is important. The recent approval of cabazitaxel by the Food and Drug Administration (FDA), based on the results of the phase III TROPIC study, provided further validation of this concept⁽⁸⁵⁾. Cabazitaxel is a novel semisynthetic taxane developed specifically to overcome docetaxel resistance, and it is typically offered as second-line therapy for patients with mCRPC previously treated with docetaxel. This promising advance suggests that further study of cabazitaxel is warranted to explore its potential to overcome taxane resistance.

Beyond docetaxel and cabazitaxel, multiple chemotherapy regimens with modest activity are routinely applied in a sequential manner to patients in the salvage setting. Examples include CVD (cyclophosphamide, vincristine, and dexamethasone); KAVE (ketoconazole plus doxorubicin alternating with vinblastine plus estramustine); TEC (paclitaxel, estramustine, and carboplatin); and TEE (paclitaxel, estramustine, and etoposide). However, there is no standard chemotherapy in the salvage setting, and we do not have randomized comparisons testing whether the sequential application of therapy prolongs survival.

More recent studies have demonstrated clinical responses to platinum-based therapy in combination with taxanes⁽⁸⁶⁻⁸⁸⁾. Ross et al tested the activity of docetaxel/carboplatin in patients that had progressed during or within 45 days after the completion of docetaxel⁽⁸⁹⁾. PSA declines of 50% or greater were noted in 18% of patients, and measurable responses

occurred in 14% of patients. As patients in this study would not be anticipated to respond to “rechallenge” with docetaxel alone, these results support the hypothesis that carboplatin has the potential to overcome docetaxel resistance mechanisms.

We are presently conducting a randomized phase I/II study of cabazitaxel with or without carboplatin in patients with mCRPC (NCT01505868). Patients are stratified by prior docetaxel exposure, performance status, and presence of anaplastic features. Preliminary results suggest excellent safety and efficacy of the two-drug combination.

Stromal-Targeting Therapies

Bone-targeting radiopharmaceuticals are examples of stromal-targeting agents in prostate cancer. The merits of targeting the bone microenvironment have been established by the use of strontium 89 (pure β -emitter radiopharmaceutical) as a single agent or in combination with cytotoxic therapy⁽⁹⁰⁾ (Table 37-8). Emerging data support the view that targeting bone will prolong overall patient survival, even in those with advanced-stage disease. Samarium-153 conjugated to ethylenediamine-tetra-methylenephosphonic acid is a β - and γ -emitter radiopharmaceutical. It was approved by the FDA in 1997 after the landmark study that showed palliation of pain associated with metastatic bone cancer using samarium-153 lexidronam⁽⁹¹⁾. However, marrow toxicity remains the principal side effect. The radioactive calcium mimetic radium-223 dichloride (Xofigo; Bayer), which specifically targets bone metastases (present in 80%–90% of patients with metastatic CRPC), is the newest treatment for mCRPC. A phase III, randomized, double-blind, placebo-controlled study (ALSYMPCA) investigated the use of radium-223 in men with CRPC and bone metastases; radium-223 showed improved OS in this patient population⁽⁹²⁾. This study led to its FDA approval for CRPC with bone metastases in 2013.

Bisphosphonates were the first class of agents investigated for prevention of skeletal-related events (SREs) in patients with mCRPC. A randomized,

Table 37-8 Rationale for Bone-Targeted Therapy

• Osseous metastases are the preferred site of castration-resistant progression.
• Osseous metastases significantly contribute to the morbidity and mortality of prostate cancer.
• Bone-targeting radiopharmaceuticals prolong symptom-free survival in patients with castration-resistant progression and skeletal metastases.

placebo-controlled trial of zoledronic acid in patients with hormone-refractory metastatic prostate carcinoma showed zoledronic acid reduced SREs in patients with prostate cancer with bone metastases⁽⁹³⁾. Currently, zoledronic acid is the only bisphosphonate approved to prevent SREs in patients with mCRPC.

Denosumab is a fully humanized monoclonal antibody that binds to the RANK-L, which results in inhibition of RANK-L-mediated bone resorption. In a phase III study, men with CRPC with bone metastases and no previous exposure to intravenous bisphosphonate compared denosumab with zoledronic acid for prevention of SREs⁽⁹⁴⁾. Denosumab was superior to zoledronic acid in delaying or preventing SREs, but there was no significant difference between treatments in survival or disease progression⁽⁹⁴⁾. It was approved by the FDA in 2010 for prevention of SREs in patients with bone metastases.

Immune-Based Therapies

Historically, there has been long-standing interest in stimulating a patient's immune system as a therapy strategy for prostate cancer. Despite enthusiasm for this paradigm, studies have consistently demonstrated no clinical benefit. Recently, several new strategies have emerged that reveal the potential of immunotherapy in treating prostate cancer. Randomized, placebo-controlled phase III trials demonstrated an OS benefit for men with CRPC treated with sipuleucel-T⁽⁹⁵⁾. GVAX, a cellular vaccine product that uses exogenous tumor cells that secrete granulocyte-macrophage colony-stimulating factor, has shown promising activity in phase II studies⁽⁹⁶⁾, although it failed to meet its primary end point of OS when compared with docetaxel in a phase III study^(97,98). Ipilimumab is a humanized anti-CTLA-4 antibody; recent data from a phase III trial of a single dose of radiation treatment followed by ipilimumab or placebo in previously treated patients showed the primary end point (ie, OS) was not met (ipilimumab vs placebo, 11.2 vs 10.0 months, respectively; however, there was an improvement in progression-free survival and PSA responses)⁽⁹⁹⁾. Another phase III trial has completed enrolling patients with less-advanced, chemotherapy-naïve mCRPC. Further development of these agents (and others) could dramatically change the way we treat prostate cancer in the coming decade.

FUTURE DIRECTIONS

The majority of patients with advanced prostate cancer demonstrate a predictable clinical pattern of progression. As elucidation of the biologic events responsible

for prostate cancer progression evolves, better classification of the disease based on the underlying molecular mechanisms of progression will facilitate the implementation of current and emerging therapies. To reflect this, we have recently proposed a “spiral” model for prostate cancer progression that describes underlying biology to predict response to therapy⁽¹⁰⁰⁾ (Fig. 37-4). The model proposes three main phases in prostate cancer progression: (1) DHT-dependent phase, (2) microenvironment-dependent phase, and (3) cell-autonomous phase.

The first phase is the *DHT-dependent phase*, during which the tumor is responsive to 5- α -reductase inhibitor treatments. In the PSA era, this phase typically occurs when patients are initially diagnosed with early-stage, localized prostate cancer. Tumors in this phase would be predicted to respond optimally to chemoprevention strategies.

The second phase is the *microenvironment-dependent phase*, when the tumor enters a progression spiral where multiple factors, including AR signaling changes, oncogene activation, tumor suppressor gene loss, and microenvironment changes, affect tumor progression. Tumors in this phase would be predicted to respond optimally to inhibitors of intratumoral androgen signaling (eg, with abiraterone and enzalutamide). Over time, however, adaptive changes in response to therapy promote resistance, leading the tumor to progress to the next turn of the progression spiral, which signals additional molecular alterations in the tumor and its microenvironment. Tumors in a new turn of the spiral will require different therapeutics that specifically target the altered molecular events that drive each turn (eg, inhibitors of Src, FGF, c-Met). Predictive biomarkers corresponding to each turn can be used to guide timely therapy application.

The third phase is the *cell-autonomous phase*, whereby cancers exit the spiral when a series of mutations arise, including the loss of AR, RB, or p53; upregulation of polo-like kinase 1 (PLK1), Aurora kinase A (AURKA); and amplification of *MYCN*. At this stage, the prostate cancer cells are no longer regulated by the microenvironment and become tumor cell autonomous. Cancers in this phase would be predicted to respond optimally to chemotherapy.

Along with the integration of improved predictive and prognostic markers, we believe it is realistic to expect individualized treatment algorithms for prostate cancer patients as details of the spiral evolve. The application of biologically based, rational therapy is the foundation of our mission at MD Anderson to cure prostate cancer. Recent progress has created a strong sense of hope that we are well on our way to achieving this goal.

FIGURE 37-4 Spiral model for prostate cancer progression. The first phase is the *DHT-dependent phase*. The second phase is the *microenvironment-dependent phase*. The third phase is the *cell-autonomous phase*. Each “turn” is defined by a predictive marker(s) that can be targeted. The pitch in each spiral reflects the duration that the tumors remain responsive to a specific therapy. The adaptive changes in tumors in response to therapy account for resistance, leading the tumor to progress to the next turn of the progression spiral, which signals additional alterations in the tumor and its microenvironment. Tumors in this new “turn” will require different therapeutics that specifically target the altered properties that define the turn. Markers that reflect the biology that drives each turn can be used to guide timely therapy application in anticipation of progression. DHT, dihydrotestosterone; AR, Androgen Receptor; IGF, Insulin Like Growth Factor; FGF, Fibroblast Growth Factor. (Reproduced with permission from Logothetis CJ, Gallick GE, Maity SN, et al. Molecular classification of prostate cancer progression: foundation for marker-driven treatment of prostate cancer, *Cancer Disco*. 2013 Aug;3(8):849-861.)

INCIDENCE AND ETIOLOGY

Incidence in United States

Penile cancer most commonly affects men between 50 and 70 years of age. The tumor is not unusual in younger men; in one large series, 22% of patients were younger than 40 years, and 7% were younger than 30 years ⁽¹⁾. In 2015, there were an estimated 1,820 new cases in the United States ⁽²⁾.

Epidemiology

Penile carcinoma accounts for less than 1% of all malignant neoplasms among men in the United States and Europe, but it may represent up to 20% of malignant neoplasms in men in some Asian, African, and South American countries ⁽¹⁾. These differences are thought to be related to the prevalence of neonatal circumcision, human papillomavirus (HPV) infection, and hygienic practices. Rates of HPV vaccination will likely become a factor in the future ⁽³⁾.

Incidence and Significance Worldwide

Among uncircumcised tribes of Africa and within uncircumcised Asian cultures, penile cancer may amount to 10% to 20% of all malignant neoplasms in men ⁽¹⁾. Carcinoma of the penis is particularly rare among the Jewish population, for whom neonatal circumcision is a universal practice ⁽⁴⁾. The annual number of new cases in total per year worldwide has been

estimated at approximately 26,000 ⁽⁵⁾. Squamous cell carcinoma is the most common histologic subtype, accounting for over 95% of cases (Table 38-1) ⁽⁶⁾.

RISK FACTORS

Lack of Circumcision

The risk of penile cancer varies according to circumcision practice, hygienic standard, phimosis, number of sexual partners, HPV infection, exposure to tobacco products, and other factors ^(1,5). Neonatal circumcision has been well established as a prophylactic measure that removes most of the risk of penile carcinoma because it eliminates the closed preputial environment where penile carcinoma most commonly develops. Phimosis is found in 25% to 75% of patients with penile carcinoma described in most large series. Reddy et al ⁽⁷⁾ studied the foreskins of 26 men undergoing circumcision because of phimosis and found epithelial atypia in one-third of the specimens. Data from most large series show that neonatal circumcision is protective, whereas circumcision delayed until after puberty is not ⁽⁸⁾.

Human Papillomavirus

Although HPV is not a reportable sexually transmitted disease, the number of new genital HPV infections has been estimated at 500,000 to 1 million annually in the United States ⁽⁹⁾. The terms *genital condyloma*, *venereal*

Table 38-1 Histopathology Subtypes of Penile Cancer

Squamous cell carcinoma
Adenocarcinoma
Lymphoma
Melanoma
Kaposi sarcoma
Leiomyosarcoma

warts, genital warts, and genital HPV infection all refer to a sexually transmitted disease caused by HPV. Factors associated with higher rates of infection with HPV include presence of foreskin, increasing numbers of sexual partners, lack of condom use, and smoking⁽¹⁰⁾. The overall prevalence of HPV in females was found to be 26.8% among US females aged 14 to 59 years and was highest among women aged 20 to 24 years (44.8%)⁽¹¹⁾. Human papillomavirus is recognized as the principal etiologic agent in cervical dysplasia and cervical cancer⁽¹²⁾.

On histologic examination, the koilocyte—a cell characterized by an empty cavity surrounding an atypical nucleus—is pathognomonic for HPV infection (Fig. 38-1)⁽¹³⁾. DNA hybridization techniques have been used to identify and classify HPV infections, and some 60 genotypes of HPV virus have been identified that involve the genital tract⁽¹⁴⁾. Virus types 6, 11, and 42 to 44 are associated with gross condylomata and low-grade dysplasia, whereas types 16, 18, 31, 33, 35, and 39 have a higher association with malignant disease⁽¹⁵⁾.

In men, a personal history of genital condylomata has been associated with squamous cell carcinoma of the penis⁽¹⁰⁾. Malignant transformation of condylomata to squamous cell carcinoma has been reported⁽¹⁶⁾. Condylomata acuminata located in the perianal, scrotal, and oral areas have also demonstrated malignant degeneration. An increased incidence of penile intraepithelial neoplasia has been found in the male partners of women with cervical intraepithelial neoplasia⁽³⁾.

More than 25 types of HPV infect genital sites. It appears that HPV-16 is the most frequently detected type in primary carcinomas and has also been detected in metastatic lesions⁽¹⁷⁾. Thus, preventive strategies are relevant, and prophylactic HPV vaccines are available for both men and women⁽³⁾. The prevalence of HPV vaccination in the United States, however, remains disappointingly low.

Although HPV infection is probably an important factor in the development of penile cancer, with evidence that 31% to 63% of tumors are HPV related, its presence is not invariable⁽¹⁸⁾. Other factors must be involved in the development of the disease or its subtypes. Human papillomavirus is most associated with

FIGURE 38-1 A. Moderately differentiated keratinizing squamous cell carcinoma. B. Human papilloma virus-related changes, including koilocytosis. C. Immunohistochemical stain for epidermal growth factor receptor. (Used with permission from Pheroze Tamboli, MD.)

the basaloid and warty tumor subtypes, which were found to contain HPV DNA in 80% to 100% of cases.

Patients with HPV-related penile cancer appear to have a better prognosis than those with HPV-unrelated tumors. A population-based study found that the detection of HPV DNA in penectomy specimens was associated with a significant advantage in

disease-specific survival (96% vs 82%)⁽¹⁹⁾. Immunohistochemical detection of p16, which is a marker for HPV infection, was also associated with improved outcome⁽²⁰⁾. Whether HPV is predictive of response to treatment (eg, chemotherapy) is unknown.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) infection may predispose affected patients to rapid development of squamous carcinoma from preexisting condyloma infection⁽²¹⁾. Poblet et al⁽²²⁾ reported on two cases of coexisting HIV-1 and HPV infection and postulated that HIV-1 could synergize with HPV to increase the progression of HPV penile lesions into penile carcinoma. Whereas there is evidence supporting this effect in cervical and anal neoplasia⁽²³⁾, definitive proof for penile cancer awaits further study.

MOLECULAR FEATURES

Overview of Molecular Features

The viral genes *E6* and *E7* are overexpressed in HPV-transformed cells, and they are known to interact with the *RB1* and *TP53* tumor suppressor pathways. These molecular events are known to play a critical role in the development of cervical cancer⁽¹²⁾, and a similar mechanism probably exists in HPV-related cases of penile cancer^(3,18).

The tumor suppressor gene *TP53* is commonly mutated in human solid tumors, where the abnormal protein accumulates and can be detected by positive immunostaining. In penile cancer, positive p53 immunostain is an independent predictor of lymph node metastasis⁽²⁴⁾. In a study by Lopes et al⁽²⁵⁾, the p53-positive cases had a lower overall survival and higher incidence of lymph node metastasis. Martins et al⁽²⁴⁾ studied 50 patients, of which 14 had clinically positive lymph nodes. After penectomy, tumors were stained for p53 and proliferating cell nuclear antigen (PCNA), and these results were compared with stage, grade, nodal status, and cause of death. Overexpression of p53 was associated with pT classification, grade, nodal metastasis, and cause-specific survival. Also, PCNA was associated with nodal metastasis but not survival. Of note, *TP53* mutations would not be expected to occur in HPV-related tumors because p53 is inactivated by HPV viral proteins.

Matrix metalloproteinases (MMPs) and cellular adhesion molecules have been studied in penile cancer. Campos et al⁽²⁶⁾ measured MMP-2 and MMP-9 expression and found that MMP-9 was an independent risk factor for disease recurrence. In the same study, low E-cadherin was associated with a greater risk of

lymph node metastasis. A Chinese study⁽²⁷⁾ found that 45% of tumors had low E-cadherin, and that it was associated with shorter cause-specific survival. These alterations have been found in both HPV-related and unrelated penile tumors⁽⁵⁾.

Epidermal Growth Factor Receptor

Multiple studies have shown that the epidermal growth factor receptor (*EGFR*) is overexpressed in the majority of penile cancer cases^(28,29). Activating mutations of *EGFR* or *KRAS*, on the other hand are uncommon. Several published case reports and one case series suggested that *EGFR* is a useful target for therapy in metastatic penile cancer⁽³⁰⁻³²⁾.

PATTERN OF METASTASIS

Anatomy of Lymphatic Drainage

Penile cancers have a predictable pattern of local, regional, and systemic spread. The earliest route of dissemination from the penis is metastasis to the regional femoral and iliac nodes. The lymphatics of the prepuce form a connecting network that joins with the lymphatics from the skin of the shaft. These tributaries drain into the superficial inguinal nodes. The lymphatics of the glans join the lymphatics draining the corporal bodies, and they form a collar of connecting channels at the base of the penis that also drain by way of the inguinal lymph nodes. From there, drainage is to the pelvic nodes (external iliac, internal iliac, and obturator). Multiple cross connections exist at all levels of drainage, so that penile lymphatic drainage is bilateral to both inguinal areas⁽³³⁾.

Frequency of Metastases: Prognostic Factors

Tumor grade, lymphovascular invasion, and perineural invasion appear to be the most important pathologic prognostic factors for nodal spread and mortality⁽³⁴⁾. Other frequently cited risk factors are pT classification, tumor thickness, anatomical site (proximal vs distal), pathologic subtype, urethral invasion, and positive margins of resection.

Lymphovascular invasion in the primary tumor has significant prognostic importance. Studies have assessed its presence or absence and found that it was an important predictor of nodal metastasis⁽³⁵⁾. The pathologist should specifically comment on the presence or absence of vascular invasion in the surgical specimen. Perineural invasion was found to be present in 36% of cases analyzed in a multi-institutional data

set of 134 patients and was also a strong predictor of lymph node metastasis ⁽³⁶⁾.

Distant Metastasis and Mortality

Metastatic penile cancer is characterized by a relentlessly progressive course, causing death for the majority of untreated patients within 2 years ⁽³⁷⁾. Metastatic enlargement of the regional nodes eventually leads to skin necrosis, chronic infection, and death from sepsis, hemorrhage secondary to erosion into the femoral vessels, and failure to thrive.

Clinically detectable distant metastatic lesions to the lung, liver, bone, or brain are uncommon at initial presentation. Such metastases usually occur late in the course of the disease after the local lesion has been

treated. Distant metastases in the absence of regional node metastases are unusual.

EVALUATION OF THE PATIENT

Staging System

The American Joint Committee on Cancer (AJCC) seventh edition TNM staging system for penile cancer (Table 38-2) differs from the sixth edition in that pT1 tumors are stratified regarding whether there is high-grade histology or lymphovascular invasion (pT1b) ⁽³⁸⁾. Considering pathologic nodal factors further, the seventh edition distinguishes patients with a single positive node (N1) from those with multiple or bilateral

Table 38-2 Definitions of TNM

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Ta	Noninvasive verrucous carcinoma
T1a	Tumor invades subepithelial connective tissue without lymph vascular invasion and is not poorly differentiated (ie, grades 3-4)
T1b	Tumor invades subepithelial connective tissue and exhibits lymph vascular invasion or is poorly differentiated
T2	Tumor invades corpus spongiosum or cavernosum
T3	Tumor invades urethra
T4	Tumor invades other adjacent structures
Regional Lymph Nodes (N)	
Clinical Stage Definition	
CNX	Regional lymph nodes cannot be assessed
cN0	No palpable or visibly enlarged inguinal lymph nodes
cN1	Palpable mobile unilateral inguinal lymph node
cN2	Palpable mobile multiple or bilateral inguinal lymph nodes
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral
Pathologic Stage Definition	
PNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in a single inguinal lymph node
pN2	Metastasis in multiple or bilateral inguinal lymph nodes
pN3	Extranodal extension of lymph node metastasis or pelvic lymph nodes(s) unilateral or bilateral
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis ^a

^aLymph node metastasis outside the true pelvis in addition to visceral or bone sites. Reproduced with permission from Edge SB, Byrd DR, Compton CC (eds): *AJCC Cancer Staging Manual*, 7th ed. New York, NY: Springer; 2010.

nodes (N2) and further recognizes the ominous prognosis (5%-18% 5-year survival) associated with extranodal extension of cancer.

Limitations of the Staging System

A study from the Netherlands Cancer Institute evaluated the practical and prognostic value of the sixth edition TNM classification for penile carcinoma (Table 38-3) ⁽³⁹⁾. The current T2 category combines tumors that invade either the corpus spongiosum or the corpora cavernosa ⁽³⁸⁾. The 5-year disease-specific survival for tumors invading the corpus spongiosum in the Dutch series was 77.7% and for tumors invading the corpora cavernosa was 52.6%, suggesting that the capacity of a tumor to penetrate the tunica albuginea covering the corpora cavernosa is a more invasive characteristic. The Dutch investigators also suggested that the T3 category appears to be obsolete because a distally located tumor that invades the urethra can still be treated with good prognosis; they proposed that invasion of the corpora cavernosa should be designated T3 ⁽⁴⁰⁾.

The Dutch study did not find a significant difference in 5-year disease-specific survival between the N1 and N2 category (70.2% and 58.3%, respectively; $P = .18$), and the authors proposed designating all unilateral inguinal (mobile) lymph node metastases as N1, bilateral inguinal (mobile) lymph nodes as N2, and any fixed groin mass as N3 ⁽³⁹⁾. They also noted the difficulty of distinguishing superficial from deep inguinal lymph nodes, which is not always possible to do either clinically or on histopathologic analysis of a surgical specimen. The seventh edition TNM does not distinguish superficial from deep inguinal lymph nodes and does recognize the prognostic significance of a fixed groin mass as N3. The N2 category,

however, still includes two or more unilateral, mobile lymph nodes, where the prognosis with two to three nodes is probably better than with more than three nodes involved ^(38, 40).

Thus, the 2010 TNM classification, while an improvement over previous versions, still necessitates caution with respect to prognosis in the assessment of deep inguinal lymph nodes (regarding whether they are truly inguinal or pelvic lymph nodes) and in considering laterality as well as the number of inguinal lymph nodes involved. Also, bulky inguinal lymph nodes that are mobile and suspected of having extranodal extension based on imaging are still classified as N1 or N2; such cases would likely be pN3 on histopathologic confirmation of extranodal involvement ⁽⁴¹⁾. Patients with clinical N1 or N2 and computed tomographic (CT) scan appearance suggestive of extranodal extension should be regarded as being at higher risk.

Evaluation of Palpable Lymph Nodes

Palpable inguinal lymph nodes are found at presentation in 28% to 64% of patients with penile cancer, but not all of these represent metastatic tumor. Lymphadenopathy is caused by metastasis in 47% to 85% of cases, whereas the rest are secondary to inflammation ⁽³⁵⁾. Approximately 25% of patients with palpable lymph nodes will have bilateral metastases. Careful note should be made of the uni- or bilateral location of palpable adenopathy, diameter, number in each inguinal area, whether mobile or fixed, relationship to other structures (eg, skin) with respect to infiltration or perforation, and presence of leg or scrotal edema. The National Comprehensive Cancer Network and European Association of Urology guidelines for penile cancer recommend fine-needle aspiration (FNA) of palpable inguinal lymph nodes ^(42, 43).

Table 38-3 Stage Grouping for Penile Cancer

Stage 0	Tis	N0	M0
	Ta	N0	M0
Stage I	T1a	N0	M0
Stage II	T1b	N0	M0
	T2	N0	M0
	T3	N0	M0
Stage IIIa	T1-T3	N1	M0
Stage IIIb	T1-T3	N2	M0
Stage IV	T4	Any N	M0
	Any T	N3	M0
	Any T	Any N	M1

Staging Groin Dissection

While treatment of the primary tumor and a period of antibiotics may be useful to help sterilize the inguinal region, this practice is no longer advocated as a tool to select patients who either should or should not undergo lymphadenectomy. One alternative to immediate lymphadenectomy for all patients has been to observe patients with normal findings on inguinal examination. Lymphadenectomy is subsequently reserved for those patients who develop palpable lymph nodes. The reluctance to advocate automatic ilioinguinal lymphadenectomy in all patients with penile cancer stems from the substantial morbidity the procedure can produce. Early complications of phlebitis, pulmonary embolism, wound infection, flap necrosis, and permanent and disabling lymphedema of the scrotum and lower limbs were frequent after both inguinal and ilioinguinal node dissections⁽³⁵⁾. Postoperative complications have been reduced by improved preoperative and postoperative care and advances in surgical technique. The mortality of complete inguinal lymph node dissection by an experienced surgeon is about 3%⁽⁴⁴⁾.

Several studies have analyzed the survival of men undergoing early versus delayed lymphadenectomy according to pathologic evaluation of nodal status. McDougal et al⁽⁴⁵⁾ reported a series of 23 patients with invasive primary lesions and nonpalpable nodes; 9 patients were treated with immediate adjunctive lymph node dissection (6 were positive), and 14 were treated with surveillance and delayed lymph node dissection. The 5-year survival in the node-positive immediate adjunctive lymphadenectomy group was 83% (5 of 6 patients), whereas in the surveillance group, the 5-year survival was 36% (5 of 14 patients). A third subset in this series had palpable nodes at presentation and had immediate therapeutic lymph node dissection, with 10 of 15 patients (66%) surviving 5 years. The best results were from immediate adjunctive lymph node dissection (83%), with the next best from immediate therapeutic lymphadenectomy (66%). The worst results were from the surveillance and delayed lymphadenectomy group (36%), in whom dissection was delayed until palpable nodes developed. The interval of opportunity for cure in this third group appears to have been lost.

Similarly, Fraley et al⁽⁴⁶⁾ reported that immediate adjunctive lymphadenectomy resulted in a 5-year disease-free survival in 6 of 8 node-positive patients (75%) compared with 1 of 12 patients (8%) who had been followed up and then treated by delayed lymphadenectomy when nodal enlargement occurred. Six other patients in that series also presented with unresectable adenopathy after initial surveillance, and all

died of disease. Although only two of six immediate lymphadenectomy patients had more than two positive nodes, all the patients treated by delayed lymph node dissection had three or more positive nodes.

A series from MD Anderson Cancer Center⁽⁴⁷⁾ compared 5-year disease-free survival of 14 patients undergoing early lymphadenectomy for clinically suspicious and histologically node-positive disease with that of 8 patients who were followed up and later underwent lymphadenectomy when clinical nodal enlargement was undisputed. The primary tumors were of similar stage. The 5-year disease-free survival was 57% for early lymphadenectomy compared with 13% for delayed node dissection. Of note, the number of involved nodes in the immediate lymphadenectomy group (median 2) was half that of the delayed lymphadenectomy group (median 4), and no patient with more than two positive nodes survived more than 5 years.

Data from these and other studies suggest that a policy of immediate adjunctive or early lymphadenectomy gives greater assurance that surgical intervention will occur when tumor volume is small. For patients at highest risk of lymph node metastases based on features in the primary tumor, surgical staging can be performed by complete bilateral inguinal lymph node dissection, which may also be curative in cases of small-volume metastases. Moreover, experience has suggested that lymphadenectomy in the setting of microscopic disease may be less likely to produce complications than node dissection in the presence of bulky nodal metastases. This is presumably due to the reduced amount of lymphatic tissue removed, preservation of venous drainage, and blood supply compromised, which affect the viability of skin flaps and lymphatic flow.

In patients with nonpalpable inguinal lymph nodes, if ultrasound-guided FNA of any questionable lymph node is tumor negative, dynamic sentinel lymph node biopsy (DSNB) can be performed if the equipment and expertise are available^(35, 48). In patients at intermediate risk of inguinal lymph node metastases, sentinel lymph node biopsy or modified (superficial) inguinal lymph node dissection may be performed if DSNB is not feasible.

Computed Tomographic Imaging

Patients with clinically palpable lymph nodes should undergo imaging to define the full extent of disease. Both CT and magnetic resonance imaging (MRI) scanning techniques depend primarily on lymph node enlargement for detection of metastases but are unable to define the internal architecture of normal-size nodes⁽⁴⁸⁾. Because CT and MRI have similar

FIGURE 38-2 A CT scan showing bulky metastasis in left external iliac lymph node.

accuracy in detecting lymphadenopathy in other cancers, CT has often been the imaging modality chosen in penile cancer to examine the inguinal and pelvic areas as well as to rule out more distant metastases (Fig. 38-2).

Computed tomographic scanning facilitates the examination of the inguinal region in obese patients or in those who have had prior inguinal surgery, for whom the physical examination may be unreliable. In addition, in patients with known inguinal metastases, CT-guided biopsy of enlarged pelvic nodes may provide important information for consideration of neoadjuvant chemotherapy. Otherwise, the addition of CT imaging does not appear to improve the sensitivity

or specificity of lymph node detection when compared to physical examination in patients with a normal inguinal examination.

Positron Emission Tomographic Imaging

Scher et al (⁴⁹) evaluated positron emission tomography (PET)/CT among 13 patients with penile cancer. Five of thirteen patients had metastatic disease, and PET/CT detected four of five patients (80% sensitivity). There may be a role for PET/CT in the detection of lymph node disease in penile cancer; however, the sensitivity of PET/CT is limited for smaller size lymph nodes (Fig. 38-3).

FIGURE 38-3 Computed tomographic and PET images of bilateral inguinal and left external iliac lymph node metastases.

TREATMENT

Local Control

Surgical amputation of the primary tumor remains the oncologic gold standard for rapid definitive treatment of the penile primary tumor; local recurrence rates range from 0% to 8%⁽⁴⁵⁾. Amputation is often necessary for bulky stage T2-T4 tumors, but it has been shown to decrease sexual quality of life⁽⁵⁰⁾. It is generally accepted that patients with penile primary tumors exhibiting favorable histologic features (stages Tis, Ta, T1; grades 1 and 2 tumors) are at a lower risk for metastases. These patients are also best suited for organ-sparing or glans-sparing procedures, with the goal of preserving glans sensation where possible or at least to maximize penile shaft length. Such approaches include topical treatments (fluorouracil or imiquimod cream for Tis only), radiotherapy, Mohs surgery, limited excision strategies (eg, circumcision), and laser ablation⁽⁵¹⁻⁵⁵⁾.

Partial or total penectomy should be considered in patients exhibiting adverse features that defy adequate control by organ preservation strategies. These include tumors of size 4 cm or more, grade 3 lesions, and those invading deeply into the glans, urethra, or corpora cavernosa.

Therapeutic Lymph Node Dissection

The biology of penile cancer is such that it exhibits a prolonged locoregional phase before distant dissemination. Lymphadenectomy alone can be curative and should be incorporated into the treatment planning for most patients. However, due to the morbidity of traditional lymphadenectomy, especially among those patients with clinically negative groins, contemporary controversial issues include the following: (1) the selection of patients for lymphadenectomy versus careful observation; (2) the types of procedures to correctly stage the inguinal region with low morbidity; and (3) multimodality strategies (eg, neoadjuvant chemotherapy, see further in the chapter) to improve survival among patients with bulky inguinal metastases.

The presence and the extent of metastasis to the inguinal region are the most important prognostic factors for survival in patients with squamous cell carcinoma of the penis. The survival rates for therapeutic lymph node dissection in patients with established regional lymph node metastases are variable, averaging about 60% (range, 0%-86%)^(35, 46, 48). This variability in survival rates is directly attributable to the extent of nodal metastasis. Patients with pN1 or pN2 with a minimal number of lymph nodes involved have an average 5-year survival of 77%,

compared with only 25% when a greater degree of nodal involvement is present. In one study⁽⁵⁶⁾, the 5-year survival of patients with extranodal involvement was only 6% (1 of 17 patients). The combined results of several small series suggest an average 5-year survival of 15% when pelvic lymph nodes are present.

Taken together, these data suggest that the pathologic criteria that predict long-term survival (ie, 80% 5-year survival rate) after attempted curative surgical resection of inguinal metastases are (1) minimal nodal disease (up to two involved nodes in most series); (2) unilateral involvement; (3) no evidence of extranodal extension of cancer; and (4) absence of pelvic nodal metastases.

Chemotherapy for Stage IIIB/IV Penile Carcinoma

The first candidate drugs for the chemotherapeutic treatment of stage IIIB/IV penile carcinoma included cisplatin, vincristine, methotrexate, fluorouracil, mitomycin, and bleomycin^(37, 57). In a multicenter study conducted by the Southwest Oncology Group (SWOG)⁽⁵⁸⁾, 26 patients with metastatic penile cancer received single-agent cisplatin at a dosage of 50 mg/m² on days 1 and 8 of each 28-day cycle. Only four patients (15%) experienced responses that persisted for 1 to 3 months.

The combination of bleomycin, methotrexate, and cisplatin (BMP) was studied in phase II clinical trials. In a single-institution study conducted at MD Anderson Cancer Center⁽⁵⁹⁾, 30 patients with squamous cell carcinoma of the urinary tract, including 21 men with metastatic penile carcinoma, received bleomycin at a dosage of 50 mg/m² on days 2 to 6, cisplatin at 20 mg/m² on days 2 to 6, and methotrexate at 200 mg/m² with leucovorin rescue on days 1, 15, and 22 of each 28-day cycle. There were 12 responses (55%) in the group with penile carcinoma, and the median duration of response was 4.7 months for the entire study. A second phase II study was conducted by the SWOG⁽⁶⁰⁾, in which patients received bleomycin at a dosage of 10 U/m² on days 1 and 8, methotrexate at 25 mg/m² on days 1 and 8, and cisplatin 75 mg/m² on day 1 of each 21-day cycle. Among 40 evaluable patients, there were 5 complete and 8 partial responses for an overall response rate of 32.5%, which narrowly exceeded the predetermined target rate of 30%. The median response duration was 16 weeks, and the estimated median survival time was 28 weeks. The toxicity of the regimen was considerable, however, with five treatment-related deaths due to bleomycin lung toxicity, other pulmonary causes, and infection. The BMP regimen and bleomycin in particular are

Table 38-4 Cisplatin-Based Chemotherapy Regimens Without Bleomycin

Reference	Regimen	Overall Response Rate (PR + CR)	Median Overall Survival (Months)
Theodore et al (2008)	Irinotecan Cisplatin	31%	Not reported
Pagliaro et al (2010)	Paclitaxel Ifosfamide Cisplatin	50% ^a	17.1 ^a
Di Lorenzo et al (2012)	5-Fluorouracil Cisplatin	32%	8
Nicholson et al (2013)	Docetaxel Cisplatin 5-Fluorouracil	38.5%	13.9
Houede et al (2015)	Gemcitabine Cisplatin	8%	15

^aPatients in this study had metastases confined to inguinal or pelvic lymph nodes (Tx N2-N3 M0) and underwent surgical consolidation when possible.

no longer recommended for the treatment of penile cancer because of the unacceptable toxicity.

Other cisplatin-based drug combinations demonstrated response rates of 8% to 50% (Table 38-4) (⁶¹⁻⁶⁵). A regimen would be of interest if it has an overall response rate greater than 30% with acceptable toxicity. The study of irinotecan/cisplatin conducted by the European Organization for Research and Treatment of Cancer (⁶¹) was a prospective study with 26 evaluable patients, but was interpreted as having a negative result by the authors because the response rate had an 80% confidence interval of 18.8% to 45.1%, extending well below 30%. In another study, paclitaxel, ifosfamide, and cisplatin was given to patients with metastases limited to the inguinal and pelvic lymph nodes (⁶²). In this neoadjuvant study, patients with response or stable disease after four courses underwent surgery with curative intent. The response rate was 50%, and the safety profile of this regimen was an improvement over BMP, with no treatment-related deaths. In another study of taxane drugs for the treatment of metastatic penile cancer, docetaxel, 5-fluorouracil, and cisplatin resulted in a response rate of 38.5% (⁶³). The response rate was not high enough to recommend this regimen in preference to 5-fluorouracil and cisplatin, and grade 3 and 4 toxicities were frequent.

5-Fluorouracil and cisplatin were studied in a retrospective series of patients with metastatic penile cancer (⁶⁴). Partial responses had been seen in 8 of 25 evaluable patients (32%). While there have been no randomized controlled trials to establish a single standard of chemotherapy treatment for metastatic penile cancer, either 5-fluorouracil plus cisplatin or paclitaxel, ifosfamide, and cisplatin have been endorsed by contemporary guidelines (^{42, 43}).

Multimodality Therapy

Neoadjuvant Chemotherapy

As discussed in the section on therapeutic lymph node dissection, the 5-year overall and disease-free survival rates with surgery alone are as high as 80% for unilateral, superficial inguinal lymph node involvement with no more than two nodes (stage N1 or limited N2), only 10% to 20% for stages N2 and N3 (multiple, bilateral, or pelvic lymph nodes involved), and less than 10% in the presence of extranodal extension (⁶⁶). Nearly all recurrences are detected within 2 years of surgery, and an aggressive, multimodality approach to the treatment of high-risk patients could result in better overall survival (^{37, 57, 67}).

In 1988, a team of Italian investigators reported their experience with adjuvant or preoperative (neoadjuvant) bleomycin, vincristine, and methotrexate for patients with penile carcinoma and metastases confined to the inguinal lymph nodes (⁶⁸). In the neoadjuvant group, five patients with fixed inguinal nodes received weekly bleomycin (30 mg intramuscularly), vincristine (1 mg intravenously), and methotrexate (30 mg orally). Three of those five patients had a sufficient tumor response that they could undergo surgical consolidation, and they were reported to be alive and disease free at 20, 27, and 72 months after surgery. The other two patients experienced less-than-partial responses, did not undergo surgery, and survived less than 12 months. This study, although small, demonstrated that perioperative chemotherapy for locally advanced penile carcinoma was feasible.

A group from the Netherlands reported on their retrospective analysis of 20 patients who had received preoperative chemotherapy to downstage unresectable disease (⁶⁹). Seventeen patients had had bulky

FIGURE 38-4 A patient with bilateral bulky superficial and deep inguinal lymph node metastases, shown (A) at baseline, (B) after two courses, and (C) after four courses of paclitaxel, ifosfamide, and cisplatin chemotherapy. Bilateral inguinal and pelvic lymph node dissections revealed no viable tumor (ie, a pathologic complete response).

lymph node metastases (Tx, N3), and the other three had had advanced primary tumors (T3-T4, N0-N1). The most commonly used regimens in the Dutch series, which spanned a 34-year period, had been BMP ($n = 10$); bleomycin, vincristine, and methotrexate ($n = 5$); and single-agent bleomycin ($n = 3$). Severe toxicity had occurred in four patients, including three treatment-related deaths. Twelve patients had experienced an objective tumor response; nine of the twelve had undergone surgery, and eight had achieved long-term disease-free survival. Two patients had no residual tumor in the surgical specimen. The finding of pathologic complete responses suggested that this finding could be used as a screen for efficacy.

A retrospective study from MD Anderson Cancer Center reported a series of 10 patients who had received neoadjuvant chemotherapy⁽⁷⁰⁾. The reported experience spanned a 15-year period at one institution and was limited to patients who had undergone aggressive lymph node dissections after having experienced a response or stable disease after chemotherapy. The regimens given preoperatively had been BMP ($n = 3$); paclitaxel and carboplatin ($n = 2$); and paclitaxel, ifosfamide, and cisplatin ($n = 5$). Four patients had complete responses, and one had a partial response. Three patients had a pathologic complete response in the lymph nodes; all of these patients had received paclitaxel, ifosfamide, and cisplatin, and all had biopsy-confirmed metastases prior to chemotherapy. Four patients had experienced long-term disease-free survival.

Neoadjuvant chemotherapy was next studied prospectively in a phase II clinical trial conducted at MD Anderson Cancer Center⁽⁶²⁾. Thirty patients with clinical TX N2-N3, M0 penile cancer received four courses of paclitaxel, ifosfamide, and cisplatin prior to a planned complete bilateral inguinal lymph node dissection and uni- or bilateral pelvic lymph node dissection. Fifteen patients (50%) experienced a partial or complete response to chemotherapy. Twenty-two patients (73%) were able to complete the neoadjuvant

chemotherapy and surgery, of whom there were three patients (14%) with a pathologic complete response in the lymph nodes (see Fig. 38-4). Objective response to chemotherapy, absence of bilateral residual tumor, and absence of extranodal extension in residual tumor were associated with a higher rate of overall and progression-free survival in a univariable analysis (Fig. 38-5).

The overall and progression-free survival rates in N2-N3 disease achieved with neoadjuvant paclitaxel, ifosfamide, and cisplatin are an improvement over the expected survival with surgery alone. Despite the absence of a randomized controlled trial, contemporary guidelines have recommend neoadjuvant paclitaxel, ifosfamide, and cisplatin for patients presenting with bulky/high-risk regional lymph node metastases⁽⁴²⁾.

Adjuvant Chemotherapy

Adjuvant chemotherapy has the advantage of allowing patient selection based on accurate pathologic staging. Unfortunately, a randomized controlled trial of adjuvant chemotherapy would not be feasible due to the low incidence of penile carcinoma and the large number of patients necessary to power such a trial. The development of neoadjuvant chemotherapy as standard treatment appears to be more achievable and has advantages of downstaging to facilitate surgery, better tolerance of chemotherapy in the preoperative setting, and earlier exposure of micro-metastases to the chemotherapy agents. Tumor response can be detected in the neoadjuvant setting, but not in the adjuvant setting, and the histopathologic findings of post-chemotherapy surgery provide an early indicator of the treatment effect and prognosis (Fig. 38-6)⁽⁷¹⁾.

In cases where patients have undergone surgery without neoadjuvant chemotherapy and are found to have multiple inguinal or any pelvic lymph nodes involved or extranodal extension, then a regimen such as paclitaxel, ifosfamide, and cisplatin can

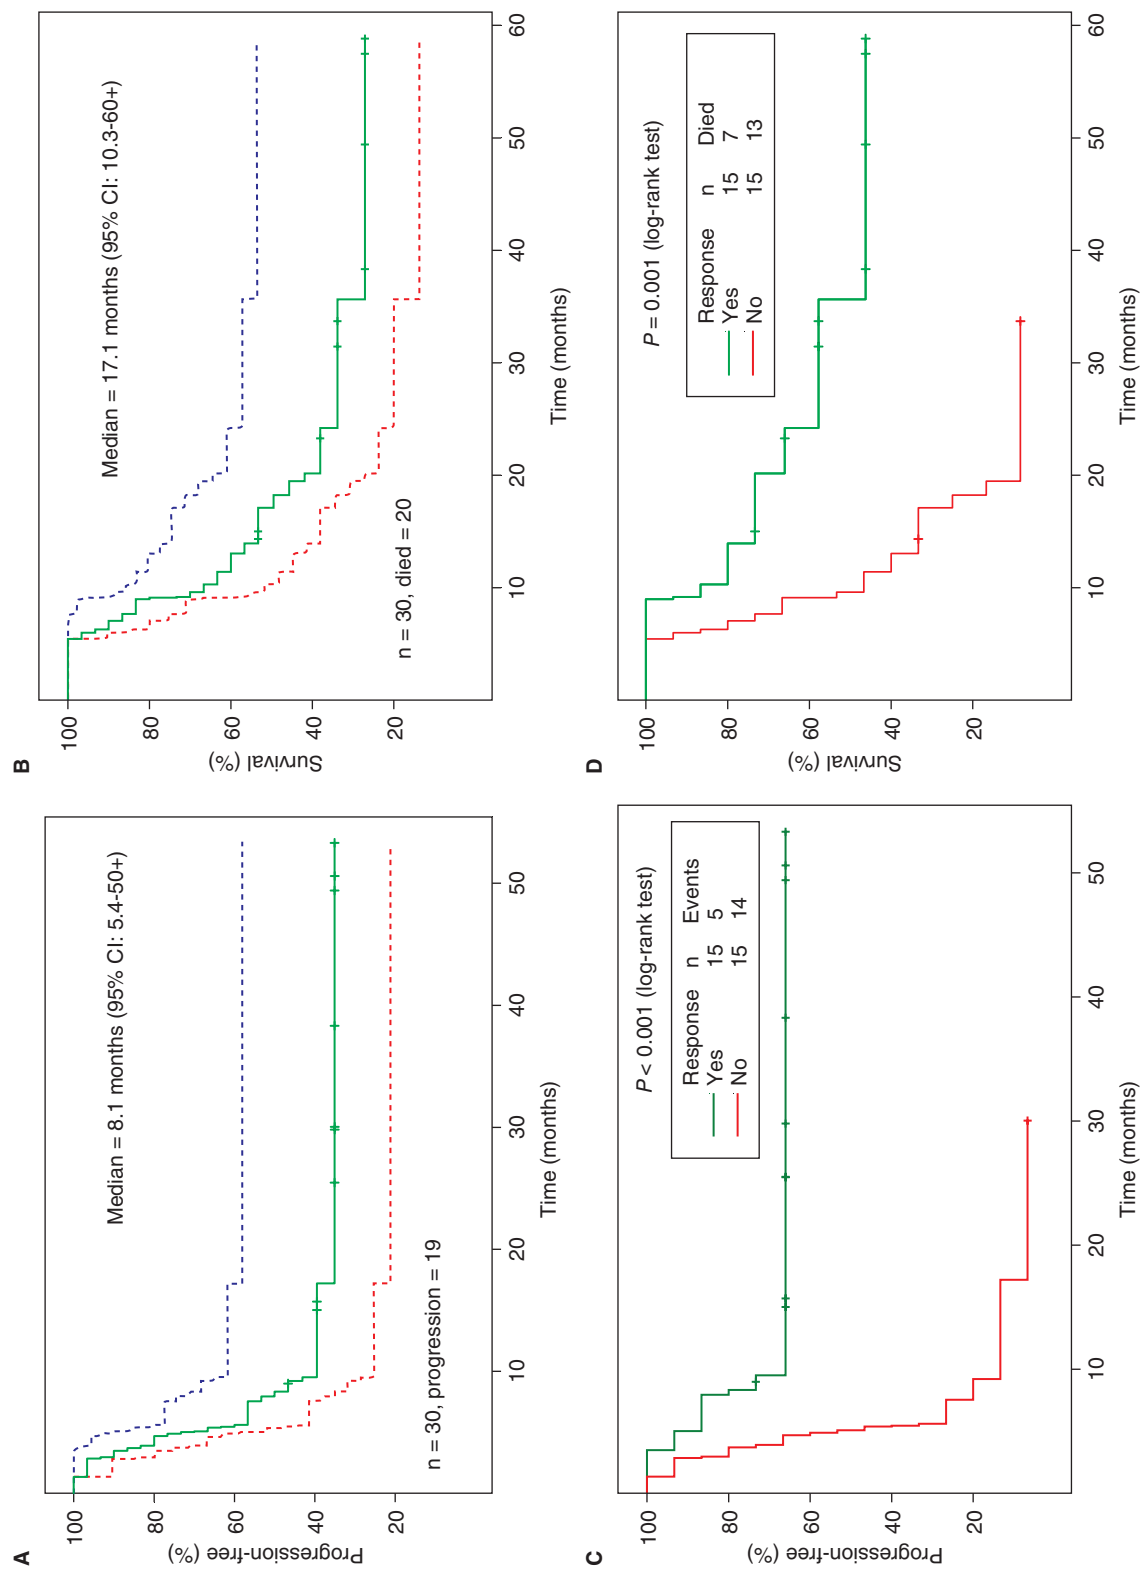

FIGURE 38-5 Kaplan-Meier plots (with 95% CIs as dotted lines) of (A) time to progression of disease, (B) overall survival; patients are grouped by response for (C) time to progression and (D) overall survival. Treatment consisted of neoadjuvant paclitaxel, ifosfamide, and cisplatin. be administered as adjuvant therapy on the basis of extrapolation from the neoadjuvant data.

Radiotherapy Combined With Surgery or Chemotherapy

Studies of radiotherapy in penile carcinoma have included penis-sparing treatment for small (T1-T2, <4 cm) primary tumors, treatment of lymph node metastases, postoperative radiotherapy, and chemoradiotherapy^(54, 57). There are no published randomized trials of multimodality treatment with radiotherapy in penile cancer, as there are in squamous cell carcinomas from other sites. For example, radiotherapy with surgical lymphadenectomy has been studied in women with cancer of the vulva, a disease site that has natural history and nodal drainage similar to those of the penis. On the basis of these studies, the standard of care for metastatic vulvar cancer is radiotherapy to the pelvis rather than pelvic lymph node dissection⁽⁷²⁾. Pelvic lymph node dissection remains the standard of care for penile cancer patients following definitive treatment of inguinal lymph node metastases⁽⁴²⁾. Thus, a randomized trial in penile cancer would be informative concerning the optimal method for consolidation of pelvic lymph nodes.

International Randomized Trial

It has not been possible to conduct randomized controlled trials in penile cancer to answer basic questions. One of the studies currently being developed and discussed by the International Rare Tumors Initiative (IRCI) is a 400-patient trial to be conducted in the United Kingdom, United States, and Canada⁽⁷³⁾. The International Penile Advanced Cancer Trial (InPACT) uses a Bayesian design for randomized treatment of patients with inguinal lymph node metastases from penile cancer. The trial has two independent randomizations, addressing key questions in the clinical pathway: first, the role of neoadjuvant therapy prior to standard surgery, by randomizing to chemotherapy, chemoradiotherapy, or no neoadjuvant therapy; and second, the role of

prophylactic pelvic lymph node dissection following the standard surgery with therapeutic inguinal lymph node dissection. The primary outcome measure of the InPACT study is overall survival.

CONCLUSION

The treatment of men with squamous cell carcinoma of the penis has evolved considerably in recent years, along with our understanding of its molecular biology. Penis-sparing strategies for early-stage disease allow for better outcomes in terms of comfort, dignity, and quality of life. Neoadjuvant chemotherapy is now standard of care for patients presenting with bulky regional lymph nodes. An ambitious international randomized trial proposes to compare neoadjuvant and adjuvant as well as surgical and radiotherapeutic strategies in this clinical setting. Meanwhile, vaccination of both men and women against HPV offers to reduce the risk of cancer, particularly for uncircumcised men who are already at increased risk. Viral antigens are a promising target for the immunotherapeutic treatment of penile cancer and suggest a possible role in this disease for drugs that exert immune checkpoint blockade. On the basis of these considerations, one could conclude that we are entering a period of rapid development in the treatment of patients with penile cancer.

Testicular Cancer

Maryam N. Shafaei
Nizar M. Tannir
Lance C. Pagliaro

INTRODUCTION

Testicular germ cell tumors (GCTs) account for the majority of testicular cancers and are highly curable. This chapter primarily discusses GCTs arising in the testicle, dividing this category into seminoma versus nonseminoma germ cell tumors (NSGCTs). Then, the rare entity of extragonadal GCTs, which can arise in the mediastinum, retroperitoneum, or pineal body, is described.

OVERVIEW OF GERM CELL TUMORS

Epidemiology

The GCTs are the most common new cancer diagnosis in young men. Roughly an estimated 8,430 new cases were expected to be diagnosed in 2015 ⁽¹⁾. Highlighting the high curability of this cancer, GCTs only claimed approximately 380 lives in 2015 ⁽¹⁾ and carry a 5-year overall survival (OS) rate of approximately 95% ^(2, 3). The GCTs have a bimodal age distribution, with most men diagnosed between ages 15 and 25. There is a second peak of diagnosis around age 60, which largely represents seminoma histology and a lower mortality risk. Lifetime risk for the development of GCTs is approximately 0.5% or 1 in 200 ⁽⁴⁾.

Worldwide, GCTs are six times more common in developed countries, with the largest incidence reported in Denmark and Switzerland and the lowest in Japan, Finland, and Israel ⁽⁴⁾. In the United States, the overall incidence of GCTs appears to be gradually

increasing. The incidence has specifically increased among African Americans, with the greatest increase in seminoma histology. This does not appear to be related to screening or earlier diagnosis ⁽⁵⁾. Caucasian men, although still representing the group most likely to be diagnosed, are more likely to be identified at an earlier stage than in the past ⁽⁶⁾.

Risk Factors

Cryptorchidism is one of the few identifiable risk factors for the development of GCTs, although representing at most about 10% of cases. When present, cryptorchidism imparts a relative risk between 2.5 and 17.1 ^(7, 8). This increased risk includes the contralateral testicle, even if descended normally or via orchiopexy. It is unclear if orchiopexy reduces the lifetime risk of GCTs, although data showing increased incidence even in the contralateral testicle support the theory that the etiology of GCTs lies in abnormal gonadal development rather than anatomic malposition ^(9, 10). Men with a prior history of GCTs also have an increased risk of GCTs in the contralateral testicle, suggesting a genetic predisposition, although men with a family history of GCTs account for only 1.5% of patients with new diagnosis ⁽¹¹⁾. A personal history of GCT carries an increased lifetime risk of secondary cancers, irrespective of histologic type ⁽¹²⁾.

Tumor Biology

The most common genetic abnormality found in GCTs is an isochromosome of the short arm of chromosome

12, which has been identified in approximately 80% of GCTs (¹³). This abnormality can be found in all histologic subtypes except spermatocytic seminoma (^{14, 15}). Overexpression of *c-kit* is seen in seminoma (¹⁶). Of note, p53 is rarely altered in GCTs, and single-gene mutations in general are uncommon (¹⁷).

Carcinoma in situ (CIS), or intratubular germ cell neoplasia (ITGCN), has been identified as the precursor lesion in most GCTs. It is histologically described as atypical germ cells in the seminiferous tubules. Such changes are found adjacent to most invasive GCTs, with the notable exception of spermatocytic seminoma. The ITGCN cells express numerous proto-oncogenic proteins that play a role in tumorigenesis, including the receptor tyrosine kinase CD-117 or *c-kit*, a protein normally involved in germ cell migration and early differentiation (^{18, 19}).

Histologic Classification

The main histologies encountered in GCTs are seminoma, embryonal carcinoma, endodermal sinus tumor (EST, also known as yolk sac tumor), choriocarcinoma, and teratoma. The last can be further classified as mature, immature, or teratoma with malignant transformation. It is common to see more than one histologic subtype within a tumor. Importantly, the clinical course can be largely inferred from the histology. The GCTs that show exclusively the seminoma histology constitute pure seminomas, while those containing any other histologic pattern are classified as NSGCTs, even if the dominant histologic pattern is seminoma. Thus, the term *seminoma* is used in two very different ways: as a histologic pattern and as a main subdivision of GCTs. The biology and clinical expression are dominated by the nonseminoma component, and thus the presence of any histologic component other than seminoma places the tumor in the category of NSGCT.

Clinical Presentation

Most patients with GCTs present with painless testicular swelling or a nodule. In some cases, testicular swelling can be accompanied by pain secondary to bleeding or infarction within the tumor. In the presence of pain or a history of injury, an appropriate differential diagnosis would include testicular torsion, epididymitis, orchitis, hydrocele, spermatocele, and hematoma. *It is extremely important that regardless of pain or other associated symptoms, all scrotal masses should be approached as if they were malignant.* In patients who present with gynecomastia, especially bilateral, GCTs should be considered (²⁰). Other symptoms can include fever, weight loss, back pain, and hemoptysis (most often seen in patients presenting with high-volume disease).

Diagnosis

The importance of prompt diagnosis and treatment cannot be stressed enough because the extent of disease at presentation predicts overall prognosis. Awareness of GCT prevalence among young men is important for both general practitioners and the general public. Radiographic evaluation of a suspected primary should include high-resolution, trans-scrotal ultrasonography with color Doppler of both testicles, and any suspicious lesion should be definitively evaluated with radical orchiectomy.

Trans-scrotal biopsy is contraindicated in the diagnostic workup of a suspected testicular neoplasm, as this procedure can disrupt regional lymphatics, potentially altering the otherwise-predictable nodal spread. Because the diagnosis of GCTs is rarely in question, the preferred diagnostic and therapeutic procedure for a testicular mass is radical inguinal orchiectomy. If a tissue diagnosis is felt to be necessary prior to orchiectomy, an open biopsy should be performed via an inguinal incision to allow for proper examination and tissue sampling with minimal risk of inguinal or scrotal contamination.

Serum Tumor Markers

Serum markers, specifically human chorionic gonadotropin (hCG), α -fetoprotein (AFP) and lactate dehydrogenase (LDH), have unique diagnostic and prognostic significance in GCTs. These markers enable the clinician to infer clinical behavior, monitor therapy, decide when to apply surgical consolidation, and detect residual or recurrent disease.

Elevated in pregnancy, hCG is not normally detectable in males except in the setting of GCTs. With a half-life of 18 to 36 hours, hCG can also be markedly elevated in gestational trophoblastic disease and occasionally in epithelial cancers (²¹). It is composed of two subunits, α and β , which exist in multiple isoforms. The α subunit has sequence similarity to the α subunit of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH), which leads to “cross-talk” between these hormones and hCG. For this reason, hCG assays measure the β subunit. This “cross talk” can be clinically significant in high-volume disease accompanied by high levels of hCG, where hCG causes hyperthyroidism by binding to the TSH receptor. *Extreme elevation of hCG in males should be considered pathognomonic for GCTs and, in selected cases of threatening disease, justifies initiation of therapy even before tissue confirmation.*

Normally produced by the fetal yolk sac, AFP also exists in multiple isoforms. It is elevated in GCT cells derived from the embryological yolk sac, including endodermal sinus tumor and embryonal carcinoma.

It has also been found to be elevated in other neoplasms, such as hepatocellular carcinoma and pancreatic, gastric, and lung cancer, and has a serum half-life of approximately 5 days⁽²²⁾. Seminoma does not produce AFP, and in the setting of GCT, an elevated AFP implies a nonseminomatous histology⁽²³⁾.

Lactate dehydrogenase is neither cancer specific nor germ cell specific. Of the LDH isoforms, LDH-1 is most specific for GCTs; however, there is no established routine use for the fractionation of LDH and precise measurement of LDH-1. Total LDH can be used to estimate the prognosis in advanced NSGCT at the time of diagnosis or to detect recurrent disease⁽²⁴⁾.

Anatomic Progression

The GCTs follow a distinct pattern of spread and metastasis. The lymphatic drainage from the testicle reflects embryologic origin, and thus the right testicle drains to the interaortocaval lymph nodes, and the left testicle drains to the left para-aortic lymph nodes. These initial nodes of spread are termed the “landing zone.” Epididymal lymphatics drain via the external iliac chain and scrotal lymphatics via the pelvic chain; therefore, locally advanced disease (involving the epididymis and scrotum) can present with involvement of these nodal basins. Distant metastasis involves the lungs principally, followed by the liver, brain, and bones.

STAGING

Table 39-1 shows the American Joint Commission on Cancer (AJCC) TNM staging of testicular cancer⁽²⁵⁾. This system is based on the anatomic characteristics of the tumor, the presence of elevated tumor markers, and the presence of distant disease. These well-defined risk factors are used to group patients into stages I-III. In general, stage I disease is confined to the testis, stage II disease has nodal metastases confined to the retroperitoneum with markers in the good prognosis range (S1), and stage III disease includes nodes that extend beyond the retroperitoneum, extranodal metastases, or elevation of tumor markers to the intermediate- or poor-prognosis range (S2-S3).

Fertility Considerations

Of particular importance to men with GCTs is the preservation of fertility. Both the diagnosis and treatment of GCTs are associated with impaired fertility. It is recommended that, if clinically feasible, the patient be counseled about and offered the opportunity to pursue sperm banking prior to starting chemotherapy.

It is not recommended to delay chemotherapy in symptomatic poor-risk patients, as poor physical condition often makes sperm donation difficult or even impossible⁽²⁶⁾.

TESTICULAR SEMINOMA

Histology

Under microscopic visualization, classic seminoma has a “fried-egg” appearance, defined as a monotonous proliferation of large, rounded cells arranged in sheets or cords with large centralized nuclei and nucleoli. These tumors can be difficult to distinguish from lymphoma if there is a background of lymphocytic infiltration. Further confirmation (ie, negativity for lymphocyte markers such as common leukocyte antigen) is often required. Although not specific, seminomas stain positive for placental alkaline phosphatase (PLAP) and are routinely negative for AFP and hCG. Figure 39-1 shows the histological appearance of classic seminoma.

On pathologic examination of the testis, seminoma tends to be a semisolid tumor that readily oozes onto the gross examination table. This makes the presence of malignant cells on the surface of the spermatic cord and at the margins of resection a ubiquitous finding. Thus, the clinician must be careful not to be unduly influenced by reports of “margin positivity” and “involvement of the spermatic cord” in the pathology report⁽²⁷⁾. Figure 39-2 shows the typical gross appearance of seminoma.

Even in the presence of significant metastatic disease, it is not uncommon to find only a scar in the testicle. This phenomenon is known as “burned-out” seminoma and can also occur in NSGCT. The biological basis for this spontaneous regression of the primary is not known. Seminomas are typically associated with significant inflammatory infiltration, and metastatic deposits characteristically leave a dense desmoplastic residual mass after treatment, often making them difficult to resect.

Clinical Features

Pure seminoma is the most common GCT of the testicle, accounting for approximately 50% of GCTs. By definition, seminomas have no evidence of a nonseminoma component and do not produce AFP but may have modest elevation of β -hCG. Spermatocytic seminomas, a rare variant comprising only 10% of seminomas, are not associated with ITGCN. These tumors typically occur in men over 50 years old, in stage I disease, and have a low metastatic rate. This subtype portends an excellent prognosis with resection alone

Table 39-1 Germ Cell Tumor: The New AJCC TNM Staging of Testicular Cancer

Primary Tumor (T)	
The extent of primary tumor is usually classified after radical orchiectomy, and for this reason a pathologic stage is assigned.	
PTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor (eg, histologic scar in testis)
PTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion; tumor may invade into the tunica albuginea but not the tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion, or tumor extending through the tunica albuginea with involvement of the tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion
Regional Lymph Nodes (N) Clinical	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension or multiple lymph nodes, none > 2 cm in greatest dimension
N2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension; or multiple lymph nodes, any one mass > 2 cm but not > 5 cm in greatest dimension
N3	Metastasis with a lymph node mass > 5 cm in greatest dimension
Pathologic (PN)	
PNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension and ≤ 5 nodes positive, none > 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension; or > 5 nodes positive, none > 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass > 5 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional nodal or pulmonary metastasis
M1b	Distant metastasis other than to nonregional lymph nodes and lungs
Serum Tumor Markers (S)	
SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH $< 1.5 \times N$ AND hCG (mIU/mL) $< 5,000$ AND AFP (ng/mL) $< 1,000$
S2	LDH $> 1.5-10 \times N$ OR hCG (mIU/mL) 5,000-50,000 OR AFP (ng/mL) 1,000-10,000
S3	LDH $> 10 \times N$ OR hCG (mIU/mL) $> 50,000$ OR AFP (ng/mL) $> 10,000$
N indicates the upper limit of normal for the LDH assay.

(with or without radiotherapy) ⁽²⁸⁾. Seminomas tend to spread via lymphatics initially, with late hematogenous spread, and are more likely to spread locally, as evidenced by positive margins and involvement of the spermatic cord on histology. The most common

hematogenous spread is to the lungs, and metastatic seminomas rarely metastasize to the brain. Remarkably, bulky tumors rapidly respond, with dramatic loss of tumor bulk, but tumor lysis syndrome is never encountered.

**FIGURE 39-1** Histological appearance of classic seminoma.**FIGURE 39-2** Gross appearance of seminoma.

Prognosis

The International Germ Cell Cancer Collaborative Group (IGCCCG) established a standard risk classification for both seminomas and NSGCTs (Table 39-2). Patients with metastatic seminoma are divided into either good- or intermediate-risk categories, with no definable “poor-risk” seminoma. The one characteristic that predicted worse outcome for seminoma was the presence of nonpulmonary visceral metastases (intermediate prognosis). The prechemotherapy tumor markers do not predict prognosis (unlike in NSGCTs,

discussed further in the chapter). Ninety percent of patients with seminoma fall into the good-prognosis category, with a 5-year OS of 86%. Patients with seminoma in the intermediate-prognosis category have a 5-year OS of 72% (?).

Management of Clinical Stage I Seminoma

Patients with clinical stage I seminoma, representing 70% of patients at diagnosis, have disease confined to the testicle with no evidence of nodal or distant metastasis. Most patients will be cured by radical orchiectomy alone, but approximately 20% recur without adjuvant intervention. The disease-specific survival is nearly 100% with or without adjuvant treatment because patients who recur on surveillance are readily salvaged with standard treatment.

Table 39-2 IGCCCG Classification Prognostic Risk Stratification

Seminoma	Nonseminoma
Good Risk	
Any primary site	Testis/retroperitoneal primary
and	and
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
and	and
Normal AFP, any hCG, any LDH	AFP <1000 ng/mL
	hCG <5000 mIU/mL
	LDH <1.5 × ULN
82% 5-year PFS; 86% 5-year OS	86% 5-year PFS; 90% 5-year OS
Intermediate Risk	
Any primary site	Testis/retroperitoneal primary
and	and
Nonpulmonary visceral metastases	No nonpulmonary visceral metastases
and	and
Normal AFP, any hCG, any LDH	AFP 1,000-10,000 ng/mL
	hCG 5,000-50,000 mIU/mL
	LDH 1.5-10 × ULN
67% 5-year PFS; 72% 5-year OS	75% 5-year PFS; 80% 5-year OS
Poor Risk	
—	Mediastinal primary
	or
—	Nonpulmonary visceral metastases
	or
	AFP >10,000 ng/mL
—	hCG >50,000 mIU/mL
	LDH >10 × ULN
—	41% 5-year PFS; 48% 5-year OS

Active Surveillance

The benefits of surveillance include avoidance of unnecessary treatment in patients who are likely to be already cured by orchiectomy. Warde et al reported data on 638 patients with clinical stage I seminoma managed with surveillance with a median follow-up of 7 years. Patients with a primary tumor less than 4 cm maximum dimension and without invasion of rete testis had 5-year risk of relapse of only 12%. Patients with both risk factors had a risk of recurrence of 32%, while one of the two risk factors portends a 16% risk of relapse (²⁹). Because of excellent outcomes of patients later treated for recurrent disease, active surveillance is considered a reasonable option for most patients, including those with both risk factors.

Radiotherapy

The recurrence rate after prophylactic radiotherapy for clinical stage I seminoma is about 4%, and most of those patients who recur after radiation survive with additional treatment (chemotherapy). Treatment of para-aortic lymph nodes to a dose of 20 Gy was associated with excellent local control approaching 100%. A randomized trial of 20 Gy versus 30 Gy showed no difference in rate of recurrence. Omission of ipsilateral iliac lymph nodes from the treatment field resulted in less toxicity (infertility, gastrointestinal effects) and minimal loss of efficacy. Radiotherapy is contraindicated for patients with horseshoe kidney or inflammatory bowel disease.

Radiotherapy was once viewed favorably because it reduced the number of computed tomographic (CT) scans that were necessary for follow-up, with a net reduction in the cost of treatment. There is, however, a risk of second malignant neoplasms related to treatment. Studies of testicular cancer survivors 25 or more years after treatment have revealed an increase in mid-line cancers, such as gastrointestinal and genitourinary malignancies. This added risk has brought about a

reassessment of whether radiotherapy is warranted, especially considering that 80% of patients with clinical stage I seminoma will be treated unnecessarily, and that there is no survival benefit. At MD Anderson Cancer Center (MDACC), we no longer offer prophylactic radiation to men with stage I testicular seminoma.

Chemotherapy

A randomized controlled trial was conducted to compare a single infusion of carboplatin, with dose based on area under the curve (AUC) of 7, versus radiotherapy for the adjuvant treatment of clinical stage I seminoma⁽³⁰⁾. Median follow-up was 4 years, and the relapse-free survival was similar in both treatment arms, 96.7% and 97.7%, respectively, showing noninferiority of the one-cycle, single-agent carboplatin. There are limited data comparing the long-term safety of carboplatin to that of radiotherapy, leading many practitioners to adopt surveillance as the preferred option. Figure 39-3 outlines an approach to therapy for stage I seminoma.

Management of Nonbulky, Good-Risk Seminoma (Stages IIA/IIB)

Patients with stage II seminoma are often divided into nonbulky versus bulky disease for treatment discussion. In general, nonbulky disease is defined as nodes

less than 5 cm in cross-sectional dimension on CT or magnetic resonance imaging (MRI) at MDACC. The primary mode of therapy for patients in this category is radiotherapy unless the patient has a contraindication or is unable to tolerate radiation treatment.

Radiotherapy

It is no longer recommended that patients with stages IIA and IIB seminoma receive high-dose radiation (30-35 Gy), mediastinal radiation, or left supraclavicular radiation. At MDACC, our current approach is to give 20 Gy to the para-aortic and ipsilateral iliac nodal fields with a 6-Gy boost to the para-aortic lymph nodes⁽³¹⁾. Occasionally, radiographic evidence for residual disease is present post-radiotherapy, but if the abnormality is less than 3 cm, observation is recommended.

Alternatives to Radiotherapy

A subset of patients exists who will not be able to receive radiation therapy for various reasons. These reasons may include patient refusal, inflammatory bowel disease, horseshoe or pelvic kidney, and history of abdominal surgery. In this setting, systemic chemotherapy could be offered. In a series published by Xiao et al⁽³²⁾, patients with good-prognosis seminoma were included in the analysis and were treated with four cycles of etoposide

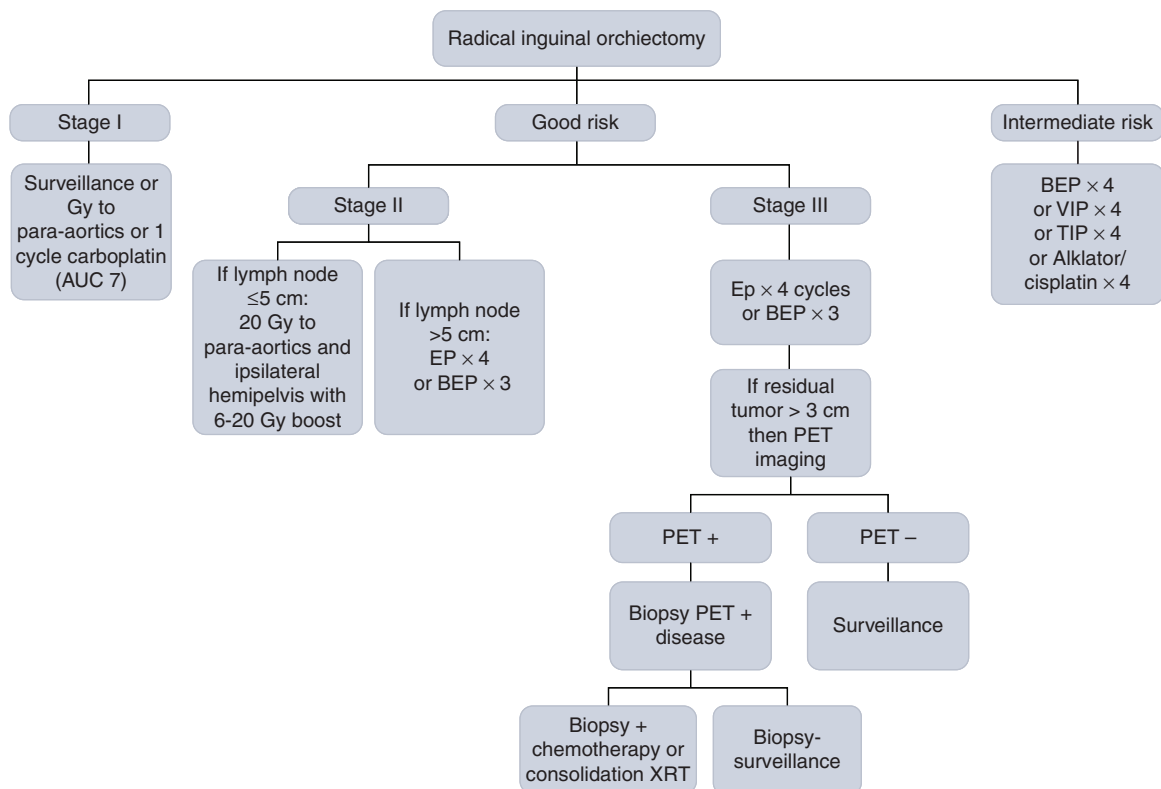

FIGURE 39-3 Management of testicular cancer (seminoma). BEP, bleomycin, etoposide, and cisplatin; EP, etoposide and cisplatin; TIP, paclitaxel, ifosfamide, cisplatin; VIP, etoposide, ifosfamide, cisplatin.

and cisplatin (EP). Although this does not represent the standard of care for stages IIA and IIB seminoma, it is a reasonable alternative for patients who absolutely cannot receive radiation therapy.

Management of Advanced, Good-Risk Seminoma (Stages IIC/III)

This treatment group includes patients with stage II with bulky lymphadenopathy (≥ 5 cm) and patients with stage III with good-risk disease. In this group of patients, the risk of recurrence remains high despite local therapy; therefore, the primary treatment recommendation is systemic chemotherapy. It is also in this category of patients that the role of positron emission tomographic (PET) scan may be introduced in its limited role for GCTs.

Chemotherapy

The recommended systemic chemotherapy regimen for patients with good-risk advanced seminoma (stage IIC or IIIA) is three cycles of bleomycin, etoposide, and cisplatin (BEP) or its equivalent. The evidence for use of three cycles of BEP versus four cycles was presented by de Wit et al.⁽³³⁾ These investigators showed that three cycles of BEP are equivalent to four cycles, with 2-year progression-free survival (PFS) of 90.4% and 89.4%, respectively.⁽³³⁾ Alternatively, patients who are unable or refuse to receive bleomycin or are older than 50 years can be successfully treated with four cycles of EP.

Residual Disease After Chemotherapy and the Role of Positron Emission Tomography

After completion of chemotherapy, restaging CT scans are performed. If a patient is found to have residual mass measuring 3 cm or less in size with normal tumor markers, active surveillance should be pursued. After chemotherapy, residual disease measuring greater than 3 cm can be further evaluated by PET imaging. Evidence for the role of PET imaging in the setting of residual disease greater than 3 cm was presented by De Santis et al.⁽³⁴⁾

In this evaluation of 33 patients with follow-up time of 23 months, the positive predictive value of fluorodeoxyglucose (FDG) PET was 100%, with specificity and sensitivity of 100% and 89%, respectively, for the identification of residual disease in lesions larger than 3 cm. Although encouraging, the role of PET imaging in this setting is being reexamined because several false-positive cases from our institution have been recently identified⁽³⁵⁾.

Positron Emission Tomography–Negative Disease Postchemotherapy

If there is no evidence of avid uptake on PET after chemotherapy, the patient enters the active surveillance strategy. If the patient is unable to have PET imaging, surgical biopsy can be considered for those patients with residual disease measuring greater than 3 cm.

Positron Emission Tomography–Positive Disease Postchemotherapy

At MD Anderson, a positive PET scan requires a confirmatory biopsy. If residual disease is confirmed, several options can be considered. First, salvage radiation therapy to the residual mass can be offered, but this does not provide long-term control. Second, the patient can be offered salvage chemotherapy. Finally, the patient may undergo high-dose chemotherapy with autologous stem cell transplantation. See Fig. 39-3 for the algorithm of our management strategy.

Management of Advanced, Intermediate-Risk Seminoma

Patients with advanced, intermediate-risk seminoma have nonpulmonary visceral metastasis. The most common sites of disease are the liver and bone. These rare patients are offered systemic chemotherapy on presentation (see Fig. 39-3). The chemotherapy regimens commonly used are four cycles of BEP, four cycles of etoposide, ifosfamide, cisplatin (VIP), or four cycles of paclitaxel, ifosfamide, cisplatin (TIP)⁽³⁶⁾.

Case 39-1: Seminoma Presenting With Renal Insufficiency

A 37-year-old man had a left inguinal orchiectomy for classic seminoma. Laboratory data at presentation to MDACC revealed serum creatinine of 1.8 mg/dL, calcium 12.7 mg/dL, hemoglobin 10.5 g/dL, hCG 113 mIU/mL, alkaline phosphatase 194 IU/L, and LDH 1,773 IU/L (ULN 618). A CT scan of abdomen and pelvis revealed a large retroperitoneal mass with marked left hydronephrosis (Fig. 39-4A). The patient initially received one cycle of cyclophosphamide and carboplatin. Repeat laboratory data revealed serum creatinine of 1.1 mg/dL, calcium 8.2 mg/dL, LDH 483 IU/L, and undetectable hCG. He subsequently received three full cycles

of EP with excellent response. Repeat imaging shown in Fig. 39-4B revealed marked improvement in the size of the mass (from 14 to 7 cm). Postchemotherapy PET imaging showed the residual mass to be metabolically inactive.

Comment: A patient with advanced seminoma presenting with hydronephrosis and renal insufficiency may receive induction chemotherapy with cyclophosphamide and carboplatin rather than placing nephrostomy tubes to allow administration of BEP or EP in the first cycle. The patient can subsequently receive standard therapy after normalization of renal function.

FIGURE 39-4A Baseline imaging from Case 39-1 showing a large left retroperitoneal mass with left hydronephrosis.

FIGURE 39-4B Repeat imaging from patient in Case 39-1 showing marked improvement in mass after three cycles of chemotherapy.

Salvage Therapy for Refractory/Recurrent Seminoma

The primary treatment for recurrence after radiotherapy is salvage chemotherapy. For patients with lung metastasis (good-risk category), the standard of care is administration of either three cycles of BEP or four cycles of EP. In patients with bone or liver metastasis (intermediate-risk category), salvage chemotherapy is

pursued with four cycles of BEP, TIP, or VIP. Bleomycin should be avoided in men older than 50 years.

Clinical signs of chemotherapy-refractory disease should be approached with an aggressive change of strategy, including the option of high-dose chemotherapy and stem cell transplantation. Usually reserved for BEP failures, the role of stem cell transplantation in refractory/recurrent advanced seminoma was addressed by Einhorn et al.⁽³⁷⁾ Nineteen percent of a series of 184 patients were patients with metastatic testicular seminoma. At a median follow-up of 48 months, 26 of 35 patients with seminoma treated were in complete remission. Patients in this category should be considered for referral to transplant centers if possible.

NONSEMINOMATOUS GERM CELL TUMORS

Histology

Embryonal Carcinoma

Embryonal carcinoma is the second most common pure presentation of GCT. It is rarely seen at the extremes of age, most commonly presenting in the 20- to 30-year age group, and presents with metastasis in one-third of cases. Microscopically, embryonal carcinoma cells are the most undifferentiated of the GCT types and are characterized by microscopically varied cells with indistinct borders and scant cytoplasm, giving the appearance of overlapping nuclei. Tumor cells can be seen in sheets or arranged as papillary or tubular structures with a high mitotic rate. There is a propensity for vascular invasion. Phenotypic characterization can reveal positivity for cytokeratin, CD30, PLAP, AFP, and hCG. Modest elevations of both AFP and hCG are typical, but importantly, pure embryonal cancers can be marker negative in the serum. [Figure 39-5](#) shows the typical histologic appearance of embryonal carcinoma.

Endodermal Sinus Tumors (or Yolk Sac Tumors)

Pure yolk sac tumors are extremely rare in the adult patient but account for the majority of childhood GCTs. In adults, EST or yolk sac elements are commonly seen as a component of mixed NSGCTs. Microscopically, EST can manifest as macrocystic, papillary, solid, or a glandular/alveolar pattern with perivascular arrangements of epithelial cells known as glomeruloid or Schiller-Duval bodies. Very high serum AFP levels generally reflect the presence of an EST component, and serum levels of AFP immediately prior to the start of chemotherapy are important prognostically in the classification of good- (AFP <5,000 ng/mL), intermediate- (5,000-10,000 ng/mL), and poor-risk (>10,000 ng/mL) metastatic NSGCTs. [Figure 39-6](#) shows the typical histological appearance of an EST carcinoma.

FIGURE 39-5 Histological appearance of embryonal carcinoma.

FIGURE 39-6 Histological appearance of EST carcinoma.

FIGURE 39-7 Histological appearance of choriocarcinoma.

Choriocarcinoma

Also rare in the pure form in the adult population, choriocarcinoma frequently presents as a component of mixed NSGCTs. Choriocarcinomas comprise both syncytiotrophoblasts and cytotrophoblasts, typically arranged in sheets or nests. Choriocarcinomas generally make copious amounts of hCG, and the level of this marker is also an indication of prognosis in metastatic NSGCTs. Levels of hCG greater than 50,000 mIU/mL are a marker of poor-prognosis NSGCT and are typical of metastatic choriocarcinoma. Half of choriocarcinomas are PLAP positive. Choriocarcinoma elements tend to dominate the clinical course and frequently metastasize to the brain. Symptoms of hyperthyroidism are common, owing to stimulation of the TSH receptor by hCG, and treatment such as a β -blocker is indicated while chemotherapy is initiated. **Figure 39-7** shows the typical histological appearance of choriocarcinoma.

Teratoma

Teratomas possess somatic cells from at least two germ cell layers (ectoderm, endoderm, and mesoderm). Variable degrees of differentiation allow for the subclassification of mature and immature forms. A mature teratoma consists of terminally differentiated tissues and can form cystic structures. Although histologically bland, this low-grade malignancy can grow to a threatening dimension and become unresectable. Only about 2% to 3% of all GCTs show mature teratoma as the only histologic component, but teratoma is commonly present as an element of a mixed GCT. An adult man presenting with teratoma as the only histologic pattern should be presumed to have a mixed GCT and be treated as such. An immature teratoma is less differentiated, although this distinction has no known clinical significance.

One of the unfortunate manifestations is the development of somatic (non-GCT) malignancy within a teratoma. Sometimes known as “teratoma with malignant transformation,” this entity typically displays the biology of whatever histology develops and can range from leukemias to sarcomas to carcinomas. In general, transformation to somatic malignancy carries a poor prognosis, and the best prevention is to surgically remove all residual teratoma whenever possible⁽³⁸⁾. **Figures 39-8** and **39-9** represent the typical histological and gross appearance of teratoma, respectively.

Clinical Features

As described previously, approximately half of testicular GCTs show histologic elements other than seminoma or produce serum elevation of AFP indicating nonseminoma. These cancers are collectively known

FIGURE 39-8 Histological appearance of teratoma.

as mixed GCTs or NSGCTs, and they form a group of histologically and clinically diverse cancers (³⁹). The NSGCTs are more likely to spread hematogenously with increased risk of distant metastasis when compared to seminomas. Because of the unique and heterogeneous nature of NSGCTs, there are several clinical presentations that warrant further discussion because of their significance to patient care and prognosis.

Growing Teratoma Syndrome

Residual teratoma is a low-grade, slow-growing malignancy that can be fatal by inexorable growth. This can take 10 or even 20 years to become threatening and thus can be missed without dedicated lifelong follow-up of patients with NSGCTs. One of the most remarkable and clinically important features of teratomas is that they are

often “pushing” and rarely invasive. Thus, at surgery, even very large masses are sometimes removed far more easily than would be expected on the basis of the preoperative imaging. It is important to consult a center where sufficient surgical experience is available before concluding that a residual teratoma is “unresectable” (⁴⁰).

Choriocarcinoma Syndrome

As the name implies, choriocarcinoma syndrome is seen in the setting of high-volume NSGCT that shows predominantly choriocarcinoma histology and is associated with very high (in some cases over 1 million mIU/mL) levels of β -hCG. This syndrome is characterized by prominent constitutional symptoms that represent the effects of both a bulky cancer and secondary hyperthyroidism caused by cross-reaction of hCG with TSH receptors. Typically, patients are rapidly losing weight, tachycardic, anxious, and diaphoretic and have tender gynecomastia from secondary hyperprolactinemia. In addition, most patients have high-volume lung metastases with impending respiratory compromise from the burden of pulmonary metastasis. This is a medical emergency, and treatment should not be delayed for histologic confirmation because this is a pathognomonic constellation in a young man. Metastatic choriocarcinoma has a propensity for brain metastasis, although this is not always apparent on baseline imaging.

Prognosis

As described for seminoma, the IGCCCG developed a prognostic staging system for NSGCTs, with extrapulmonary visceral metastasis found as a major factor in prognosis. Unlike seminoma, prechemotherapy tumor

FIGURE 39-9 Gross appearance of teratoma.

markers were identified as significant in the prognosis of these patients. The prognostic categories are outlined in Table 39-2. In general, patients with mediastinal primary, nonpulmonary visceral metastasis and “poor-risk markers” as defined in the table are considered to have a poor prognosis and have a 5-year OS of 48% with standard treatment. Patients with testis or retroperitoneal primary and no extrapulmonary visceral metastasis are placed in the good-prognosis category based on tumor marker levels as described in the table. Patients with a good prognosis have a 5-year OS of 92%. All others are placed in the intermediate-risk group and have a 5-year OS of 80% ⁽²⁾. Van Dijk et al ⁽³⁾ updated the 5-year OS data for NSGCTs in a pooled meta-analysis. The authors reported a 5-year OS of 94% for good prognosis, 83% for intermediate prognosis, and 71% for poor prognosis. This illustrates the improving survival rates in the high-risk group.

Management of Clinical Stage I Nonseminoma Germ Cell Tumors

In general, individuals with clinical stage I NSGCT include patients with normal markers postorchietomy and no evidence of disease outside the resected testis, epididymis, or cord. As with seminoma, radical inguinal orchiectomy is the initial therapy for early-stage NSGCT. Appropriate surgery will cure approximately 70% of patients in clinical stage I. The two identified risk factors in these patients include percentage of embryonal histology and presence of lymphovascular invasion (LVI), with LVI the most predictive ⁽⁴¹⁾. Patients are considered low risk for recurrence postorchietomy if there is less than 50% embryonal component in the tumor and no evidence of LVI. The role of percentage of embryonal component is debatable, as it is often seen together with LVI. In fact, European guidelines utilize only absence of LVI for determination of “low risk” for recommendation of observation ⁽⁴²⁾.

Observation

Observation is a reasonable strategy for the reliable low-risk patient, which in practice can be those with absence of LVI. The active surveillance schedule as outlined by the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology recommends that patients should have a physical examination and tumor marker measurements every 2 months during the first year, every 3 months during the second year, and every 4 to 6 months during the third year. Chest x-ray is recommended at 4 and 12 months, then annually. Abdominal and pelvic CT is recommended approximately every 4 months during the first year and annually for years 2 and 3 ⁽⁴³⁾.

Observation is also acceptable for high-risk patients. The NCCN guidelines recommend more frequent imaging, with chest x-ray every 2 months in the first year, every 3 months in the second year, and every 4 to 6 months in the third year. Also recommended are abdominal and pelvic CT every 4 months in the first year, every 4 to 6 months in the second year, and every 6 months in the third year.

Retroperitoneal Lymph Node Dissection

Retroperitoneal lymph node dissection (RPLND) is a surgical removal of the “landing zone” lymph nodes and is an accurate staging strategy. However, its role in primary prevention of recurrence in patients with stage I NSGCT is controversial. Morbidity of RPLND includes sympathetic nerve damage that may lead to failure of ejaculation and infertility; however, use of a modified surgical template is a nerve-sparing approach that can preserve the sympathetic nerves and may facilitate antegrade ejaculation in 90% or more patients. Stephenson et al ⁽⁴⁴⁾ reported that RPLND in patients with clinical stage I yielded a 4-year progression-free probability of 96% and is an option for therapy in this patient population. Higher failure rates have been reported for patients with high-risk clinical stage I NSGCT. Patients who do not undergo prophylactic RPLND must undergo periodic CT scanning of the abdomen to rule out growing teratoma in the retroperitoneum. At MDACC, we have abandoned prophylactic RPLND for stage I NSGCT in favor of active surveillance.

Chemotherapy

Adjuvant chemotherapy for clinical stage I NSGCT consists of one or two cycles of BEP. In a randomized controlled trial, Albers et al ⁽⁴⁵⁾ compared RPLND to one cycle of BEP in 382 patients with a median follow-up of 4.7 years. The 2-year recurrence-free survival was 99.46% in the chemotherapy group and 91.87% in the RPLND group, suggesting an advantage of one cycle of BEP chemotherapy. Tandstad et al ⁽⁴⁶⁾, in the Swedish and Norwegian Testicular Cancer Project (SWENOTECA) study, reported that one cycle of BEP reduced the risk of recurrence by 90% in patients with or without LVI. In practice, adjuvant chemotherapy should only be offered to patients with either LVI, embryonal carcinoma-predominant tumor, or both. Our algorithm for management of nonseminoma testicular cancer is shown in Fig. 39-10.

Management of Good-Risk Clinical Stages IIA and IIB Nonseminoma Germ Cell Tumors

Patients with tumor marker—negative stages IIA or IIB NSGCTs—present a unique clinical situation. At our institution, these patients are divided into groups by

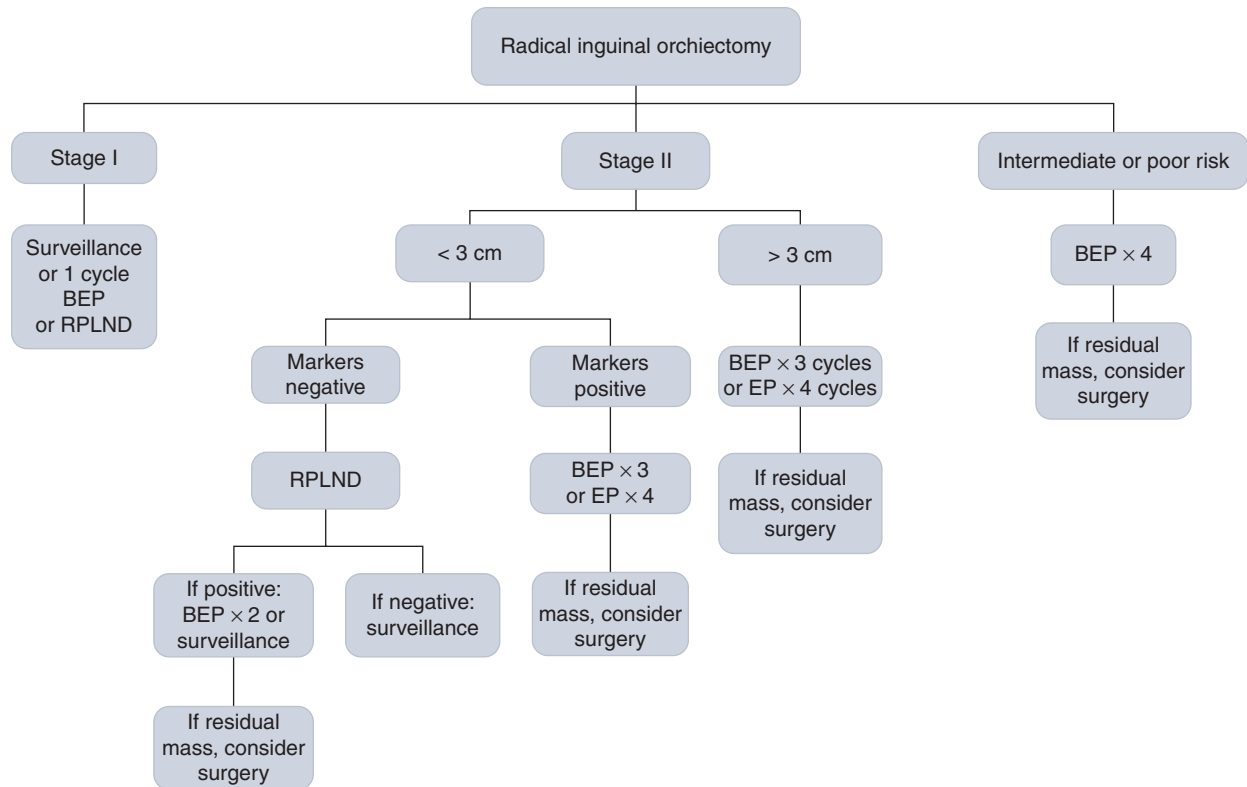

FIGURE 39-10 Management of testicular cancer (nonseminoma).

CT evidence of disease greater than or less than 3 cm. If patients have negative tumor markers with a retroperitoneal mass less than 3 cm after orchiectomy, the options are close follow-up or primary RPLND. Patients with elevated serum tumor markers or retroperitoneal mass larger than 3 cm are treated with primary chemotherapy with three cycles BEP or four cycles EP. If residual mass greater than 1 cm is detected on follow-up staging, surgical resection is recommended.

Management of Good-Risk Stages IIC and III Nonseminoma Germ Cell Tumors

Patients with bulky retroperitoneal disease of greater than 5 cm or pulmonary metastasis with relatively low serum markers constitute those with advanced disease, but still with favorable prognosis. These patients may be either stage IIC or IIIA according to the AJCC criteria and are considered together in this discussion. The primary mode of treatment in this patient population is systemic chemotherapy. This may be administered before or after radical orchiectomy as long as surgical resection of the primary is performed after completion of therapy. Once again, three cycles of BEP chemotherapy are considered standard of care, and four cycles of EP are considered a reasonable alternative for patients with a contraindication to receive

bleomycin. Resection of residual disease present on restaging should be performed.

Pathology of the resected tumor after salvage chemotherapy is different from after primary chemotherapy. Following primary chemotherapy, viable GCT, fibrosis, and teratoma are found in approximately 20%, 40%, and 40% of pathological specimens, respectively, compared to 50%, 10%, and 40% following salvage chemotherapy, respectively. Patients with greater than 10% viable GCT in the residual pathology specimen after primary chemotherapy should receive an additional two cycles of platinum-based chemotherapy (see Fig. 39-10).

Management of Intermediate- and Poor-Risk Advanced-Stage IIB and IIIC Nonseminoma Germ Cell Tumors

Patients with advanced NSGCTs who present with intermediate- or poor-risk features are managed with systemic chemotherapy consisting of four cycles of BEP or its equivalent (VIP or TIP). In selected cases, the treatment may be started based on clinical diagnosis prior to radical orchiectomy. Patients with persistent elevation of tumor markers after four courses of first-line chemotherapy in most cases should go on to receive salvage chemotherapy or high-dose chemotherapy with autologous stem cell transplantation.

Personalized Strategy Based on Tumor Marker Decline

Failure of either AFP or hCG to normalize is a well-recognized feature of chemotherapy resistance⁽⁴⁷⁾. The rate of tumor marker decline has also been studied as a predictor of poor outcome. For patients presenting with stage IIIC NSGCT, it is possible to identify a subgroup of about 25% who, based on favorable marker decline, will do comparatively well and a larger group of about 75% whose outcome with standard therapy is poor⁽⁴⁸⁾. This observation led to a phase III clinical trial in which patients with stage IIIC NSGCT received BEP in the first cycle, and at completion of the first cycle, those with normalization or favorable decline in both tumor markers remained on BEP (four courses total) and the rest were randomized (1:1) to BEP or an intensified regimen. Final results of this study confirmed superior PFS and OS in the group with favorable decline compared to unfavorable decline (treated with BEP) and demonstrated a statistically significant improvement in 3-year PFS for patients randomized to intensified treatment versus BEP⁽⁴⁹⁾.

Management of Recurrent and Refractory Nonseminoma Germ Cell Tumors

Several chemotherapy regimens with clinical activity in the salvage setting have been reported, and these include VIP, TIP, VeIP (vinblastine, ifosfamide, cisplatin), or gemcitabine/oxaliplatin. In general, many patients respond and some are even cured with salvage

chemotherapy and surgical consolidation, especially those with a small or moderate volume of disease.

High-Dose Chemotherapy

High-dose induction chemotherapy with autologous peripheral blood stem cell transplantation has been studied in first recurrence and later recurrence of GCT. Einhorn et al⁽³⁷⁾ retrospectively reviewed 184 patients (149 patients with advanced NSGCT) with a median follow-up of 48 months. Ninety of the 149 patients (60%) with NSGCT treated with high-dose chemotherapy and subsequent autologous stem cell transplantation were disease free at follow-up. The authors advocated the use of this aggressive treatment as second-line therapy, suggesting that it is more advantageous than when it is used in the third-line setting. Based on this study and despite the absence of a randomized trial, patients with recurrent or refractory advanced-stage NSGCT may be considered for this aggressive, yet effective, treatment strategy.

Special Considerations

Pitfalls in Tumor Marker Elevation

Mild elevation of β -hCG (usually <20 mIU/mL) may occur secondary to hypogonadism or marijuana use and therefore should not always be attributed to residual or recurrent tumor. Modest elevation of AFP may be present with residual teratoma and will normalize following surgical resection, but it may also be

Case 39-2: BEP/TIP Failure

A 24-year-old man presented with lower back pain, anorexia, night sweats, and weight loss. Imaging studies revealed extensive retroperitoneal lymphadenopathy, a right testicular mass, and bilateral lung nodules. Tumor markers were hCG 33,261, AFP 4.1, and LDH 1,847. A fine-needle aspiration of the retroperitoneal mass revealed embryonal carcinoma. Chemotherapy with BEP was initiated. The kinetics of decline of serum hCG levels were as shown next for the first three of four planned cycles:

- s/p cycle 1: 1,507
- s/p cycle 2: 279
- s/p cycle 3: 323

Salvage chemotherapy commenced after the third cycle of BEP. The patient received four cycles of TIP, with

decrease in adenopathy and decline of serum hCG to an undetectable level. The patient was then referred for RPLND and right radical orchiectomy. Pathology revealed no viable tumor. Two months postoperatively, serum hCG rose to 161. He received one cycle of irinotecan, paclitaxel, and oxaliplatin with tumor marker normalization. He then underwent tandem peripheral blood stem cell transplantation with high-dose Ifosfamide, Carboplatin and Etoposide (ICE). He remains disease free 3.5 years later.

Comments: For symptomatic patients with intermediate- or poor-risk GCTs, chemotherapy can be initiated before orchiectomy. Rising tumor markers during BEP chemotherapy signal BEP failure and dictate a change of therapy. The best results are achieved with high-dose chemotherapy and stem cell transplantation.

Case 39-3: The Challenge of Managing Intercurrent Illness

A 35-year-old man who was a heavy smoker and marijuana user underwent a left orchiectomy for a 3.5-cm mixed NSGCT and presented 2 months later to MDACC with left groin pain and left thigh numbness. Tumor markers were AFP 6,575, hCG 1,059, and LDH 2,441. Computed tomographic scans revealed bilateral lung nodules, a large (14.7-cm) retroperitoneal mass, left hydronephrosis, and multiple other enlarged abdominal and pelvic lymph nodes. During the first BEP chemotherapy cycle, he suffered an inferior myocardial infarction (MI) secondary to an occluding atherosclerotic plaque in the right coronary artery. After coronary stenting and optimal medical therapy, the patient was able to complete four cycles of BEP on schedule and at full dose, without delay or significant complications, except for moderate peripheral neuropathy. His tumor markers declined as follows:

- s/p cycle 1 AFP = 3,853, hCG = 34.7
- s/p cycle 2 AFP = 542, hCG = 5.2

- s/p cycle 3 AFP = 88.1, hCG = 4.6
- s/p cycle 4 AFP = 42, hCG = 4.7

The patient received intramuscular testosterone injection for a low serum testosterone level, and 3 weeks later serum hCG was <1.0. Six months after his MI, the patient had resection of the large left retroperitoneal mass, the left kidney, and left adrenal gland; RPLND; and segmental resection of the left psoas muscle. Pathology of the specimen revealed 98% necrosis and only two microscopic foci of residual viable EST in transition to adenocarcinoma. The patient has been recurrence free for 3 years.

Comments: This case illustrates three points. The first is the importance of pursuing chemotherapy while managing an intercurrent illness. The second point is to remember that there are causes of elevated tumor markers other than tumor. The third point is that we do not treat foci of Malignant transformation of Teratoma (MTT).

constitutionally elevated or indicate the presence of liver disease. In addition, elevated tumor markers may indicate unidentified central nervous system disease or residual primary testicular tumor.

Role of Desperation Surgery

There are patients with NSGCTs who have rising tumor markers despite optimal systemic therapy. In these instances, “desperation surgery” to resect all visible disease may be the only option. It is estimated that up to 20% of patients who fit these criteria can be cured with surgical resection. Patients with isolated retroperitoneal lymph node disease, those with AFP-only elevation, and those who undergo a complete resection of residual disease have the most favorable outcome. Referral to a center with high surgical expertise in this setting is recommended, as potentially large en bloc resections may be required to achieve the desired outcome of complete resection.

Treatment of Late Relapse

Late relapse is defined as disease recurrence after 24 months from chemotherapy treatment. Teratoma and EST are the most common histologies in this setting, with pure teratoma conferring a better prognosis. Surgery is the preferred initial treatment in these cases if the tumor is anatomically resectable.

Late Complications of Therapy

Although rare, there are specific complications associated with treatment of GCTs that are especially important in this patient population because curability may lead to a normal life expectancy. Secondary leukemias occur in fewer than 0.5% of patients and are associated with use of etoposide. Bleomycin toxicity can appear early and is most associated with dose greater than 200 IU. Patients may also have increased risk of vascular side effects, including Raynaud’s syndrome and hypertension. Up to 25% of patients may develop the metabolic syndrome. Additional complications include renal insufficiency, chemotherapy-induced peripheral neurotoxicity, sensorineural hearing loss, chronic electrolyte abnormalities, and neuropsychiatric abnormalities.

EXTRAGONADAL GERM CELL TUMORS

Patients with pure seminoma arising in the mediastinum have similar prognosis as patients with testicular seminomas and are treated with four cycles of EP at our institution, provided they do not have extrapulmonary visceral metastasis. Nonseminomatous extragonadal GCTs represent a distinct subset of GCTs and carry a poor prognosis. The most common origin is the

Case 39-4: Desperation Surgery

A 46-year-old man presented with back pain and was found to have an 11-cm retroperitoneal mass, biopsy of which revealed high-grade GCT (Fig. 39-11A). He underwent a left radical orchiectomy for a 2.8-cm mixed GCT (99% seminoma, 1% teratoma). Postoperatively, serum AFP was greater than 10,000. He received six cycles of EP, followed by one cycle of VeIP but never achieved tumor marker normalization (Fig. 39-11B). At presentation to MDACC, his serum AFP was 604. The patient received multiple additional cycles of rotating salvage chemotherapy, including actinomycin-D, cyclophosphamide, and etoposide (ACE); TIP, cisplatin, vincristine, methotrexate, and bleomycin (POMB); doxorubicin, paclitaxel, and gemcitabine (ATG); and cisplatin, cyclophosphamide, and doxorubicin (CisCA) (Fig. 39-11C). The patient developed renal insufficiency, recalcitrant anemia, and grade 3 peripheral neuropathy and had transient normalization of serum tumor markers while awaiting surgical resection. At the time of surgery, serum AFP was 46.9. The patient underwent RPLND with excision of retroperitoneal masses, left radical nephrectomy, and excision of retrocrural lymph node masses. Pathology demonstrated metastatic mixed GCT, including areas of EST, mature teratoma, and focal areas suspicious for embryonal carcinoma and choriocarcinoma. He remains disease free past 5 years from the time of his salvage surgery.

Comments: Four cycles of BEP and not EP is the standard for patients with intermediate- and poor-risk NSGCT. In rare cases, where the tumor markers do not normalize, even after exhausting all chemotherapeutic options, patients may be salvaged surgically. Patients who have primarily AFP elevation and EST or teratoma benefit the most from such an approach.

mediastinum, but they can also arise in the retroperitoneum or pineal region. Rare cases involve the vagina, prostate, liver, and orbit.

Mediastinal extra-gonadal germ cell tumors (EGCT) appear as large anterior masses on radiographs. This subset is characterized by prominence of EST and teratoma histology compared to primary testicular GCTs⁽⁵⁰⁾. Initial diagnosis may be aided by elevations of AFP or hCG. Klinefelter syndrome is associated with increased risk of primary mediastinal NSGCTs⁽⁵¹⁾. Additional associations include acute megakaryoblastic leukemia, acute myeloid leukemia, myelodysplastic syndrome, and malignant histiocytosis. Some of these cases represent malignant transformation of immature teratoma elements.

FIGURE 39-11B Repeat imaging of patient in Case 39-4 after six cycles of EP.

FIGURE 39-11C Imaging of patient from Case 39-4 showing residual disease despite multiple lines of salvage chemotherapy prior to desperation surgery.

Case 39-5: Germ Cell Tumors With Occult Primary

A 29-year-old man presented with weight loss and left supraclavicular lymphadenopathy (Fig. 39-12A) but had a negative testicular examination and ultrasound. Imaging studies confirmed a 5-cm left supraclavicular lymph node and showed a small left pleural effusion. A biopsy of the supraclavicular lymph node demonstrated poorly differentiated adenocarcinoma. Embryonal carcinoma could not be excluded. Immunostains for PLAP and Ki-1 were positive but were negative for AFP and inconclusive for hCG. Laboratory evaluation revealed azoospermia but normal serum chemistries and tumor markers. The patient was treated with three cycles of BEP and achieved a complete remission; he is now disease free for 5 years without surgical consolidation (Fig. 39-12B).

Comments: The case of unknown primary carcinoma in a young man, even if tumor markers are negative, should raise the diagnosis of GCT and should be treated as such. Surgical consolidation is not always necessary when a clinical complete response is achieved with chemotherapy.

Mediastinal NSGCTs are classified as poor-prognosis GCTs⁽²⁾, and data suggest that long-term survival is approximately 50%⁽⁵²⁻⁵⁴⁾. The aggressive nature of this entity is coupled with the surgical difficulty of resection of residual disease after therapy. Early

FIGURE 39-12A Baseline imaging of patient described in Case 39-5 showing bulky left supraclavicular adenopathy.

FIGURE 39-12B Imaging after three cycles of chemotherapy.

diagnosis and aggressive resection of mediastinal NSGCTs may improve the outcome. At our institution, the treatment strategy for this rare entity includes presurgical chemotherapy to optimum response and then consolidation surgery.

CONCLUSION

The GCTs represent the paradigm of curable solid tumors. Optimal management of patients with GCTs requires a multidisciplinary approach, integrating chemotherapy and surgery, to achieve the highest cure rates. Patients who pose a unique diagnostic or therapeutic challenge should be considered for early referral to a large tertiary care center.

OVERVIEW

Brain tumors are a heterogeneous group of lesions that range from benign, slow-growing tumors found only incidentally on autopsy, to malignant, rapidly growing tumors that cause death within months. The most common intracranial tumors are brain metastases from systemic cancer, estimated at 200,000 new cases per year in the United States, based on a 10% to 15% incidence (¹). In comparison, the incidence of primary brain and spinal cord tumors for 2014 was estimated at 23,380 new cases (American Cancer Society 2014 Facts and Figures [<http://www.cancer.org/acs/groups/content/@research/documents/webcontent/acspc-042151.pdf>] (or, cancer.org]).

Because of the heterogeneous histology and often-refractory nature of primary brain tumors, their management is complex, ideally requiring a multidisciplinary team and individualized treatment. The diagnosis is made on the basis of histology, so an accurate characterization of the lesion pathology is crucial, often necessitating confirmation at a specialized cancer center. Optimal outcomes involve the coordination of neurosurgery, radiation oncology, and neuro-oncology specialists. Despite advances in neurosurgical techniques, radiation therapy, and chemotherapy, the prognosis for patients with high-grade gliomas such as glioblastoma (GBM), the most common form of glioma, remains dismal. Recent large clinical trials have reported a median survival of only 14 to 16 months with a 26% to 33% 2-year survival rate (^{2,3}). A review of eight consecutive phase II chemotherapy trials for recurrent GBM demonstrated only a 6% response rate

(complete response [CR] and partial response [PR]), with a 6-month progression-free survival (PFS) of 15% and a 1-year survival of 21% (⁴). It is therefore important to consider patients with high-grade gliomas for entry into clinical trials at all stages of disease because new therapies target patients from initial diagnosis, with presurgical protocols, to salvage therapy at relapse. This chapter provides basic principles that can be used for diagnosing and treating patients with brain tumors along with an introduction to the molecular mechanisms underlying gliomagenesis.

CLASSIFICATION AND INCIDENCE

Brain tumors are either primary tumors that arise de novo or secondary metastases, the latter being far more common. Most commonly, brain metastases result from lung cancer, followed by breast, melanoma, renal, and colorectal cancers. Most patients with brain metastases die from progression of their systemic cancer, although, because of improvements in systemic therapy, brain metastases are now seen more frequently and with increasing morbidity and mortality. On a more hopeful note, advances in treating brain metastasis with surgery and radiotherapy (RT) have improved overall survival when systemic disease is controlled.

Primary brain tumors are classified by the World Health Organization (WHO) grading system (Table 40-1), which is based on the histologic pattern of cell differentiation in the tumor, in addition to histologic features associated with biological aggressiveness

Table 40-1 World Health Organization (WHO) Classification of Tumors of the Central Nervous System

WHO grade I	
Pilocytic astrocytoma	Meningioma
Myxopapillary ependymoma	Craniopharyngioma
Subependymoma	
WHO grade II	
Diffuse astrocytoma	Ependymoma
Pleomorphic xanthoastrocytoma	Pineocytoma
Oligodendroglioma	Atypical meningioma
Oligoastrocytoma	
WHO grade III	
Anaplastic astrocytoma	Anaplastic oligoastrocytoma
Anaplastic oligodendroglioma	Anaplastic ependymoma
Anaplastic (malignant) meningioma	
WHO grade IV	
Glioblastoma	Pineoblastoma
Gliosarcoma	Medulloblastoma

(ie, mitotic figures, necrosis, vascular proliferation). Tumor grade is inversely correlated with prognosis. The most common primary brain tumors are gliomas (all glial tumors), followed by meningiomas, nerve sheath tumors, and pituitary tumors ⁽⁵⁾.

EPIDEMIOLOGY

Brain Metastases

Brain metastases occur far more commonly than primary brain tumors. Nearly any type of primary cancer can metastasize to the brain, including hematologic malignancies. Most commonly, brain metastases originate from lung cancer, which represents the second most common systemic cancer in men and women ⁽⁶⁾. The next most common pathology to metastasize to the brain is breast cancer, followed by melanoma, renal cancer, and colorectal cancer ⁽⁷⁾. Among solid tumors, melanoma has the highest propensity to metastasize to the brain. Based on autopsy findings, 40% to 60% of patients with melanoma develop brain metastases ⁽⁸⁾. Most brain metastases, particularly melanoma, present with multiple lesions, although when renal cancer metastasizes to the brain, it often results in a single lesion. Approximately 10%

of metastatic lesions will present as an intraparenchymal hemorrhage. Hemorrhagic metastases are most commonly seen in patients with melanoma, renal cell carcinoma, thyroid carcinoma, and choriocarcinoma. The pattern of distribution of metastases in the brain varies depending on the primary cancer.

The incidence of brain metastases appears to be rising, which may be a consequence of increasingly sensitive imaging modalities such as magnetic resonance imaging (MRI), greater use of imaging, and the increasingly prolonged survival of patients with metastatic disease. The development of brain metastases usually occurs in the context of systemic relapse, although relapses can be isolated to the central nervous system (CNS). The impermeability of the blood–brain barrier (BBB), which often limits chemotherapy penetration into the CNS, may be the culprit in circumstances of isolated brain relapse.

Primary Brain Tumors

Gliomas are the most frequently occurring primary brain tumors and include astrocytomas, oligodendrogliomas (ODs), and ependymomas. Combined, these histologies account for approximately 40% of all primary brain tumors and over 80% of all malignant CNS tumors ⁽⁹⁾. The next most common tumor is meningioma (32%), followed by nerve sheath tumor (9%) and pituitary tumor (8%) ⁽⁹⁾. The most recent data from the Central Brain Tumor Registry of the United States reported an incidence of all primary benign and malignant CNS tumors of 21.03 cases per 100,000 for a total count of 326,711 incident tumors ⁽¹⁰⁾.

The incidence of primary brain tumors differs by age. Glioblastomas, which account for more than half of all gliomas, typically peak in incidence between ages 65 and 74, anaplastic gliomas peak between ages 45 and 54, and low-grade gliomas are most typically seen between ages 20 and 34 ⁽⁵⁾. In addition to the disparities of age, gender differences are seen in the incidence of primary brain tumors. The incidence of malignant brain tumors per 100,000 person-years in males is 7.7, compared with 5.4 for females ⁽¹⁰⁾ (Fig. 40-1).

Primary CNS lymphoma (PCNSL), concordant with AIDS, has decreased since its peak in the early 1990s, when it reached 10.2 per 1 million person-years. By 1998, the incidence decreased to 5.1 per 1 million person-years, which was attributed to the treatment of human immunodeficiency virus (HIV) with highly active antiretroviral therapy (HAART) in males under the age of 60 ⁽¹¹⁾. An increased incidence in PCNSL is seen not only in HIV/AIDS but also in iatrogenic immunosuppression, such as organ transplant, autoimmune disease, and cancer. The rate for

FIGURE 40-1 Distribution of all primary brain and central nervous system tumors by histology, Central Brain Tumor Registry of the United States (CBTRUS) 2007-2011 (n = 343,175). (Reproduced with permission from Ostrom QT, Gittleman H, Liao P, et al: CBTRUS statistical report: primary brain and central nervous system tumors diagnosed in the United States in 2007-2011, *Neuro Oncol* 2014 Oct;16 Suppl 4:iv1-63).

persons over 60 years of age, however, has remained stable since 1994, at approximately 16 per 1 million person-years⁽¹¹⁾.

Although many factors have been considered as putatively involved in gliomagenesis, therapeutic ionizing radiation is the strongest established causative agent underlying the development of brain tumors. Children with acute lymphoblastic leukemia (ALL), following prophylactic cranial irradiation, have an increased risk for both gliomas and meningiomas⁽¹²⁾. Increased risk of brain tumors has been seen following therapeutic irradiation for pituitary tumors. Even low doses of radiation previously used to treat scalp ringworm increased the risk of developing nerve sheath tumors, meningiomas, and gliomas⁽¹³⁾. Fortunately, diagnostic radiation does not appear to be strongly associated with the development of gliomas⁽¹⁴⁾.

While a link between brain tumors and chemical exposure has been suggested, no specific agent has been identified with a link to brain tumors that can be validated with an exposure-disease correlation. No consistent link has been proven for the occurrence of cancer in agricultural workers. Positive correlations, but not causation, have been drawn between the occurrence of brain tumors and occupations involving exposure to synthetic rubber, vinyl chloride, and petroleum refining⁽¹⁵⁾. Whereas smoking is implicated in an increased risk for many cancers, it is not associated with an increased risk of brain tumors. Exposure to cured foods has been linked to meningiomas, and nitrosamines have been associated with gliomas with a relative risk of 1.48 in adults with a high intake of

cured meat⁽¹⁶⁾. No correlation between alcohol intake or cosmetic use and brain tumors has been found⁽¹⁷⁾.

There has been concern, particularly in the popular press, about the relationship between exposure to cell phones and the risk for brain tumors. Thus far, several case-control studies and a cohort study have failed to establish such a link.

Other than the increased incidence of PCNSL in patients with HIV infection, associations between viral exposures and brain tumors have not been consistent. Human cytomegalovirus (CMV) has recently garnered increasing attention in regard to its role in gliomagenesis. There is sufficient evidence that CMV sequences and viral gene expression exist in most gliomas and that CMV could modulate the malignant phenotype in GBM, but a specific role of CMV in glioma development has yet to be defined⁽¹⁸⁾.

A protective effect of allergies (asthma, eczema, and hay fever) was noted in a meta-analysis of over 3,000 patients, with a relative risk of glioma incidence of 0.61⁽¹⁹⁾, supporting a role for immune modulation in brain tumor genesis. A retrospective case-control series demonstrated a decreased incidence of glioma in patients who reported histories of chickenpox, shingles, herpes simplex virus and Epstein-Barr virus⁽²⁰⁾, and as a surrogate for exposure to infections in early life, birth order was correlated with increased risk for the development of glioma in adulthood⁽²¹⁾.

Relatively few brain tumors are attributable to heredity; studies have cited from 1% to 5%⁽²²⁾. Brain tumors can arise as a component of familial tumor syndromes, such as neurofibromatosis type 1 (NF1).

Patients with NF1 are at increased risk for the development of gliomas originating predominantly in the optic pathway and brainstem. These neoplasms are typically pilocytic astrocytomas with a tendency toward a more indolent course in comparison to their sporadic counterparts. Neurofibromatosis type 1 is caused by a mutation of the *NF-1* gene and is also associated with leukemia and pheochromocytoma. Neurofibromatosis type II is marked by a mutation of the *NF-2* gene and is associated with bilateral vestibular schwannomas, meningiomas, and gliomas, including an increased risk for ependymomas. The Li-Fraumeni syndrome results from an autosomal dominant mutation of the *p53* tumor suppressor gene, located on chromosome 17p. This *p53* mutation results in many types of malignancies, including glioma and medulloblastoma, as well as sarcoma, breast cancer, leukemia, and adrenocortical cancer. Turcot syndrome is an autosomal dominant disease characterized by multiple polyps of the gastrointestinal tract as well as brain tumors. Two separate mutations have been identified in Turcot syndrome. One involves the *APC* (adenomatous polyposis coli) gene, which is associated with medulloblastoma. A mutation of the *hMLH1* DNA mismatch repair gene is associated with GBM.

BIOLOGY AND MOLECULAR GENETICS

The understanding of cancer relies on uncovering the underlying molecular biologic mechanisms and signaling pathways that drive tumorigenesis. Delineating such mechanisms is complicated by the tremendous degree of intertumoral and intratumoral heterogeneity. Newer drugs target specific extracellular receptors or block intracellular signal transduction systems.

Glial Tumors

Pathway Alterations

Malignant glial tumors often exhibit significant histologic heterogeneity, which is reflected at the molecular level. Large-scale profiling efforts have accelerated our understanding of gliomas. The landscape of somatic genomic alterations has been comprehensively characterized by The Cancer Genome Atlas (TCGA). In the most recent publication by TCGA in 2013, alterations in three core overlapping pathways were described: receptor tyrosine kinase/RAS/phosphatidylinositol 3 kinase (RTK/RAS/PI3K) signaling (altered in 90% of GBMs), *p53* signaling (altered in 86% of GBMs), and RB signaling (altered in 79% of GBMs). The alterations affecting the *p53* pathway (*MDM2*, *MDM4*, and *TP53*); the Rb pathway (*CDK4*,

CKD6, *CCND2*, *CDKN2A/B*, and *RB1*); and the PI3K pathway (*PIK3CA*, *PIK3R1*, *PTEN*, *EGFR*, *PDGFRA*, and *NF1*) were found to be mutually exclusive⁽²³⁾. Of the 251 GBMs analyzed, at least one RTK was found altered: *EGFR* (57.4%), *PDGFRA* (13.1%), *MET* (1.6%), and *FGFR2/3* (3.2%). Mutations of PI3Kinase were found in 25.1% of GBMs and were found to be mutually exclusive for *PTEN* mutations/deletions. The *p53* pathway was found to be altered in 85.3% of tumors through mutations/deletion of *TP53* (27.9%), amplification of *MDM1/2/4* (15.1%), or deletion of *CDKN2A* (57.8%)⁽²³⁾. The most recent TCGA analysis also identified mutations in genes for which targeted therapies have been developed, including *BRAF*⁽²⁴⁾ and *FGFR1/FGFR2/FGFR3*⁽²⁵⁾.

The epidermal growth factor (EGF) pathway was found to be altered in 57.4% of GBMs in the most recent TCGA data. An alternate mutation in the external domain generates a truncated receptor, the EGFRvIII mutant, which is constitutively activated in gliomas⁽²⁶⁾. Growth factors such as EGF and platelet-derived growth factor (PDGF) activate multiple signal transduction pathways that lead to cell survival and proliferation. The *EGFR* can activate the PI3Kinase pathway, which is also frequently mutated in glioma. When the PI3Kinase pathway is activated, the activation of *AKT* (protein kinase B) is triggered, in turn activating multiple prosurvival pathways, such as nuclear factor kappa B (NFκB), forkhead, and glycolysis. The activation of the PI3Kinase pathway has been associated with the reduced survival of patients with glioma⁽²⁷⁾. Growth factors can also stimulate the *ras* pathway, which initiates a signal cascade through *Raf/MEK/Erk* and also promotes cell survival and tumorigenesis⁽²⁸⁾. *PTEN* has phosphatase activity that inhibits the PI3Kinase pathway. The deletion of *MMAC/PTEN* leads to *AKT* pathway activation. The activation of *p53* can result in either apoptosis or cell cycle arrest and initiation of DNA repair mechanisms. The abrogation of *p53* activity would be expected to increase proliferation and mutations, leading to genetic instability, the prodrome of tumorigenesis.

Cell cycle regulation is a key target of carcinogenesis. Cell cycle checkpoints are affected by multiple proteins, acting either as accelerators or inhibitors of cell regulation. Important molecules in this process include *p53*, *p21*, and *MDM*. Another cell cycle regulation pathway important for glial tumors involves the retinoblastoma (*RB*) gene. When the *RB* gene is phosphorylated, the E2F transcription factor is released and activates cellular proliferation. The regulation of *RB* activity is complex and involves multiple cyclins (cyclin D), cyclin-dependent kinases (*CDK4/6*), and *CDK* inhibitors (*p16*), whose activities are under investigation⁽²⁹⁾.

Gliomagenesis

The majority of GBMs (~90%) are primary, characterized by rapid development in the absence of any clinical or histologic evidence of a lower-grade lesion, in contrast to secondary GBMs, which progress from a low-grade astrocytoma or anaplastic astrocytoma (AA). Primary and secondary GBMs arise from distinctly different genetic pathways. Primary GBMs are postulated to develop quickly from glial progenitor cells over a period of a few months, potentially acquiring mutations in *EGFR*, *TP53*, or *PTEN*. In contrast, secondary GBMs are believed to arise from a stepwise accumulation of mutations.

Isocitrate dehydrogenase (*IDH*) mutations are believed to be a very early event in gliomagenesis that persist during progression to secondary GBM. The *IDH1/2* mutations likely occur prior to the acquisition of a *TP53* mutation, a driving force toward astrocytic differentiation, and prior to the acquisition of 1p/19q loss, believed to be the driving force toward oligodendroglial differentiation. Codeletion of 1p/19q has been classified as the genetic signature of ODs. Recent exomic sequencing has revealed that mutations in the *CIC* gene at 19q13.2 and *FUBP1* gene at 1p are also frequently observed in ODs. In addition to the acquisition of *TP53* mutations, *ATRX* mutations are often noted in WHO grade II and III astrocytomas and secondary GBMs⁽³⁰⁾.

Predictive and Prognostic Factors

In anaplastic oligodendrogliomas (AODs), allelic losses of chromosomes 1p and 19q (1p19q LOH) have emerged as markers of chemotherapeutic response and longer survival⁽³¹⁾, qualifying 1p19q loss as a prognostic factor. Recent studies have confirmed that 1p/19q LOH is also predictive of response to chemotherapy. In independent seminal studies by the European Organization for Research and Treatment of Cancer (EORTC) and Radiation Therapy Oncology Group (RTOG), patients with AODs harboring 1p/19q LOH did significantly better when treated with a combination of radiation and chemotherapy compared to treatment with radiation alone. Tumors without 1p/19q LOH did not incur a survival benefit⁽³²⁻³⁴⁾.

O6-Methylguanine-DNA methyltransferase (*MGMT*) is a DNA repair protein that reverses DNA damage induced by alkylating agents such as temozolomide and has been implicated as a major mechanism of resistance to alkylating agents. Hypermethylation of the promoter region of the *MGMT* gene, which inactivates *MGMT* gene transcription, has been associated with response to alkylating agents and increased survival in glioma patients⁽³⁵⁾.

Isocitrate dehydrogenase mutations were first reported in 2008⁽³⁶⁾ and quickly became a seminal

discovery. The *IDH* mutations now definitively distinguish primary from secondary GBM and have been established as a positive prognostic factor with an increase in overall survival noted in patients harboring an *IDH* mutation over those with wild-type *IDH*⁽³⁷⁾. In low-grade glioma, anaplastic glioma, and GBM, *IDH* mutation status appears to be the most important prognostic factor^(36,38). In a study of 382 patients with high-grade gliomas, *IDH1* mutation was found to be of greater prognostic relevance than histological diagnosis according to the current WHO classification system. The sequence of more favorable to poorer outcome was (1) AA with *IDH1* mutation, (2) GBM with *IDH1* mutation, (3) AA without *IDH1* mutation, and (4) GBM without *IDH1* mutation⁽³⁸⁾.

Meningiomas

A mutation in the tumor suppressor *NF2* gene on chromosome 22q12, has been closely associated with meningiomas and is disrupted in approximately half of meningiomas⁽³⁹⁾. Germline mutations of this gene result in neurofibromatosis type 2, an autosomal dominant disorder that can manifest as multiple meningiomas, bilateral schwannomas, gliomas, and intracranial calcifications⁽⁴⁰⁾. Merlin, the product of the *NF2* gene, functions as a tumor suppressor gene and is a member of a family of cytoskeleton-associated proteins linked to RTK activity and ECM interactions⁽⁴¹⁾.

In a recent study, whole-genome or whole-exome sequencing was performed on 17 sporadic meningiomas. The majority of meningiomas harbored simple genomes, with fewer mutations, rearrangements, and copy number alterations than observed in other adult tumors. Focal *NF2* inactivation was confirmed in 43% of tumors. A subset of meningiomas lacking *NF2* alterations exhibited recurrent oncogenic mutations in *AKT1* and *SMO* with immunohistochemical (IHC) evidence of activation of their pathways. Mutations involving *SMO* were observed in 3/17 tumors, and *AKT1* mutations were noted in 5/17 samples. Interestingly, these mutations were seen in the more therapeutically challenging tumors involving the skull base and were of higher grade⁽⁴²⁾. Hyperactive Hedgehog (Hh) signaling has been linked to many other cancers and is under active investigation in meningiomas highlighting *SMO* as a potential therapeutic target⁽⁴³⁾. Inhibitors of PI3K/AKT/mTOR are also under active investigation for meningiomas harboring *AKT1* mutations.

Brain Metastases

The development of brain metastases is an intricate sequential process. In addition to proliferating, tumor cells must migrate and enter the systemic circulation, survive, travel/transport through the blood to the

brain, adhere to and extravasate through the endothelium, invade the brain parenchyma, and proliferate, which requires the recruitment of a secondary blood supply. Failure at any of these steps will halt the metastatic process. Each of these steps requires complex interactions between the tumor cell and its changing microenvironment.

An understanding of the biological processes of brain metastases and the role of the BBB provides potential targets for intervention to improve treatment. There are multiple complex regulators of cell adhesion, including molecules such as integrins, cadherins, selectins, and heparin sulfate proteoglycans (⁴⁴). In addition, integrins can recruit intracellular signaling molecules such as focal adhesion kinase and src, which can lead to a cascade of cellular signaling that affects cell cycle control and proliferation. Integrins also play a part in regulating angiogenesis and tumor invasion. Other molecules that mediate invasion include the MMP family, serine proteases, and heparinase (⁴⁵).

Tumor cells must generate their own blood supply if they are to grow successfully and remain viable. Important activators of angiogenesis include vascular endothelial growth factor (VEGF), angiopoietin, hypoxia-inducible transcription factor (HIF), cyclooxygenase 2 (COX-2), PDGF, integrins, MMPs, and others. Important inhibitors of angiogenesis include angiostatin, endostatin, tissue inhibitors of matrix metalloproteinases (TIMPs), interferons, and platelet factor 4 (⁴⁶). Upregulation of activators or downregulation of inhibitors favors angiogenesis. As tumors grow, they begin to produce increasing numbers of angiogenic molecules that can participate in metastasis (⁴⁶). Because a multitude of pathways are involved in tumor growth and invasion, it is likely that if one pathway is inhibited, cells may escape through alternate pathways.

Effective drug delivery through the BBB to tumor cells is a significant obstacle to chemotherapy, both for brain metastases and primary brain tumors. The P-glycoprotein family of transporters actively exports drugs such as anthracyclines, Vinca alkaloids, taxanes, and etoposide (⁴⁷). The BBB can be breached by circulating cancer cells, which migrate across the BBB without degrading its permeability and proliferate. Once the tumor reaches a size that requires recruitment of new vessels, the BBB is disrupted, which allows imaging of brain tumors with contrast agents. In experimental models, brain metastases smaller than 0.25 mm in diameter are associated with an intact BBB, whereas larger tumors demonstrate BBB permeability (⁴⁸). Despite the presence of the BBB, studies of drug levels in brain tumors from systemic delivery have demonstrated pharmacologically relevant concentrations of drugs such as etoposide, cisplatin, cytarabine, and methotrexate. Measurements of drug levels in cerebrospinal fluid are not accurate indicators

of tissue drug levels and also vary widely depending on the agent (⁴⁹).

CLINICAL PRESENTATION, DIAGNOSIS, AND PATHOLOGY

Clinical Presentation

Brain tumors are usually diagnosed following presentation with symptoms such as seizure, headache, or focal neurologic deficits. We commonly see high-grade, malignant tumors presenting with headache, which reflects elevated intracranial pressure, and focal neurologic signs, such as weakness or aphasia. Low-grade glial tumors often come to attention with seizure, while other slow-growing tumors, such as meningioma, may be clinically silent and incidentally detected during imaging for an unrelated problem. We use contrast-enhanced MRI, the diagnostic standard, for brain tumor imaging. In addition to its superior sensitivity compared with computed tomography (CT), MRI provides more detailed anatomic as well as physiologic information that can contribute to a differential diagnosis. While contrast-enhanced CT can detect high-grade lesions that cause BBB breakdown, low-grade lesions may be detectable only on MRI, using sequences sensitive for edema and tissue changes. However, even in the case of known systemic primary cancer, contrast-enhanced CT may miss small foci of metastatic disease that are visible on MRI (Figs. 40-2 to 40-9).

FIGURE 40-2 Low-grade glioma.

FIGURE 40-3 Glioblastoma.

The brain tumor imaging characteristics seen on MRI are helpful in making a diagnosis. However, confirmation of the diagnosis with pathology is necessary in nearly all cases. Noncancerous brain lesions that may be mistaken for malignancy include infection, demyelinating disease, vascular malformations, and stroke. A particular variant of demyelinating disease (tumefactive multiple sclerosis) with large focal

FIGURE 40-5 Radiation necrosis.

tumor-like lesions, is known to resemble a malignant brain tumor. Unfortunately, some of these lesions have been irradiated, under the presumptive diagnosis of GBM, which only increases the severity of the demyelination. Conversely, patients with primary brain tumors are sometimes initially diagnosed with stroke or demyelinating disease. Further complicating the

FIGURE 40-4 Meningioma.

FIGURE 40-6 Anaplastic meningioma.

FIGURE 40-7 Central nervous system lymphoma.

picture are patients who have brain tumors in addition to stroke, which is far more prevalent with increasing age. Patients with systemic cancer, often in remission, or in stable condition, can present with brain lesions that are suspected to be brain metastases but turn out to be a primary brain tumor. These types of cases often

FIGURE 40-8 Single brain metastasis, lung adenocarcinoma.

FIGURE 40-9 Multiple brain metastases, breast.

benefit from an interpretation by a specialized neuro-radiologist who has been provided with a relevant patient history. A history of immunosuppression and multiple subcortical enhancing lesions may prompt the suspicion of a PCNSL or infection with toxoplasmosis. Further testing with brain thallium single-photon emission computed tomography (SPECT) scanning or fluorodeoxyglucose positron emission tomography (FDG-PET) imaging may serve to distinguish between the two possibilities.

Several classic radiographic appearances of brain tumors suggest malignancy. An irregular enhancing lesion with extensive edema following white matter pathways suggests a malignant glioma. Non-contrast-enhancing lesions with increased diffuse signals on FLAIR (fluid-attenuated inversion recovery) imaging suggest a low-grade astrocytoma. As a general rule for glial tumors, the presence of contrast enhancement suggests a high-grade malignancy. The WHO grade IV tumors nearly always enhance, as opposed to grade II tumors, which are typically nonenhancing. Two notable exceptions include pilocytic astrocytoma (WHO grade I) and pleomorphic xanthoastrocytoma (WHO grade II), which typically have an enhancing nodule and associated cyst. Meningiomas are typically homogeneously enhancing dural-based lesions associated with calcification. The appearance of multiple enhancing

subcortical lesions with homogeneous enhancement suggests PCNSL. However, the same lesions, if associated with a known primary malignancy, may indicate brain metastases.

Diagnosis

The discovery of a brain lesion should prompt referral to a neurosurgeon for consideration of biopsy or resection. The management of brain tumors is critically dependent on a definitive pathology for diagnosis. A referral to a specialized neuropathologist may be necessary for diagnosis of uncommon or rare tumors and also in cases where there is only limited biopsy tissue available. Biopsies must be of adequate quality and be representative of the overall tumor to allow accurate diagnosis. Our institution insists on reviewing patient diagnostic slides prior to rendering a treatment recommendation, and it is not uncommon for our neuropathologists to disagree with the diagnosis provided by the referring physician. Primary brain glial tumors are graded according to the most malignant portion of the tumor. A brain lesion that is predominantly grade III astrocytoma but has a few regions that meet the criteria for grade IV astrocytoma (GBM) should be graded as a GBM. The tumor grade may be underestimated if the most malignant portion of the tumor is not sampled. Typically, the most malignant region corresponds to an area of contrast enhancement. If a patient is suspected of having PCNSL, the use of corticosteroids should be avoided. Primary CNS lymphoma can be sensitive to steroids which are lymphocytolytic during initial presentation, and the preoperative use of even small doses of corticosteroids can lead to a nondiagnostic biopsy. These patients usually require repeat biopsy after steroid discontinuation. Patients may present with deep central lesions involving the brainstem or thalamus. These cases may require referral to a specialized neurosurgical center to evaluate whether open biopsy, resection, or stereotactic-guided biopsy is appropriate. In these cases, close coordination with a department of neuropathology will be critical in obtaining adequate tissue for diagnosis.

Pathology

Diffuse astrocytomas are characterized by well-differentiated astrocytes—either fibrillary, gemistocytic, or rarely protoplasmic—with mildly increased cellularity. The cellular morphology of the tumor cells may differ within the same tumor sample and show great variability between tumors. Necrosis and microvascular proliferation are absent. Rare mitotic figures may occur, and nuclear atypia may be present, but not sufficiently to characterize the tumor

FIGURE 40-10 Low-grade astrocytoma, WHO grade II ($\times 200$). (Used with permission from Dr. Gregory N. Fuller.)

as AA. The typical MIB-1 labeling index is less than 4% (Figs. 40-10 and 40-11).

Oligodendrogliomas are characterized by moderately cellular tumor cells with rounded, homogeneous nuclei, giving a “fried egg” artifactual appearance that is referred to as “classical OD.” A recent RTOG trial found that 80% of tumors with classical oligodendroglial morphology were associated with 1p/19q deletion, compared with only 13% of 1p and 19q deletions seen in nonclassical ODs⁽⁵⁰⁾. Microcalcifications, microcyst formation, extracellular mucin deposition, and a dense network of branching capillaries are other oligodendroglial features. Nuclear atypia may be seen, but significant mitotic activity or microvascular proliferation is suggestive of an anaplastic tumor. The MIB-1 index is typically less than 5% (Figs. 40-12 and 40-13).

FIGURE 40-11 Low-grade astrocytoma, WHO grade II ($\times 400$). (Used with permission from Dr. Gregory N. Fuller.)

FIGURE 40-12 Oligodendroglioma, WHO grade II (×200).

FIGURE 40-14 Anaplastic oligodendroglioma, WHO grade III (×40).

Anaplastic ODs are characterized by oligodendroglial cells, with signs of increased cellularity, nuclear atypia, and mitotic activity. Cellular pleomorphism may be present, with formation of multinucleated giant cells or spindle cells. Gliofibrillary oligodendrocytes and minigemistocytes are common. Although microvascular proliferation and necrosis may be present, their presence does not change the diagnosis to GBM. There is currently no designation for a WHO grade IV OD. The MIB-1 ratio is usually greater than 5% (Figs. 40-14 to 40-16.)

Anaplastic astrocytoma is characterized by diffusely infiltrating astrocytes with increased cellularity, nuclear atypia, and mitotic activity. They are more cellular than low-grade astrocytomas, and the nuclear atypia include formation of nuclear inclusions, multinucleated cells, and abnormal mitoses. Microvascular proliferation is absent; if present, it would upgrade the tumor to GBM. The typical MIB-1 labeling index

FIGURE 40-15 Anaplastic oligodendroglioma, WHO grade III (×200).

FIGURE 40-13 Oligodendroglioma, WHO grade II (×400).

FIGURE 40-16 Anaplastic oligodendroglioma, WHO grade III (×400).

FIGURE 40-17 Anaplastic astrocytoma, WHO grade III ($\times 100$).

ranges from 5% to 10% and can occasionally overlap with index values for low-grade astrocytoma and GBM (Figs. 40-17 and 40-18).

Glioblastoma and glioblastoma multiforme are synonymous; “multiforme” was dropped from the name in the 2007 WHO classification book, although glioblastoma is still commonly referred to as GBM. Glioblastoma is an anaplastic cellular tumor with marked nuclear atypia and mitotic activity, often with marked regional heterogeneity and cellular polymorphism. The presence of either microvascular proliferation or necrosis differentiate this lesion from AA. Other features associated with GBM include formation of epithelial “adenoid” structures, multinucleated giant cells, granular cells, lipidized cells, perivascular lymphocytes, and metaplasia. Glioblastoma is associated with a high proliferative rate, and MIB-1 labeling typically ranges from 15% to 20% (Figs. 40-19 to 40-21).

FIGURE 40-19 Glioblastoma, WHO grade IV ($\times 100$).

FIGURE 40-20 Glioblastoma, WHO grade IV ($\times 200$).

FIGURE 40-21 Glioblastoma, WHO grade IV ($\times 400$).

The accumulating evidence regarding the prognostic significance of *IDH* mutation status and gene expression profiling has highlighted the limitations of the current WHO criteria for the classification of diffuse gliomas. Molecular profiling is becoming an increasingly important tool in the separation of prognostic groups in diffuse gliomas. At our institution, molecular classification of diffuse gliomas has become standard. *IDH* and 1p/19q status are now routinely reported as part of an integrated diagnosis in addition to other pathologic features, including morphologic characteristics such as oligodendroglial or astrocytic phenotype, the results of other relevant IHC stains or diagnostic molecular tests (eg, p53, *EGFR* amplification, proliferation indices), and the method of molecular feature determination (eg, fluorescence in situ hybridization, IHC, comparative genomic hybridization) ⁽⁵¹⁾. This comprehensive format helps inform clinical decision making and patient counseling.

Meningiomas can have a wide range of appearances and are subtyped according to their appearance. Most meningiomas are grade I. The transitional variant has numerous concentric “onion bulb” structures. The psammomatous variant has calcified psammoma bodies. Pleomorphic nuclei and occasional mitoses are allowed, although four or more mitoses per 10 high-power fields would qualify in diagnosing atypical meningioma, grade II. Increased cellularity, high nuclear-to-cytoplasmic ratio, prominent nucleoli and foci of necrosis will also upgrade these to a grade II. Anaplastic meningiomas, grade III, have more than 20 mitoses per 10 high-power fields or obviously malignant cytology resembling carcinoma, melanoma, or high-grade sarcoma ⁽⁵²⁾ (Figs. 40-22 and 40-23).

FIGURE 40-22 Meningioma (×100).

FIGURE 40-23 Meningioma (×200).

TREATMENT AND PROGNOSIS

Low-Grade Glioma

Diffuse astrocytomas are infiltrative low-grade brain tumors. Patients commonly present with new-onset seizures. Their peak incidence is in the third decade, followed by the second decade. Overall, these low-grade tumors represent 4% of glial tumors ⁽⁹⁾. The median survival time of patients with diffuse astrocytoma is between 5 and 8 years ⁽⁵³⁾. Variation in length of survival depends on patient age, performance status at diagnosis, and total versus partial tumor (as visualized on MRI) resection ^(53, 54).

The OD is a diffusely infiltrative, well-differentiated tumor composed of oligodendrocytes. These tumors comprise 3% to 4% of all primary brain tumors and approximately 7% of glial tumors, with an incidence of 0.3 per 100,000 per year. The peak incidence is from the ages of 30 to 50. Tumors with pure OD differentiation behave more indolently than astrocytomas. The ODs appear to be more sensitive to both chemotherapy and radiation therapy than astrocytomas, and the benefit from these therapies is more pronounced and durable. Median survival ranges from 4 to 12 years, and both OD and oligoastrocytoma (OA) have been included in the reported data ⁽⁵³⁾.

The OA is a mixed tumor composed of cells that resemble both OD and diffuse astrocytoma. Based on only a few cytogenetic studies, these tumors are thought to be of monoclonal origin. Clinically, these tumors present in a similar fashion to other low-grade glial tumors, which are best imaged with MRI and have imaging characteristics that indicate a diffuse, nonenhancing tumor. There has been no demonstration of a better prognosis with an increased proportion of

the OD component. We treat these similarly to other low-grade glial tumors. Median survival ranges from 3 to 6 years. In general, these mixed tumors behave more aggressively than pure ODs but are possibly less malignant than pure astrocytomas⁽⁵⁵⁾.

Clinical Management

Once a diagnosis of low-grade glioma is suspected, we recommend proceeding with a biopsy or resection to differentiate between a low-grade glioma and a nonenhancing anaplastic glioma (Tables 40-2 and 40-3).

If gross total resection or a major resection is possible without significant morbidity, neuro-oncologists generally recommend a complete resection, which may obviate the need for irradiation and decrease the risk of malignant transformation from residual tumor cells. In multiple retrospective series, total resection of nonenhancing tumor improves survival⁽⁵³⁾. A volumetric analysis of the preoperative tumor, in addition to analysis of postoperative residual tumor, showed a correlation with time to recurrence and the likelihood of malignant transformation⁽⁵⁶⁾. There are several low-grade tumors—such as pilocytic astrocytoma, ependymoma and subependymoma, pleomorphic xanthoastrocytoma, ganglioglioma, and dysembryoplastic neuroepithelial tumor—that may be definitively

Confirmation of diagnosis with biopsy/resection is preferred, although observation is acceptable with close follow-up.
Maximal safe resection should be considered.
Observation for low-risk patients is reasonable.
For high-risk patients (age >40 or subtotal resection), consider radiation therapy followed by chemotherapy.
Radiation therapy is the current standard of treatment (focal brain irradiation to 54 Gy).
Formal serial neuropsychologic testing is helpful in assessing cognitive function.
Consider use of psychostimulants to improve cognitive function and quality of life.
Consider biopsy/resection of progressive tumor to confirm diagnosis and consider same salvage regimens as for malignant glioma.

treated by complete surgical resection alone. These patients may benefit from treatment at a specialized neurosurgical center that treats a large volume of patients with brain tumors (Table 40-4 and Fig. 40-24).

If a complete resection is not recommended, therapeutic options range from observation to treatment with focal brain irradiation or chemotherapy. Older studies of low-grade astrocytomas suggested that radiation improved survival. The 5-year survival rates ranged from 49% to 68% for irradiated tumors compared with 32% for nonirradiated tumors⁽⁵⁷⁾. The EORTC 22845 trial randomized patients to either up-front RT (54 Gy in 6 weeks) or delayed radiation therapy at progression. The PFS was 5.3 years in the early radiation group and 3.4 years in the control group. Overall survival, however, was 7.4 years in the up-front radiation group versus 7.2 years in the control group⁽²⁾. No data were collected on quality of life. These data suggest that it is acceptable to delay radiation therapy until there are signs of tumor progression, especially for asymptomatic patients or patients who have had a complete tumor resection.

Patients with low-grade glioma should be carefully assessed to determine whether their symptoms are caused by the tumor. Formal neuropsychological testing may reveal cognitive deficits that are not apparent in the simple mental status screening used for dementia. In addition, these tests can be repeated to detect subtle cognitive decline, which may lead to a decision to alter a prescribed therapy. Patients who are symptomatic from their tumor from seizures, who have altered mental status due to tumor bulk or location, or who have other focal neurologic signs would be expected to improve with treatment of the tumor.

The etiology of cognitive decline in patients with a primary brain tumor is multifactorial. The causes include direct tumor effects from invasion and

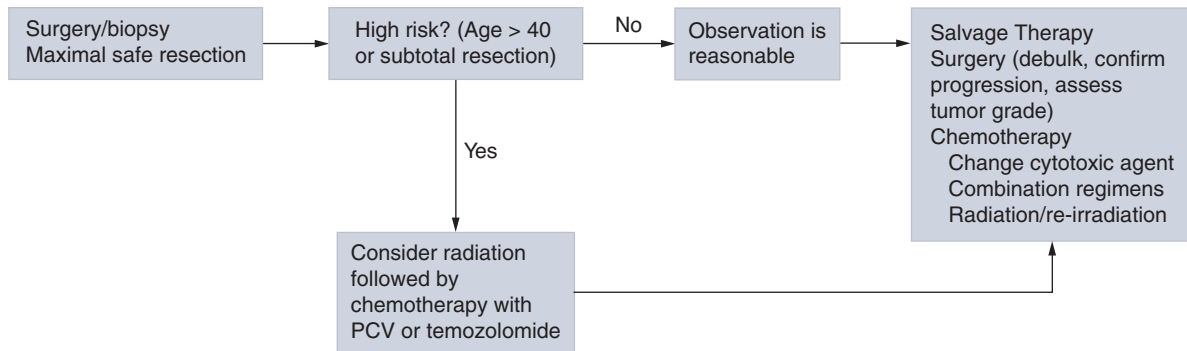

FIGURE 40-24 Treatment algorithm for low-grade glioma.

destruction as well as side effects from radiation therapy, chemotherapy, and anticonvulsants⁽⁵⁸⁾. We have found the use of psychostimulants such as methylphenidate to be helpful in improving cognitive function, mood, and fatigue⁽⁵⁹⁾.

Although there are concerns about the long-term effects of brain irradiation, radiation therapy is the current treatment standard⁽⁵⁸⁾. The dose of RT currently used by the RTOG for low-grade glioma is 54 Gy to localized treatment fields as defined by the tumor appearance on T2-weighted MRI and including a 2-cm margin. A European trial involving 379 patients with low-grade glioma did not demonstrate a benefit for higher radiation dose when comparing 45 Gy with 59.4 Gy⁽⁶⁰⁾. A second prospective study that randomized 203 patients with low-grade glioma to radiation therapy with either 50.4 or 64.8 Gy found a slightly lower survival (64% vs 72% at 5 years) and higher incidence of radiation necrosis in the group receiving the higher dose of 64.8 Gy⁽⁶¹⁾.

Much less is known about the usefulness of chemotherapy for low-grade tumors. A small study of patients with incompletely resected tumors randomized to RT alone or RT with CCNU (lomustine) demonstrated a median survival time of 4.5 years with no difference between the two treatment arms⁽⁶²⁾. An RTOG trial (RTOG 98-02) randomized patients with low-grade glioma and a high risk of recurrence (age ≥ 40 or subtotal resection/biopsy) to either radiation therapy alone or radiation therapy followed by six cycles of procarbazine, CCNU, and vincristine (PCV). The early results of this trial were presented at the American Society of Clinical Oncology (ASCO) meeting in 2014. The combination of PCV and radiation therapy prolonged both overall survival and PFS compared with radiation therapy alone in patients with high-risk grade 2 glioma, defined as patients with less than a subtotal resection and age over 40 years (ASCO abstract, *J Clin Oncol*. 2014;32:5s)^(62a).

The usefulness of chemotherapy as an initial treatment for patients with low-grade gliomas without high-risk features is unproven. The rationale for using

chemotherapy as an alternative to radiation therapy for these patients is that although radiation therapy has a proven record of treatment response, it does not improve survival and may be associated with the significant long-term side effect of cognitive decline. It is hoped that chemotherapy will delay the need for radiation therapy without reducing treatment efficacy or survival⁽⁶³⁾. Several limited studies have demonstrated an encouraging radiographic response by low-grade gliomas (primarily ODs but also astrocytomas) after treatment with temozolomide or PCV^(34,64,65). Patients who have residual tumor and would be at a high risk of cognitive side effects from radiation therapy may benefit from this strategy. However, there are no results from prospective randomized studies to recommend this approach. Patients with OD or OA may be more attractive candidates for applying this strategy, as they tend to have higher response rates to chemotherapy than patients with astrocytoma. The cytogenetic analysis of the tumor sample for LOH at 1p and 19q may predict patients who might benefit from this strategy.

MALIGNANT GLIOMAS—GRADES III AND IV

Anaplastic Oligodendroglioma

The AODs comprise between 20% and 50% of all oligodendroglial tumors and approximately 5% of anaplastic tumors. The peak incidence is between ages 40 and 50. The clinical presentation of these tumors is similar to that of other anaplastic tumors, with focal neurologic signs, seizures, or symptoms of increased intracranial pressure. These lesions, which are usually contrast enhancing, can show calcification on CT scans as well as cystic structures, necrosis, and hemorrhage.

The initial standard therapy for an AOD is surgery, with the goal of gross total resection. In RTOG 9402, random assignment of 291 eligible patients with AO/AOA was made for the patients to receive PCV plus RT versus RT alone. There was no difference in median

survival by treatment between the 148 patients randomized to PCV plus RT and the 143 patients randomized to RT (⁶⁶). However, the significance of codeletion of 1p/19q was supported by the results of EORTC 26951 with increased survival of both AOD and AOA with 1p/19q codeletion noted regardless of the treatment given: radiation alone versus radiation with chemotherapy (⁶⁷). The prognostic significance of 1p/19q was validated in the long-term results of RTOG 9402. Patients with co-deleted tumors lived longer than those with non-co-deleted tumors with the median survival of those patients with co-deleted tumors treated with PCV plus RT being twice that of patients who received RT alone. Neither timing (before, during, or following radiation treatment) nor dose intensity of PCV was found to be significant. No difference in median survival by treatment arm was appreciated in patients with non-co-deleted tumors (⁶⁶). A phase III study (CATNON) is under way to examine the appropriate treatment of anaplastic gliomas without 1p/19q codeletion.

Although PCV is the most studied regimen, in clinical practice temozolomide is typically favored for its more tolerable toxicity profile. Further study is ongoing from the RTOG/NCCTG/EORTC trial to determine if chemotherapy (PCV or temozolomide) can replace radiation and maintain the survival benefit. Despite initially high response rates, these tumors usually recur. Median survival for AOD treated with surgery, irradiation, and chemotherapy ranges from 3 to 5 years, although some patients

survive past 10 years (⁵⁵). Recurrent disease is often treated with salvage regimens similar to those used for AA and GBM (Tables 40-5 and 40-6).

Anaplastic Astrocytoma

Anaplastic astrocytomas are diffusely infiltrating with nuclear atypia and anaplasia as well as marked proliferation, features that distinguish them from low-grade astrocytomas. A lack of vascular proliferation or necrosis distinguishes these tumors histologically from GBM. The highest incidence of AA is in the fourth decade, followed by the third decade, with nearly equal incidence rates in the second, fifth, and sixth decades. These tumors account for 7.5% of all glial tumors (⁹). Some patients may have a history of prior low-grade astrocytoma. Brain imaging shows diffuse hypointense tumor on CT scans and T1-weighted MRI. There is usually more mass effect and edema compared with low-grade astrocytomas, and contrast enhancement is typical. Because these tumors can occasionally be nonenhancing, neuroimaging alone is not sufficient to distinguish these lesions from low-grade astrocytomas. The median survival for patients with AA ranges from 5 to 7 years.

Optimal initial management begins with surgery with the goal of maximal, safe resection, both to provide adequate tissue for accurate analysis of pathology and to improve survival. Following surgery, limited-field radiation therapy to a target dose of 60 Gy is commonly recommended. The target radiation field

AUC 4-5 IV on day 1 of a 28-day cycle	

^aBegin at 150 mg/m²/d for cycle 1; increase to 200 mg/m²/d for cycle 2 if no myelosuppression.
^bDose adjusted based on timing of radiotherapy.

typically includes the contrast-enhancing region of the tumor as well as the surrounding edema or nonenhancing tumor plus a 2-cm margin. The size of this field is often reduced after a 46-Gy dose has been applied to the contrast-enhancing lesion alone plus a 2-cm margin. Clinical trials using alternate radiation schemes of hyperfractionation or accelerated fractionation have not demonstrated an increased survival benefit over conventional fractionated conformal radiation therapy (⁶⁸). Adjuvant chemotherapy following radiation therapy increases time to progression and survival.

Standard agents include combination therapy composed of PCV or (see Table 40-6) temozolomide (⁶⁹). Patients with recurrent AA should be considered for clinical trials. Surgical resection should also be considered to provide a palliative benefit, relieve mass effect, allow dose reduction of steroids, and confirm histology. The recurrent tumor may actually have progressed to GBM from AA, and such patients are often eligible for a wider array of clinical trials than are available for recurrent AA. Trials have used temozolomide in combination with agents such as interferon alfa (IFN- α), *cis*-retinoic acid, metalloproteinase inhibitors, carmustine, irinotecan, and thalidomide (⁷⁰⁻⁷²). Other agents that have been used for recurrent AA include tamoxifen, carboplatin, etoposide, irinotecan, and combination chemotherapy. To date, no single trial has proven to be superior (Fig. 40-25). Reirradiation can be considered for patients who are over 2 years beyond their original radiation treatment and for patients whose site of recurrent disease lies outside the initial radiation treatment field.

Glioblastoma

Glioblastoma is the most common and most malignant glial tumor of the brain. It comprises 50% of all glial tumors, with an incidence of approximately two to three per 100,000 per year (³). Glioblastomas are characterized by poorly differentiated astrocytes with cellular polymorphism, nuclear atypia, microvascular proliferation, and necrosis. The peak incidence is in the fifth decade, followed by the sixth and fourth decades. Glioblastoma is rare in children and young adults (³). Clinically, these tumors often present with signs of increased intracranial pressure, such as headache. They can also present with seizures or focal neurologic symptoms such as hemiparesis and aphasia, often with a short history of symptoms.

Imaging with CT or MRI usually reveals a contrast-enhancing lesion with irregular borders, frequently with a necrotic center. Vasogenic edema and nonenhancing tumor often surround the area of contrast enhancement and are best seen on T2-weighted or FLAIR imaging on MRI. Glioblastomas commonly spread through white matter tracts across the corpus callosum, internal capsule, and optic radiations. Multifocal lesions are seen. If these multiple lesions truly arise independently as opposed to spreading diffusely through tracts that are not visualized by imaging or pathology, they may have a polyclonal origin.

Glioblastomas are highly lethal. Despite extensive clinical research, survival has not changed greatly during the last 20 years. Prognostic factors include age and Karnofsky performance status (KPS). Surgical resection has shown some benefit, especially gross total resection, described when 90% or more of the enhancing tumor is removed (⁷³) (Fig. 40-26).

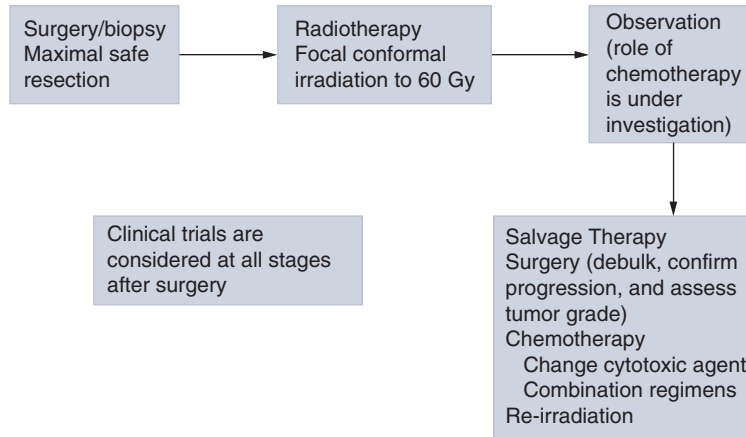

FIGURE 40-25 Treatment algorithm for anaplastic astrocytoma.

The addition of chemotherapy to radiation emerged as the standard of care for GBM based on the seminal large prospective, randomized, phase III trial from the EORTC. This trial randomized 573 patients to receive either standard RT (60 Gy in 30 daily fractions) or concurrent temozolomide (75 mg/m²/d) with RT followed by adjuvant temozolomide for 6 months (150 to 200 mg/m²/d for 5 days every 28 days). The group receiving concurrent and adjuvant temozolomide had a significant improvement in PFS (median 7.2 vs 5.0 months), survival (median 14.6 vs 12 months), and 2-year survival rate (median 26% vs 8%). Both groups had similar age, KPS, and surgical resection rates.

Our center strongly recommends patient participation in clinical trials, which enroll patients from initial

resection to radiation therapy and salvage therapy at relapse. Patients are eligible for entry into a clinical protocol for recurrent disease if it has been greater than 12 weeks since completion of concurrent chemoradiation to avoid enrolling patients with pseudoprogression (radiographic change that can mimic tumor progression but is actually due to radiation-induced changes). If a patient is not enrolled in an “up-front” trial, we recommend evaluation by our neurosurgery service to explore the prospect of gross total resection. It is not unusual for our patients to have repeat resection of tumor following biopsy or subtotal resection at an outside institution. Following resection, we treat patients with concurrent temozolomide (75 mg/m²/d throughout radiation therapy) and standard conformal

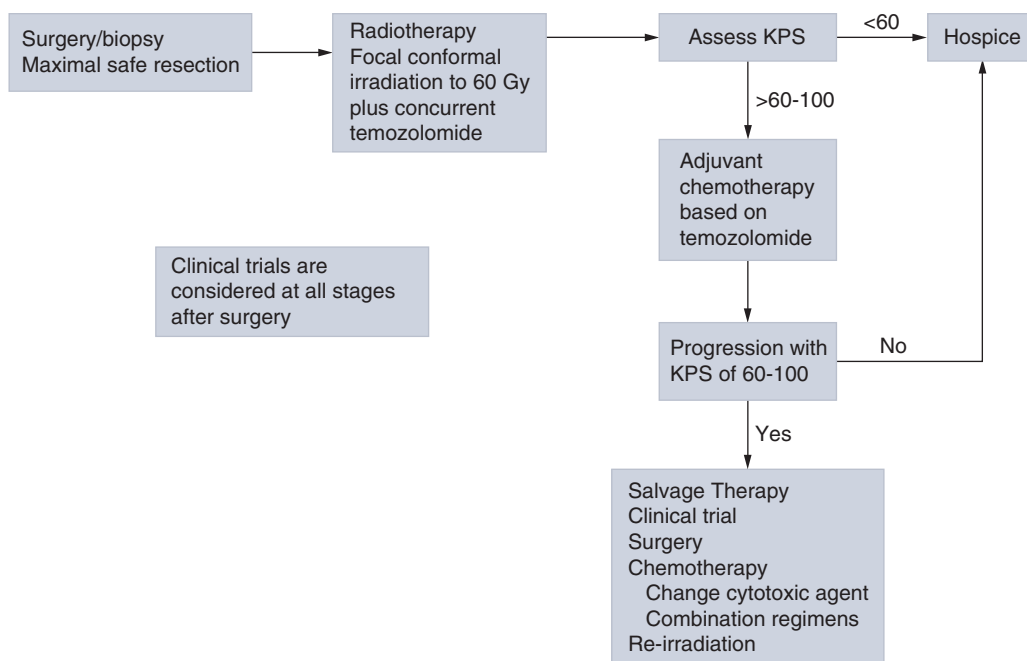

FIGURE 40-26 Treatment algorithm for glioblastoma.

radiation therapy (59.4 Gy in 1.8-Gy fractions). Following radiation therapy, we use adjuvant temozolomide or temozolomide combination therapy. Although the EORTC study only used adjuvant temozolomide for 6 months, we typically continue treatment for at least 1 year, given the lethal natural history of GBM.

Dose-dense scheduling of temozolomide was evaluated in a large randomized, phase III trial based on the premise that prolonged exposure to temozolomide would result in prolonged depletion of MGMT, possibly translating into an improved survival in patients with newly diagnosed GBM. Standard adjuvant temozolomide (days 1-5 every 28 days) was compared to a dose-dense schedule (days 1-21 every 28 days). No statistically significant difference in either median OS or median PFS was observed between the two treatment arms. Treatment toxicity was higher with the dose-dense schedule⁽³⁾.

Patients with GBM and progressive disease are offered salvage therapy if their KPS is adequate. We consider options including resection of tumor, chemotherapy, and stereotactic radiation therapy. Some novel neurosurgical clinical trials have offered local therapy with gene therapy using *p53*, although this was limited by lack of dispersion of the therapy into surrounding tissues⁽⁷⁴⁾. An interleukin 13–conjugated *Pseudomonas* exotoxin has been studied using convection-enhanced delivery to lead to higher tissue concentration with larger volumes of distribution in phase I^(75,76). Another ongoing trial uses a conditionally replication-competent adenovirus (Delta-24-RGD) injected into the resection cavity for recurrent malignant gliomas.

One advantage of re-resection of progressive disease is to confirm pathology and specifically to determine whether the progressive enhancement on MRI represents tumor or radiation necrosis. Magnetic resonance imaging dynamic contrast and MR spectroscopy imaging, FDG-PET scanning, and brain SPECT thallium imaging sometimes help to distinguish between these two possibilities. However, all of these modalities have limited sensitivity and specificity, and sometimes the pathology reveals both treatment-related necrosis and foci of active tumor. Patients with pathology-confirmed radiation necrosis are often treated with steroids. More recently, bevacizumab, a monoclonal antibody targeted against the VEGF, has been utilized to treat radiation necrosis⁽⁷⁷⁾.

Chemotherapy for recurrent disease typically produces response rates less than 10% and a 6-month PFS of 15%⁽⁴⁾. Response rates that include stable disease and complete or PRs are 40% at best, but as the 6-month PFS value indicates, these responses are not durable. It is hypothesized that the multiple mutations and alterations in GBM and the heterogeneity of the tumor cell population may partially explain the striking resistance of these tumors to therapy. Younger patients respond

best to chemotherapy, although responses to alkylating agents can be seen in patients older than 60 years of age. Long-term survivors of GBM (over 5 years) have typically had gross total resection, radiation therapy to a dose of 60 Gy, and chemotherapy, generally with temozolomide or a nitrosourea or other alkylating agent.

Salvage agents used for malignant glioma are identical to those used for recurrent AA (see Table 40-6). Rechallenge with continuous dose-intense temozolomide 50 mg/m²/d is a valuable therapeutic option as evidenced by the RESCUE study. The overall 6-month PFS for recurrent progressive GBM was 23.9%⁽⁷⁸⁾ in contrast to 15% based on a pooled analysis of eight consecutive phase II trials of cytostatic and cytotoxic agents. In this study, the greatest therapeutic benefit was observed in patients with progressive disease during the first six cycles of conventional adjuvant temozolomide therapy (150-200 mg/m² × 5 days every 28 days) or after a treatment-free interval⁽⁴⁾.

Bevacizumab has been approved by the Food and Drug Administration (FDA) for progressive disease following prior therapy, based on two trials. One study showed a 6-month PFS of 42% and overall survival of 8.7 months in patients receiving bevacizumab alone⁽⁷⁹⁾. Another study showed a response rate of 19.6% with median duration of 3.9 months. The 6-month PFS was 29%, and 6-month survival was 57%. In addition, 50% of patients experienced decreased cerebral edema, 58% were able to decrease corticosteroid dependency, and 52% had improvement in neurologic symptoms⁽⁸⁰⁾.

Bevacizumab was subsequently evaluated in phase III clinical trials for newly diagnosed GBM. Unfortunately, no effect was seen on overall patient survival. Two recent large randomized, phase III trials, AVAglio and RTOG 0825, demonstrated that the addition of bevacizumab to up-front treatment with radiation and temozolomide conferred no benefit in terms of overall survival. Progression-free survival was prolonged in both studies by approximately 3 to 4 months, reaching statistical significance in the AVAglio study but not in the RTOG 0825 study based on predefined criteria^(81,82).

Other active agents include irinotecan and carboplatin, which have been investigated as single agents in the salvage setting and in combination with bevacizumab in bevacizumab-naïve recurrent GBM⁽⁸³⁾. The optimal schedule and combination of bevacizumab with alternative drugs has not been identified. Agents targeting angiogenesis have also been studied, although the use of interferon, thalidomide, EGF-RTK antagonists, and integrin receptor antagonists is not standard. Many of these targeted therapies demonstrated only limited activity as single agents, and efforts are under way to combine them with cytotoxic therapy⁽⁸⁴⁾. Other cellular pathways being investigated with small-molecule inhibitors include the *ras* pathway with farnesyl-transferase inhibitors and the PI3Kinase pathway with

mTOR inhibitors. Other novel approaches to malignant brain tumor therapy include use of oncolytic adenovirus, vaccine and dendritic cell immunotherapy, and histone deacetylase inhibitors. An important reaction has been discovered from the interaction between anticonvulsants that induce the hepatic cytochrome P-450 3A4 enzyme and other chemotherapy agents also metabolized by this same enzyme. Pharmacokinetic studies of patients with malignant glioma on single-agent irinotecan and sirolimus found significantly lower levels of active drug in patients on enzyme-inducing anticonvulsant drugs⁽⁸⁵⁾. We recommend that patients on chemotherapy avoid the use of anticonvulsants that induce the expression of the P-450 3A4 enzyme whenever possible (Table 40-7).

Seizure Control

The management of seizures in patients with brain tumor is important to improve patient functioning and quality of life. A decline in seizure control may indicate tumor progression or worsening edema. It may also indicate a systemic infection or a drug interaction leading to decreased anticonvulsant drug effectiveness. In the case of tumor progression, a reduction in the amount of brain edema with high-potency corticosteroids (dexamethasone) may be sufficient to prevent further seizures. A second anticonvulsant is often necessary. Dexamethasone is a hepatic cytochrome P-450 3A4-inducing agent and often causes a reduction in serum levels of antiepileptic medications such as phenytoin and carbamazepine (also enzyme inducers) when the dose is increased. Similarly, patients can become symptomatic with toxic levels of anticonvulsants in the midst of a dexamethasone taper. It is important to follow serum anticonvulsant levels when using agents metabolized by the cytochrome P-450 system. Anticonvulsants that are highly protein bound

can demonstrate significant changes in levels of circulating free drug without significantly changing the total serum level. It is useful to check serum-free phenytoin or valproic acid levels when patients taking these agents have seizures or show signs of toxicity.

Despite the numerous choices of anticonvulsants, it can be difficult to control seizures. Of the newer generation of anticonvulsants, we have had success using levetiracetam and lacosamide, which are easily titrated without significant drug interactions. Phenobarbital and clonazepam can be useful in resistant cases of seizures. Short-term use of lorazepam can help bridge changes in anticonvulsant regimens.

Quality-of-Life Considerations

It is critical to provide effective supportive care to patients with brain tumors to improve their functional status and quality of life for themselves and their caregivers. This care is typically labor intensive and often beyond the means of patients and their families to provide. We involve social work and case management early in the treatment of patients. They can provide interventions that may prevent a later breakdown in care.

The incidence of depression is high among this population and should be treated early. The causes of depression are typically multifactorial and may include direct effects of the tumor, side effects of chemotherapy and radiation therapy, and side effects of steroids in addition to issues associated with a loss of independence and a diagnosis of cancer. We suggest referral to psychiatry to optimally address these issues. A related concern is the impact of fatigue and somnolence, common side effects of brain radiation. We advocate the use of psychostimulants such as methylphenidate to treat both fatigue and cognitive side effects⁽⁵⁹⁾. Although there are theoretical concerns that the use of stimulants may exacerbate seizures, we have not observed this in practice.

Patients often require high doses of steroids to manage edema and experience both acute and chronic toxicities from their administration. Acutely, the steroids may induce hyperglycemia requiring an insulin sliding scale. Patients often become agitated and irritable, suffer extreme mood swings, and even become psychotic when taking steroids. Low-dose neuroleptics can be effective in treating these side effects. Clinicians should aim to taper steroid use to the lowest doses necessary. Patients typically tolerate initial steroid weaning but often experience fatigue or worsening of neurologic function as dexamethasone doses are reduced to below 4 mg daily. This can be ameliorated with an extremely slow steroid taper and only lowering doses every 1 to 2 weeks by decrements of 1 mg or even 0.5 mg. Psychostimulants can help treat the inevitable fatigue experienced with the steroid taper. There is no effective treatment for

steroid myopathy other than tapering off steroids and initiating physical therapy and rehabilitation as early as possible.

Meningioma

Meningiomas comprise 32% of primary brain tumors, with a rate of 5.35 per 100,000 person-years. The incidence of meningioma increases with age; the median age at diagnosis is 64 years⁽⁹⁾. The tumor is often discovered incidentally without any symptoms. Clinically, these tumors typically present with headache, cognitive or personality changes, persistent focal neurologic deficits, and sometimes seizure. The main treatment is surgical resection, with the goal of complete resection when possible, accounting for relative risks and benefits depending on the patient's age and condition⁽⁸⁶⁾. Options for residual tumor include observation and radiation therapy, which can incorporate stereotactic delivery to minimize effects to local tissue⁽⁸⁷⁾.

Chemotherapy for meningioma has been used for patients who have progressive disease after resection and RT; it is sometimes used adjuvantly following RT when pathology indicates malignant meningioma. Response rates have been disappointing in small case series. Agents that have been used include hydroxyurea⁽⁸⁸⁾, IFN- α ⁽⁸⁹⁾, and liposomal doxorubicin⁽⁹⁰⁾. Results using temozolomide have been discouraging, with no responders⁽⁹¹⁾. As there are no established treatments after surgery and radiation have been exhausted and response to chemotherapy has been disappointing, the use of molecularly targeted therapy is being explored in aggressive meningioma. Frequently, EGF, PDGF, and VEGF receptors are overexpressed in meningiomas. Clinical trials using small-molecule signal transduction inhibitors such as erlotinib, gefitinib, and imatinib are being explored but have not yet shown significant efficacy^(92, 93). In a recent phase II trial, sunitinib, a small-molecule tyrosine kinase inhibitor that targets VEGF and PDGF receptors, was found to have activity in patients with recurrent atypical/malignant meningiomas and warrants investigation in a randomized trial⁽⁹⁴⁾. A novel genomic-driven clinical trial currently in development will examine the efficacy of SMO and AKT inhibitors in patients with surgery-confirmed mutations in these oncogenes.

Primary Central Nervous System Lymphoma

In contrast to most other brain tumors, chemotherapy is the initial treatment of choice for CNS lymphoma. Efforts at surgical resection have largely been discouraged as PCNSL has a tendency to involve deep brain structures and a multifocal pattern of growth. The traditional view has been that gross total resection

conferred no survival benefit over biopsy, but this view has been challenged recently. In a phase III trial of 526 patients, PFS was found to be significantly shorter in patients who were biopsied compared to patients who had undergone subtotal or gross total resections, with no difference in outcome attributable to KPS or age, suggesting that surgical resection could be considered for patients with single lesions for which resection is deemed safe⁽⁹⁵⁾.

Methotrexate-based, multiagent chemotherapy has been viewed as the treatment of choice in PCNSL. The incorporation of high-dose methotrexate (greater than 1 g/m²) has resulted in a significantly greater response and improved survival compared with previous regimens using a CHOP regimen prior to whole-brain radiation therapy (WBRT). A report by DeAngelis, incorporating methotrexate (1 g/m²), followed by whole-brain irradiation and two cycles of high-dose cytarabine (ara-C) (3 g/m²), demonstrated a median survival of 42.5 months⁽⁹⁶⁾. This strategy is the basis for current CNS lymphoma protocols that have increased the dose of methotrexate and incorporated agents that more easily cross the BBB, such as procarbazine. A follow-up clinical trial incorporating methotrexate at 3.5 g/m² with procarbazine and vincristine, followed by whole-brain irradiation and cytarabine demonstrated a median survival of 60 months⁽⁹⁷⁾. The improvement in patient survival has also brought to attention significant rates of cognitive decline and radiation-induced dementia, especially in patients older than 60 years⁽⁹⁸⁾.

Current approaches to therapy of CNS lymphoma are investigating whether radiation therapy can be avoided or delayed to reduce cognitive decline and dementia without adversely affecting survival. Preliminary results from a trial using single-agent methotrexate at 8 g/m² every 2 weeks demonstrated a PFS of 12.8 months. Median survival had not been reached at more than 22.8 months⁽⁹⁹⁾. Many clinicians at our center are cautiously delaying radiation therapy until relapse and continuing to use high-dose-based methotrexate regimens. In hoping to improve the results of single-agent methotrexate⁽⁹⁹⁾, some regimens continue to incorporate procarbazine. Other agents that may be active in this setting include temozolomide and rituximab.

Patients with recurrent disease may respond again to methotrexate. Other regimens used include PCV⁽¹⁰⁰⁾, high-dose cytarabine⁽¹⁰¹⁾, temozolomide⁽¹⁰²⁾, rituximab⁽¹⁰³⁾, and the combination of temozolomide and rituximab⁽¹⁰⁴⁾. High-dose chemotherapy with autologous stem cell rescue may also be effective⁽¹⁰⁵⁾.

Brain Metastasis

The treatment of brain metastasis involves optimal interactions between oncology, neurosurgery, and radiation therapy. Depending on the setting of relapse, patient survival may depend more on local tumor

control in the brain or on systemic control for progressive metastasis. Advances in local brain tumor control with surgery and radiosurgery will not improve patient survival if the patient ultimately succumbs to progressive systemic disease or continues to develop new brain metastases. The median survival of patients with brain metastases is 3 to 6 months⁽¹⁰⁶⁾.

The options for therapy include surgical resection, WBRT, stereotactic radiosurgery (SRS), and systemic chemotherapy. Surgical resection is the treatment option considered primarily in patients with single large tumors. Resection of brain metastases has emerged as a standard treatment option for patients with surgically accessible single lesions, good performance status, and controlled or absent extracranial disease. The advantages of surgical resection is that the mass effect can be immediately ameliorated and removal of the tumor decreases edema. Surgical resection also provides pathologic confirmation of the diagnosis. Stereotactic radiosurgery utilizes multiple convergent beams to deliver a single high dose of radiation to a discrete target volume and is usually reserved for lesions whose maximum diameter is 3 cm or less. The ability to treat locations that were otherwise considered surgically inaccessible is a distinct advantage of SRS. Whole-brain radiation therapy via 30 to 40 Gy (in daily fractions of 2 to 3 Gy) is the standard therapy for brain metastasis, with an established body of literature supporting its use for multiple metastases. This therapy has the ability to eradicate micrometastatic disease to delay recurrence^(106, 107) and is often used in conjunction with surgical resection or radiosurgery. It is well tolerated and can be effective for radiosensitive tumors such as metastases from small cell lung cancer or germ cell tumors. The greatest concern about WBRT has been the risk of neurocognitive effects, which can range from mild impairment to dementia. Hippocampal-sparing WBRT has been under active investigation in a large multicenter clinical trial (clinicaltrials.gov, identifier NCT01227954) as a technique to reduce neurotoxicity. Overall, the neurocognitive impact of WBRT in patients with brain metastases has not been well studied, and future research efforts will focus on the identification of risk factors predicting vulnerability. Neurocognitive end points should also be integrated into clinical trial designs.

We frequently treat patients at our institution with surgery if the lesions are greater than 3 cm and the patients are symptomatic. If the patient's medical condition makes a surgical procedure risky, the patient may receive WBRT. Patients who have lesions smaller than 3 cm can receive radiosurgery if they are asymptomatic or if the lesion is in a deep region not amenable to resection. However, patients with symptoms resulting from the lesions more frequently receive surgery to remove mass effect as long as their medical condition

permits. There is also debate over the role of whole-brain irradiation following surgery or radiosurgery to single lesions.

Chemotherapy for Brain Metastasis

Several small clinical trials and case reports support the concept that systemic chemotherapy demonstrates activity in treating brain metastases. Chemosensitive tumor types include breast cancer, small cell lung cancer, and germ cell tumors. The primary consideration in choosing a given regimen of chemotherapy is to use agents with known activity in a given tumor type. In many trials, response rates of brain metastases have been comparable to response rates of systemic disease. Patients who have had prior chemotherapy usually respond at lower rates.

Most clinical trials of investigational agents for solid tumors explicitly exclude patients with brain metastases. Compounding this omission is their common inclusion in studies of a heterogeneous group of patients with mixed tumor types and differing prior exposures to chemotherapy. Patients might also be expected to be more resistant to treatment with chemotherapeutic agents if they had failed RT. If chemotherapy is given during and after RT, it may be difficult to separate the efficacy due to RT versus chemotherapy. These factors make it difficult to compare treatment regimens and interpret studies⁽¹⁰⁸⁾.

Newer drugs targeting specific extracellular receptors or blocking intracellular signal transduction systems are under investigation. Owing to their specificity, they often lack the side effects commonly associated with standard cytotoxic chemotherapy. If the therapeutic target is crucial for the cancer cell's continued viability, the drug can be especially effective. The identification of *BRAF* mutations in 50% to 60% of advanced melanomas resulted in the development of potent and selective inhibitors. Vemurafenib and dabrafenib are FDA approved for the treatment of advanced melanoma and have transformed melanoma therapy, with high response rates seen in patients even with advanced, symptomatic, metastatic disease⁽¹⁰⁹⁾.

Immune checkpoint blockade is emerging as a highly effective immunotherapeutic strategy in metastatic melanoma and other solid tumors. Ipilimumab, a human immunoglobulin (Ig) G1 monoclonal antibody to cytotoxic T-lymphocyte antigen 4 (CTLA-4), has been demonstrated to result in a durable response and improved overall survival when compared to non-ipilimumab-containing treatment arms in randomized trials⁽¹¹⁰⁾. Ipilimumab has also been shown to be efficacious in the treatment of patients with melanoma with brain metastases, as evidenced by the measurable tumor reduction seen with ipilimumab used as monotherapy⁽¹¹¹⁾.

The use of chemotherapy for brain metastases is faced with great challenges. The most important imperative is to discover new agents that can overcome tumor

resistance to standard chemotherapy, whether through selection by prior pretreatment or inherent chemoresistance of tumor cell clones that metastasize from a primary site. Because most patients with brain metastases succumb to progressive systemic disease, improvement of local brain control will likely have a limited effect on survival. Conversely, the development of agents that are effective in establishing durable tumor control, both systemically and in the brain, will improve survival, as in the unique case of germ cell tumors.

Clinical variables associated with survival in the setting of brain metastases have been studied. The most well-known prognostic scoring system is the recursive partitioning analysis classification developed from 1,200 patients who received WBRT in the RTOG

database. Patients were categorized into one of three classes based on age, KPS, status of primary tumor, and extent of extracranial disease⁽¹⁰⁶⁾. Recently, the Graded Prognostic Assessment scale was developed based on the analysis of 1,960 patients in the RTOG database; it also incorporates the number of metastatic lesions in the scoring system⁽¹¹²⁾. These prognostic scoring systems may help identify patients who might benefit from chemotherapy and help design clinical trials that account for specific tumor histology and prior exposure to chemotherapy. Improvement in patient survival will result from improved local control of CNS disease if the primary disease site remains dormant, illustrating the need for a multimodality approach to the treatment of the patient with brain metastases.

Commentary: The Role of Radiation Therapy for Brain Tumors

Radiation therapy is used to enhance local control and overall survival as a sole modality or in combination with surgery or chemotherapy for many benign and malignant CNS tumors.

Radiotherapy is prescribed in the unit of Gray, which measures the energy absorbed in a material (J/kg). Typically, radiation treatments are fractionated as 1.8 to 2 Gy per day. The prescribed dose of radiation depends on the inherent radiosensitivity of the lesion and the risk to the normal tissues that are in or close to the RT volumes. For example, CNS leukemia is treated with 18 to 24 Gy in 10 to 12 fractions, whereas, GBM requires 60 Gy delivered in 30 fractions. The risk of cataract formation increases after a total dose of only 2 Gy, but brain necrosis typically will not occur below a dose of 60 Gy.

A variety of different RT techniques and modalities are available for the treatment of CNS tumors. All current treatment techniques—three-dimensional conformal radiotherapy (3DCRT), intensity-modulated radiotherapy (IMRT), SRS, proton therapy, and intensity-modulated proton therapy (IMPT)—use three-dimensional algorithms that calculate dose distributions in all planes and display dose in the axial, coronal, and sagittal views. The tumor and normal tissues are delineated using the planning CT scan and other imaging modalities, such as MRI or PET, that may facilitate this process. The tumor delineation involves determination of the gross tumor volume (GTV), which represents the macroscopic visible tumor; the clinical target volume, which is GTV with a margin that incorporates areas of possible microscopic extension; and planning target volume, which gives an additional margin for day-to-day setup differences.

The basic form of three-dimensional planning is 3DCRT. These plans use conformal fields from different angles optimized to the individual patient's needs. Any RT modality, that is, photons, electrons, or protons, can be used for 3DCRT.

Stereotactic radiosurgery and fractionated stereotactic radiotherapy (FSRT) are techniques that use stereotactic positioning by using an external fiducial system to immobilize and position patients allowing submillimeter precision for RT treatments. A large single fraction of radiation is given with SRS, whereas FSRT uses multiple fractions of repeated doses of radiation with a noninvasive stereotactic frame. Stereotactic radiosurgery is typically used for noninfiltrating tumors that are less than 3 cm and away from critical structures such as the optic chiasm. Fractionated stereotactic radiotherapy may be used for a tumor that is close to a critical structure where the highest precision for delivery is required.

Intensity-modulated radiotherapy is typically used with photon beams with a few centers now using it with proton beams (IMPT). Intensity modulation can also be implemented with the stereotactic approach, which may allow an increase in precision of delivery and conformality. The IMRT plans use multiple beams optimized for the tumor location and patient. For each beam, the multileaf collimation varies during the dose delivery to modulate the dose from that beam to “paint” a dose to allow improved conformality and reduction in normal tissue doses.

Proton RT is a modality that is becoming more available worldwide and allows treatment of larger, deeper tumors without an exit dose, thereby reducing the volume of normal tissue receiving low-to-moderate doses, which could result in a reduction in acute and late toxicities. Proton RT may be a useful technology in young patients with curable tumors.

The results of RT vary according to the type of tumor being treated. Benign tumors such as meningiomas or acoustic schwannomas have control rates as high as 90%; malignant tumors such as GBM have lower durable control rates.

Commentary: Surgical Management of Primary Brain Tumors

The primary goal in the surgical management of primary brain tumors, like gliomas, is maximum safe resection. The decision to resect or not to resect should be made after close collaboration between the neurosurgeons, neuro-oncologists, and radiation oncologists. The surgeon must consider a number of critical factors prior to making the decision to operate: age, neurologic status, location and size of the tumor, number and extent of recurrences, and whether the patient would be suitable for adjuvant treatments, including radiation and chemotherapy. In both low-grade gliomas and high-grade gliomas, compared with patients having lesser degrees of resection, those undergoing gross total resections have a better neurologic outcome on long-term follow-up without added perioperative morbidity or mortality. Recent surgical series in low-grade gliomas have shown maximum safe resection if the tumor is an independent predictor of both PFS and OS. Lacroix et al described 416 consecutive patients with GBM and demonstrated that radical resection of the main tumor mass ($\geq 98\%$ by volumetric analysis) was an independent variable that significantly prolonged survival (73). The median survival for these patients was 13.4 months compared with 8.8 months for patients who had lesser resections ($P < .0001$). The study relied on a prospective computerized measurement of the volume of tumors, with the extent of resection expressed as a percentage of the preoperative volume. A 90% resection did not result in a statistically significant survival prolongation; the greatest benefit was noted when the extent of resection was 98% or greater. These data are particularly important because of their precision of volumetric assessments and their avoidance of subjective terms such as "gross total" or "subtotal" to describe the degree of resection.

Beyond extending survival, several other benefits can result from more radical resections of gliomas in our experience. These include: (1) a diagnostic advantage in terms of better sampling of tumors and better tissue quality acquired for IHC and molecular diagnosis; (2) a symptomatic advantage through relief of mass effect, leading to improved performance status and enhanced tolerance to RT; (3) an oncologic advantage by reducing the number of neoplastic cells by almost two logs; and (4) a research advantage by harvesting ample tissue material for molecular analysis and fingerprinting, with the eventual identification of novel and specific molecular targets that will form the basis of future therapies.

Several technological adjuncts to surgery are available to aid in localizing the brain mass, in identifying zones of brain function, and in aiding the surgeon to maintain proper orientation in reference to the mass

and to its surrounding anatomic structures. Of these, intraoperative ultrasound is an inexpensive, readily accessible surgical tool that allows localization of the mass in real time and aids in the assessment of the completeness of tumor resection. Most gliomas and metastases are hyperechoic with respect to normal brain and thus can be localized easily with the ultrasound probe. It is almost inconceivable to perform such procedures without intraoperative ultrasound.

Frameless stereotactic systems have provided significant assistance on many levels, including adequate placement and sizing of the bone flap, identification of the surface margins, and localization of the mass and the navigational direction for the dissection around or into the mass. The obvious drawback of these systems is their inability to provide a true assessment of residual tumor because of brain shifts that occur necessarily during surgery. Experience with these systems and correlation of the image-derived data with the ultrasound data and with what is visible in the operative field are necessary for the safe use of these techniques in obtaining maximum tumor resection. Recently, intraoperative MRI has been introduced in a few centers, including ours. This technique identifies residual tumor more accurately than other methods. Its main drawback is that it is expensive to install and can prolong operation times. Early systems had low field magnetic strength and as such were less sensitive and provided more indistinct images than the current generation of high-field (1.5-T and higher) magnets.

Neurophysiologic techniques are employed primarily when the tumor is in or adjacent to eloquent brain (those parts of the brain that control language, motor, or sensory function). The most commonly used techniques for cortical mapping include somatosensory evoked potentials, continuous motor evoked potentials, and direct cortical and subcortical stimulation. For motor and sensory localization, the patient is usually (although not invariably) under general anesthesia; for speech localization, however, an awake craniotomy is necessary. The introduction of these techniques has made it possible to perform larger resections with an increased margin of safety in both high- and low-grade gliomas.

Existing data concerning the benefits of surgical resection suggest a survival advantage in patients with gliomas who undergo complete tumor mass resection. Careful preoperative planning should allow for the gross total resection of most gliomas. Until convincing data to the contrary, the goal of a neuro-oncologic operation should be a complete resection of the tumor mass.

INTRODUCTION

Melanoma is the most aggressive form of skin cancer. Although its incidence pales in comparison to basal cell carcinoma and squamous cell carcinoma (SCC), melanoma is the cause of approximately 75% of all skin cancer–related deaths. The majority of patients who are diagnosed with early-stage melanoma have very good outcomes with appropriate surgical management. In contrast, patients with regional and distant metastases have historically had poorer outcomes, because agents that have proven efficacious in other malignancies (eg, chemotherapy) generally have had limited activity in this disease. However, the management of melanoma is evolving rapidly due to parallel breakthroughs in the understanding and targeting of the molecular drivers of this disease and the regulators of the antitumor immune response. These advances are rapidly translating into improved outcomes in patients with advanced melanoma and the consideration of new diagnostic and therapeutic approaches across the full continuum of this disease.

EPIDEMIOLOGY AND RISK FACTORS

Melanoma is the fifth most common cancer in men and the sixth most common cancer in women in the United States ⁽¹⁾. The age-adjusted incidence for cutaneous melanoma from 2007 to 2011 was 21.3 per 100,000 per year in the United States ⁽²⁾. In contrast to the favorable trends that have been observed with almost all other major cancers, the annual incidence of

melanoma continues to rise by approximately 2% to 3% per year and has increased overall more than 500-fold since the 1950s ⁽³⁾.

A number of factors have been identified that correlate with an increased risk of being diagnosed with melanoma (Table 41-1). Many of these factors reflect the strong association between melanoma and ultraviolet radiation (UVR) exposure, which is supported by epidemiologic studies ⁽⁴⁾. More recently, whole-exome sequencing studies have demonstrated that melanomas are characterized by a higher rate of somatic mutations than almost all other solid tumors and that the majority of mutations that are identified bear the molecular signature of UVR-related DNA damage ⁽⁵⁾. Several risk assessment aids have been developed to identify high-risk individuals, including the Melanoma Risk Assessment Tool (MRAT), which is available online (<http://www.cancer.gov/melanomariskscore/>). Individuals at increased risk of developing melanoma should have awareness of the signs of melanoma and regular screening examinations.

Patients with dysplastic (atypical) nevi with irregular borders, multiple colors, and >5 mm diameter have a 3- to 20-fold higher risk of developing melanomas than the general population ⁽⁶⁾. Although the majority of melanomas are sporadic, these nevi can be inherited in a familial pattern. The familial atypical multiple mole and melanoma (FAMMM) syndrome is an autosomal dominant disorder characterized by the occurrence of melanoma in one or more first- or second-degree relatives and the presence of a high number of acquired nevi or atypical nevi. This syndrome is associated with germline mutations of the *CDKN2A* gene and is also

Table 41-1 Factors Associated With Increased Risk of Melanoma

Risk Factor	Features
Personal history of melanoma	9× increased risk of developing a second melanoma (vs general population)
Family history of melanoma	First-degree relatives have a higher risk, and 10% of all melanomas are familial (FAMMM syndrome and dysplastic nevus syndrome)
Total number of nevi	Relative risk of 5 to 17 with presence of >50 nevi
Congenital nevi	6% lifetime risk with large (>20 cm) congenital nevi
Dysplastic nevi	3- to 20-fold higher risk of developing melanoma than general population
Immunosuppression	Chronic immune suppressant use, HIV infection, and organ transplantation
MC1R variants	Associated with fair skin, red hair, and freckles
Exposure to ultraviolet light	Tanning bed use, sunburn

FAMMM, familial atypical multiple mole and melanoma.

associated with an increased risk of other cancers, especially pancreatic cancer (7). Congenital nevi can also be a precursor of melanoma, and individuals with large congenital nevi (>20 cm) have been shown to be at increased risk of developing melanoma (8).

CLASSIFICATION

Cutaneous melanomas, which are the most common manifestation of this disease, arise from melanocytes in the skin. The four major types of cutaneous melanoma are superficial spreading, nodular, lentigo maligna, and acral lentiginous melanoma. Melanomas can also arise from melanocytes in other areas, including the uveal tract of the eye (uveal melanomas) and mucosal surfaces throughout the body (mucosal melanoma). Desmoplastic melanomas represent a distinct subtype that arise from melanocytes in the skin, generally in areas with chronic sun exposure, that are characterized by highly invasive local growth that often tracks along nerves. Very rare subtypes include primary central nervous system (CNS) melanomas, which arise from melanocytes in the leptomeninges, and melanomas of soft parts (also known as clear cell sarcoma), which arise in soft tissues and dermis. Although the melanoma subtypes are not independent prognostic factors, they can be associated with distinct clinical (Table 41-2) and molecular (Table 41-3) features (9).

MOLECULAR BIOLOGY

Cutaneous melanomas are characterized by an extremely high rate of somatic mutations. The first cutaneous melanoma analyzed by whole-genome sequencing identified more than 33,000 somatic changes in the tumor (10). The majority of the somatic

changes detected in cutaneous melanomas are typical of DNA damage induced by UVR. Despite the challenges presented by this overall high background mutation rate, confirmed driver mutations are detectable in the majority of cutaneous melanomas. A number of important molecular events have also been identified in other melanoma subtypes.

RAS-RAF-MEK-ERK Pathway

The RAS-RAF-MEK-ERK pathway promotes cellular proliferation and survival, and activation of this pathway has been implicated in multiple tumor types. Genetic events that activate this pathway are detected in almost all cutaneous melanomas (11). The most common alterations detected are point mutations in the BRAF gene. BRAF encodes a serine-threonine kinase in the RAS-RAF-MEK-ERK cascade. Point mutations in BRAF are detected in approximately 45% of cutaneous melanomas, and approximately 95% of these mutations result in substitutions for valine at position 600 in the BRAF protein (12). The most common mutations result in the substitution of a glutamic acid (BRAF^{V600E}, 70%) or lysine (BRAF^{V600K}, 20%) residue. These and other substitutions at codon 600 increase the kinase activity of the BRAF protein ≥200-fold and result in constitutive activation of downstream components of the RAS-RAF-MEK-ERK pathway. The BRAF^{V600E} mutation is also frequently detected in benign nevi, supporting that this molecular event occurs very early in melanoma development (13). Consistent with this theory, BRAF mutation status is highly concordant between primary melanomas and their metastases. Mutations at other sites in BRAF (BRAF^{Non-V600}) are detected in approximately 5% of cutaneous melanomas. These mutations have variable effects on BRAF’s catalytic activity, but preclinical data supports that they still activate the RAS-RAF-MEK-ERK

Table 41-2 Melanoma Subtypes

Type	Frequency	Sites	Features
Cutaneous			
Superficial Spreading	70%	Any site (more common on the upper back in both sexes and the lower extremities in women)	Most common subtype of cutaneous melanomas
Nodular	15%-30%	Any site (common on the trunk or legs)	Presents with vertical growth phase without radial growth phase
Lentigo maligna	4%-15%	Sun-exposed area (the head and neck and arms)	
Acral lentiginous	2%-8%	The palms, soles, and beneath the nail plate	More common in African Americans and Asians
Uveal	Rare	Uveal tract of the eye (iris, ciliary body, and the choroid)	Frequent, and often exclusive, metastatic involvement of the liver
Mucosal	Rare	Mucosal surfaces (head and neck, respiratory, gastrointestinal, and genitourinary tracts)	Poor prognosis, potentially due to delayed diagnosis and the rich lymphovascular supply of the mucosa
Desmoplastic	Rare	Areas with chronic sun exposure, especially head and neck	High risk for local recurrence and growth along nerves
Primary CNS	Rare	Leptomeninges	
Melanoma of soft parts (clear cell sarcoma)	Rare	Soft tissues, dermis	Associated with fusions involving the <i>EWSR1</i> gene

CNS, central nervous system.

pathway⁽¹⁴⁾. Recently, translocations involving the *BRAF* locus have also been identified as rare events in melanoma⁽¹⁵⁾. These translocations generate fusion proteins that again appear to activate the RAS-RAF-MEK-ERK pathway.

Mutations in *NRAS* are detected in 20% of cutaneous melanomas⁽¹¹⁾. These mutations overwhelmingly occur in hotspot regions that result in substitutions at amino acid residues Q61 (approximately 80%) or G12/G13 (approximately 20%). Similar to *BRAF*^{V600E}, the mutant *NRAS* proteins potently activate the RAS-RAF-MEK-ERK

pathway, and they are also commonly detected in benign nevi. Notably, hotspot mutations in *NRAS* are essentially mutually exclusive (<1% co-occurrence) with *BRAF*^{V600E} mutations, but they co-occur relatively frequently with *BRAF*^{Non-V600} mutations⁽¹⁶⁾. Mutations in *KRAS* and *HRAS*, which are members of the RAS family of GTPases, are also detected as rare events (<2%) in melanoma. Loss-of-function mutations of *NF1*, a negative regulator of RAS, are detected in approximately 15% of cutaneous melanomas, predominantly in melanomas without *NRAS* or *BRAF*^{V600} mutations.

Table 41-3 Classification of Melanoma by Oncogenic Mutations

Melanoma Subtype	Mutations			
	<i>BRAF</i>	<i>NRAS</i>	<i>KIT</i>	<i>GNAQ/GNA11</i>
Cutaneous without CSD	50%	15%-20%	1%-2%	—
Cutaneous with CSD	5%-30%	10%-15%	2%-17%	—
Acral lentiginous	10%-15%	10%-15%	15%-20%	—
Mucosal	5%	5%-10%	15%-20%	—
Uveal	—	—	—	85%

CSD, chronic sun damage.

Additional Pathways Implicated in Cutaneous Melanomas

The PI3K-AKT pathway is a key regulator of many cellular processes, including proliferation, survival, motility, and metabolism. As studies in multiple cancer types have shown that oncogenic *RAS* mutations use this pathway in addition to RAS-RAF-MEK-ERK to transform cells, the identification of *NRAS* mutations was the first evidence supporting a role for PI3K-AKT activation in melanoma. This pathway may also be activated by loss of function of *PTEN*, which is a lipid phosphatase that normally inhibits the activation of the PI3K-AKT pathway. Loss-of-function mutations and deletions involving *PTEN* are detected in up to 30% of cutaneous melanomas (¹¹). Loss of *PTEN* appears to be largely mutually exclusive in melanomas with *NRAS* mutations, but it occurs frequently in tumors with concurrent *BRAF*^{V600} mutations. Experiments in preclinical models have shown that loss of *PTEN* cooperates with *BRAF*^{V600} mutations to promote transformation, invasiveness, and metastasis of melanocytes, providing functional support for this clinical association (¹⁷). Rare (<2% each) activating mutations in *AKT1*, *AKT3*, and *PIK3CA* have also been detected in cutaneous melanomas, again generally in tumors with *BRAF*^{V600} mutations.

Alterations in key cell cycle regulators are also pervasive in cutaneous melanomas. Germline loss-of-function mutations in the *CDKN2A* gene are the most common events detected in familial melanoma. The *CDKN2A* gene encodes two different proteins, P14^{ARF} and P16^{INK4A}. P16^{INK4A} regulates cell cycle progression by binding to cyclin-dependent kinase 4 (CDK4). Point mutations in the gene that encodes CDK4 are the most common germline event detected in familial melanoma cases without *CDKN2A* mutations. The mutations alter the site in CDK4 that P16^{INK4A} normally binds to, thereby promoting cell cycle progression (¹⁸). Somatic mutations and copy number changes in both *CDKN2A* and *CDK4* are detected commonly in cutaneous melanomas. Cyclin D1, which forms a protein complex with CDK4 or CDK6 to promote cell cycle progression, can also be amplified in this disease (¹⁹). Loss of function of P14^{ARF} inhibits the function of *TP53* via increased MDM2 activity. In addition, mutations in *TP53* are present in approximately 20% of cutaneous melanomas (¹¹).

Molecular Features of Noncutaneous Melanomas

Activating mutations in *BRAF* are relatively rare events in acral lentiginous (approximately 15%) and mucosal (approximately 5%) melanomas, and they are not

detected at all in uveal melanomas (⁹). However, several other prevalent oncogenic events have been identified in these melanoma subtypes.

KIT is a type III transmembrane receptor tyrosine kinase that activates several pro-survival signaling pathways following binding of its ligand, stem cell factor (SCF). *KIT* amplifications and mutations are frequently (20%-30%) detected in acral, mucosal, and cutaneous melanoma with chronic sun-induced damage, whereas few are detected in cutaneous melanoma without chronic sun-induced damage (<5%) (²⁰). The two most common *KIT* mutations in melanoma are *L576P* (34% of *KIT* mutations) and *K642E* (15%) in exons 11 and 13, respectively, and overall, 70% of *KIT* mutations occur in exon 11, which encodes the juxtamembrane domain (²¹). *KIT* mutations in exon 11 prevent the juxtamembrane domain's inhibitory function and induce the constitutive activation of KIT and its associated pathways.

GNAQ and *GNA11* encode regulatory subunits of G-protein-coupled receptors that are frequently mutated in uveal melanomas. Hotspot mutations affecting residues Q209 (exon 5) and R183 (exon 4) in these genes are mutually exclusive events. Combined, mutations in either *GNAQ* or *GNA11* are present in 85% of uveal melanomas (²²). The mutant *GNAQ*/11 proteins hyperactivate a number of cellular signaling pathways, including RAS-RAF-MEK-ERK and PI3K-AKT. *GNAQ* and *GNA11* mutations appear to be extremely rare (≤1%) in cutaneous melanomas, but they have been detected in both blue nevi and primary CNS melanoma.

STAGING

Once patients are diagnosed with melanoma, staging of melanoma is important for prognosis and treatment. The seventh edition of the American Joint Committee on Cancer (AJCC) staging system for cutaneous melanoma based on the primary tumor (T), regional lymph node (N), and distant metastasis (M) was published in 2009 and took effect in 2010 (Tables 41-4 and 41-5) (²³). Prognostic factors for primary tumor staging are Breslow thickness, ulceration, and (for melanomas with Breslow thickness <1 mm) mitoses (²⁴). For regional lymph nodal staging, the number of involved lymph nodes is the strongest predictor of outcome, but tumor burden (microscopic vs macroscopic) and pattern of involvement (lymph nodes, in-transit disease) are also prognostic (²⁴). In patients with distant metastasis, staging is organized into three subgroups (M1a, M1b, and M1c) reflecting the site(s) of metastasis and serum lactate dehydrogenase (LDH) levels.

Table 41-4 American Joint Committee on Cancer Staging System for Melanoma (Seventh Edition)

T Classification	Primary Tumor (Breslow) Thickness (mm)	Ulceration Status/Mitoses
Tis	NA	melanoma in situ
T1	≤1.00	a: without ulceration and mitosis <1/mm ² b: with ulceration and/or mitoses ≥1/mm ²
T2	1.01-2.00	a: without ulceration b: with ulceration
T3	2.01-4.00	a: without ulceration b: with ulceration
T4	>4.00	a: without ulceration b: with ulceration
N Classification	No. of Metastatic Nodes	Nodal Metastatic Burden
N1	1	a: micrometastasis ^a b: macrometastasis ^b
N2	2-3	a: micrometastasis ^a b: macrometastasis ^b c: in-transit met(s)/satellite(s) without metastatic lymph nodes
N3	4+ metastatic nodes, or matted lymph nodes, or in-transit met(s)/satellite(s) with metastatic node(s)	
M Classification	Distant Metastatic Site(s)	Serum Lactate Dehydrogenase (LDH) Level
M1a	Distant skin, subcutaneous, or nodal met(s)	Normal
M1b	Lung met(s)	Normal
M1c	All other visceral met(s) Any distant met(s)	Normal Elevated

LDH, lactate dehydrogenase; mets, metastases; NA, not applicable.

^aMicrometastases are diagnosed after sentinel lymph node biopsy.

^bMacrometastases are defined as clinically detectable lymph node metastases confirmed pathologically (or by finding of gross [not microscopic] extracapsular extension).

Reproduced, with permission, from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. *J Clin Oncol*. 2009;27(36):6199-6206.

SURGICAL MANAGEMENT OF EARLY-STAGE MELANOMA

For patients with primary cutaneous melanoma and clinically negative regional lymph nodes, surgery represents the mainstay of initial clinical management. It is useful to consider this approach in the context of two themes: (1) wide excision and (2) approach to the regional nodal basin. Prior to definitive surgery, it is important to identify other lesions suspicious for a second primary melanoma; evidence, if any, of regional metastasis; and signs/symptoms that may raise suspicion for distant metastatic disease. Such findings may alter treatment plans.

Recommended wide excision margins are based on primary tumor thickness (Breslow thickness), and they are measured from the melanoma biopsy site edges or residual intact disease (²⁵). Wide excision

includes subcutaneous tissue down to the level of, but generally not including, underlying muscular fascia. Recommended margins of excision are summarized in [Table 41-6](#).

The surgical approach to the regional nodal basin is guided by Breslow thickness and other tumor and host factors. The technique of lymphatic mapping and sentinel node biopsy (SNB) is based on the observation that finite regions of skin drain via afferent lymphatics to regional lymph nodes, termed sentinel nodes, and that these represent the most likely nodes to contain occult metastatic disease, if any are involved (²⁶). Overall, for patients with clinically negative regional nodes, the risk of regional lymph node metastasis ranges from <1% for patients with very thin primary tumors to approximately 50% for patients with thick, ulcerated primary tumors. Sentinel node biopsy has been widely recommended for patients with primary cutaneous melanomas ≥1 mm in tumor thickness (²⁷). In contrast, a selective approach to

^aClinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

^bPathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial (ie, sentinel node biopsy) or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes. Reproduced, with permission, from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. *J Clin Oncol*. 2009;27(36):6199-6206.

SNB is entertained for patients with thin (T1) melanomas due to the overall low risk of microscopic regional metastasis. Although indications for SNB among patients with thin melanoma continue to evolve, SNB should be considered for a patient whose primary tumor is

≥0.75 mm and/or has other high-risk features (²⁸). Preoperative lymphoscintigraphy is generally recommended to identify regional nodal basins at risk and to localize the sentinel nodes; a dual-modality approach (ie, in the United States, isosulfan blue dye and technetium-99 sulfur colloid) along with a hand-held gamma probe is used intraoperatively (^{26, 29}). Following surgery, enhanced histologic analysis is performed, generally as a combination of step sectioning and immunohistochemical analysis. In contrast to many other solid tumors, intraoperative frozen section assessment is rarely employed.

Sentinel node pathologic status is an important independent predictor of survival (^{30, 31}). Although complete lymph node dissection (CLND; also known as completion lymphadenectomy or early therapeutic lymph node dissection) has been a standard of care for patients with a positive sentinel node for over two decades, its role continues to evolve. The recently completed Multicenter Selective Lymphadenectomy Trial-I (MSLT-I) prospective, randomized, clinical trial

Table 41-6 Recommended Wide Local Excision Surgical Margins

Primary Tumor Thickness (mm)	Excision Margin (cm)
In situ	0.5–1
0–1	1
1–2	1 or 2 ^a
2–4	2
>4	2

^aA 1 cm margin is appropriate in anatomically restricted areas; otherwise a 2 cm margin is preferred.

compared wide excision and SNB (with CLND for patients with a positive SNB) to wide excision and nodal observation (followed by lymphadenectomy for patients who developed nodal recurrence). This trial confirmed the strong prognostic significance of SNB in patients with early-stage melanoma, but it did not demonstrate an overall survival (OS) benefit for the procedure. However, subset analysis among all node-positive patients did show a survival advantage to SNB-positive patients who had CLND compared to patients who had nodal observation and subsequently recurred in regional nodes⁽³¹⁾. The role of CLND for patients with at least one positive sentinel node is currently being investigated in the randomized international MSLT-II trial and the European Organization for Research and Treatment of Cancer (EORTC) registry-based MINITUB clinical trial.

MANAGEMENT OF REGIONAL DISEASE

Adjuvant Radiation

Recurrences at the primary tumor site after surgery are rare and occur in <5% of cutaneous melanomas⁽³²⁾. However, in some cases, the risk of regional recurrence may be increased and the use of adjuvant radiation may improve local disease control. Inadequate margins due to anatomic restrictions, satellitosis in the surgical specimen, or recurrence at the primary site are relative indications for adjuvant radiation at the primary tumor site. Thick (>4 mm) tumors, especially those that originate in the head and neck region, are also sometimes considered for adjuvant radiation. In particular, desmoplastic melanomas, which overall are rare but frequently (>60%) occur in the head and neck region⁽³³⁾ and tend toward neurotropic spread rather than classical lymphatic spread, have a high local failure rate (20%-50%). Retrospective reports of postoperative adjuvant radiation in desmoplastic melanoma patients have demonstrated a significant decrease in recurrence rate with postoperative adjuvant radiation versus observation alone (local recurrence, 24% vs 7%; $P = .009$)⁽³³⁾.

Retrospective analyses have also established risk factors that correlate with increased risk of nodal basin recurrence, including involvement of more than three nodes, nodal size >3 cm, presence of extracapsular extension in the lymph node(s), and recurrent disease in the nodal basin⁽³⁴⁾. The Trans-Tasman Radiation Oncology Group (TROG) and Australia and New Zealand Melanoma Trials Group (ANZMTG) completed a prospective, randomized trial of patients with high risk of nodal basin relapse⁽³⁵⁾. Two-hundred fifty patients were randomized to receive observation or adjuvant radiation consisting of 48 Gy in 20 fractions.

Adjuvant radiation treatment significantly reduced the risk of lymph node recurrence (hazard ratio [HR], 0.56; $P = .041$). However, this did not translate into an OS benefit (HR, 1.37; $P = .12$). Adjuvant radiation is not without complications. In the head and neck region there is a 10% rate of associated hearing loss, ear pain, wound dehiscence, and bone exposure⁽³⁶⁾. Outside of this area, chronic lymphedema remains an impediment with significant morbidity to afflicted patients. Patients with a body mass index defined as obese and those undergoing groin radiation are at increased risk for complications from therapy⁽³⁷⁾.

Adjuvant Interferon

Early reports of activity of interferon α -2b (IFN) in metastatic melanoma led to it being studied in the adjuvant setting following definitive surgery. The Eastern Cooperative Oncology Group (ECOG) 1684 trial randomized 287 patients to receive 1 year of treatment with IFN, a regimen known as high-dose IFN (HDI), or observation⁽³⁸⁾. Eligible patients included those with melanomas greater than 4 mm in depth without lymph node involvement (T4N0M0), melanomas of any thickness with lymph node involvement (TxN1-3M0), or regional lymph node recurrence after definitive therapy for primary melanoma. Patients in the HDI arm received induction intravenous IFN 20 million units (MU)/m²/d for 5 days per week for 4 weeks followed by maintenance subcutaneous IFN 10 MU/m²/d three times a week for 48 weeks. Treatment with HDI resulted in a statistically significant improvement in relapse-free survival (RFS) compared to observation (1.72 vs 0.98 years, $P = .0023$) as well as an improvement in median OS (3.82 vs 2.78 years, $P = .0237$). High-dose IFN is associated with significant toxicities including flu-like symptoms of fever, myalgia, and malaise; biochemical abnormalities including transaminitis, leukopenia, and thrombocytopenia; and psychological symptoms such as depression with suicidal ideation. On the basis of ECOG 1684, the US Food and Drug Administration (FDA) approved HDI as adjuvant therapy for patients with high-risk melanoma (Table 41-7). Long-term follow-up studies of the patients included in this trial confirmed the significant improvement in RFS. However, the difference in OS initially observed between the two groups was not significant with additional follow-up ($P = .18$)⁽³⁹⁾. The unclear impact of HDI on OS led to several follow-up studies investigating intermediate-dose IFN, duration of IFN treatment, and induction IFN alone. None of these studies demonstrated a significant OS benefit.

Pegylation of IFN increases the half-life of the drug in the body, diminishing the need for frequent injections compared with standard IFN. The EORTC 18991 trial was a phase III randomized controlled trial

Table 41-7 Approved Systemic Therapies for Melanoma

Agent	Year of FDA Approval	Indication
Dacarbazine	1974	Unresectable or metastatic disease
Interferon	1995	Stage IIB/IIC/III (adjuvant)
Interleukin-2	1998	Unresectable or metastatic disease
Pegylated interferon	2011	Stage III (adjuvant)
Ipilimumab	2011	Unresectable or metastatic disease
Vemurafenib	2011	Unresectable or metastatic disease with $BRAF^{V600}$ mutation
Dabrafenib	2013	Unresectable or metastatic disease with $BRAF^{V600}$ mutation
Trametinib	2013	Unresectable or metastatic disease with $BRAF^{V600}$ mutation
Dabrafenib + trametinib	2014	Unresectable or metastatic disease with $BRAF^{V600}$ mutation
Pembrolizumab	2014	Unresectable or metastatic disease after ipilimumab (and after BRAF inhibitor if $BRAF^{V600}$ mutation present) ^a
Nivolumab	2014	Unresectable or metastatic disease after ipilimumab (and after BRAF inhibitor if $BRAF^{V600}$ mutation present) ^a
Ipilimumab + nivolumab	2015	$BRAF^{V600}$ wild-type, unresectable or metastatic disease
Vemurafenib + cobimetinib	2015	Unresectable or metastatic disease with $BRAF^{V600}$ mutation

^aAdditional indications in stage IV patients under consideration.

comparing pegylated IFN (PEG-IFN) for 5 years versus observation (⁴⁰). In this trial, 1,256 patients with node-positive stage III melanoma were randomized with a primary end point of recurrence-free survival, a composite end point defined as the length of time from randomization to the first of local or regional or distant recurrence or death from any cause. Pegylated IFN did significantly improve recurrence-free survival (34.8 vs 25.6 months, $P = .01$), but it did not significantly impact time to distant relapse or OS. These results were maintained with additional follow-up (⁴¹). Subset analysis found that patients with an ulcerated primary tumor and microscopic nodal involvement appear to have the greatest benefit from PEG-IFN treatment, as they were characterized by statistically significant improvements in recurrence-free survival, distant metastasis-free survival, and OS. These findings support previous evidence that ulceration and lower nodal burden are predictive factors associated with response to IFN-based adjuvant treatments (⁴²). An important feature of EORTC 18991 was the ability to dose reduce PEG-IFN early during treatment to keep patients on study. Prolonged therapy even with dose reduction had already been shown to delay relapse (EORTC 18952), and EORTC 18991 continued this modification to maintain patients at an ECOG performance status of 0 to 1 (⁴³). After year 1, only 12% of patients discontinued due to toxicity. Adjuvant PEG-IFN was approved by the FDA in 2011 (Table 41-7).

Adjuvant Biochemotherapy

Biochemotherapy consists of cisplatin, vinblastine, and dacarbazine chemotherapy combined with

interleukin-2 and IFN biotherapy. In the metastatic setting, response rates up to 30% to 60% have been seen in treatment-naïve patients using this regimen (^{44, 45}). The S0008 trial was a cooperative intergroup randomized phase III trial comparing the efficacy of three cycles of biochemotherapy, with cycles given every 3 weeks, versus 1 year of HDI in improving RFS and OS in patients with resected stage III melanoma (⁴⁶). With a median follow-up of 7.2 years, biochemotherapy treatment resulted in a significantly prolonged RFS (median, 4.0 vs 1.9 years; $P = .029$) but not OS (median, 9.9 vs 6.7 years; $P = .55$). Biochemotherapy was associated with more grade 4 toxicity, but it was of shorter duration than that seen with HDI. The grade 3 and 4 toxicity combined rates were similar between biochemotherapy and HDI (76% vs 64%, respectively), as were discontinuation rates (15% vs 19%, respectively). Biochemotherapy may be considered based on S0008 for select patients who can tolerate higher grade toxicities for a shorter duration, at centers with experience in managing the toxicities of biochemotherapy, and in patients for whom HDI or 1 year's worth of adjuvant therapy is not appropriate.

Adjuvant Therapy for Mucosal Melanoma

Mucosal melanoma is the only subtype of melanoma with OS data supporting the use of adjuvant systemic therapy. A randomized three-arm phase II trial assigned 189 patients with surgically resected mucosal melanoma to observation versus HDI versus cisplatin 25 mg/m² on days 1 to 3 and temozolomide 200 mg/m² on days 1 to 5 every 3 weeks for six cycles (⁴⁷). Chemotherapy with

cisplatin and temozolomide showed statistically significant improvements in both RFS and OS compared to both HDI and observation. High-dose IFN resulted in improved RFS and OS versus observation as well. Fever and fatigue were more common in the HDI arm, whereas anorexia and nausea/vomiting were more common in the chemotherapy arm. Both HDI and chemotherapy are safe and effective therapies for patients with resected mucosal melanoma.

MANAGEMENT OF METASTATIC DISEASE

Chemotherapy

Dacarbazine is the only chemotherapy agent approved for the treatment of metastatic melanoma (see Table 41-7). Approved in 1975, dacarbazine achieves clinical responses in 5% to 10% of patients. The overwhelming majority of these responses are short-lived, and dacarbazine has never been proven to be superior to another agent in a phase III trial. Temozolomide is an orally available prodrug that is metabolized to the same active intermediate as dacarbazine. Temozolomide was shown to be noninferior to dacarbazine in a phase III trial⁽⁴⁸⁾. Temozolomide is able to cross the intact blood-brain barrier. However, in a large phase II trial, temozolomide achieved clinical responses in only 7% of patients with previously untreated melanoma brain metastases and in 3% of patients with previous brain-directed treatments⁽⁴⁹⁾. Fotemustine was shown to achieve a higher response rate than dacarbazine (15.2% vs 6.8%, $P = .04$), and there was a trend for improved OS (median, 7.3 vs 5.6 months; $P = .067$) in a randomized phase III trial. However, its use remains limited⁽⁵⁰⁾.

In addition to these single agents, a variety of combination chemotherapy regimens have been evaluated in melanoma⁽⁵¹⁾. Although these regimens achieve clinical responses in up to 20% to 25% of patients, none have been shown to significantly improve OS versus single-agent chemotherapy, and all are associated with increased toxicity.

Targeted Therapy

Targeted therapies are agents that inhibit the proteins and/or pathways that are activated in tumors by oncogenic events. Targeted therapies demonstrated efficacy in a number of cancers in which critical oncogenes have been identified, including chronic myelogenous leukemia (*BCR-ABL*), breast cancer (*HER2/neu*), and gastrointestinal stromal tumors (*KIT*), among others. The extremely high rate of somatic mutations suggested that such strategies might be effective in melanoma as well.

BRAF Inhibitors

As noted previously, point mutations that cause substitutions at the V600 residue of the BRAF protein (*BRAF^{V600}*) are the most common oncogenic event in cutaneous melanoma. Shortly after the identification of these mutations, several clinical trials of sorafenib were initiated in metastatic melanoma patients. Sorafenib is a small-molecule inhibitor of many kinases, including BRAF. However, sorafenib achieved clinical responses in <5% of metastatic melanoma patients as a single agent, and it failed to improve outcomes when it was combined with paclitaxel and carboplatin in a randomized phase III study^(52, 53). Analyses of smaller trials support that sorafenib failed to achieve significant inhibition of the RAS-RAF-MEK-ERK signaling pathway at clinically tolerated doses, likely explaining its lack of activity⁽⁵⁴⁾.

Although the results of sorafenib were disappointing, much more impressive activity has been observed with second-generation BRAF inhibitors. These agents are highly selective for inhibition of BRAF over other kinases, and they have greater affinity for the *BRAF^{V600}* mutant proteins than the wild-type *BRAF* protein. The first such agent to enter into clinical trials was vemurafenib (also known as PLX4032 or RO5185426). After promising early-phase trials, the BRIM-3 trial, a phase III randomized clinical trial, compared vemurafenib versus dacarbazine chemotherapy⁽⁵⁵⁾. A total of 675 metastatic patients were randomized, and all patients had a *BRAF^{V600}* mutation. This trial was halted at its first interim analysis because vemurafenib resulted in significant improvements in progression-free survival (median, 5.3 vs 1.6 months; HR, 0.26; $P < .001$) and OS (HR, 0.37; $P < .001$). The overall response rates were 48% for vemurafenib and 5% for dacarbazine; the disease control rate for vemurafenib was approximately 90%. Vemurafenib was approved for the treatment of metastatic melanoma patients with a *BRAF^{V600}* mutation in 2011 (Table 41-7).

Dabrafenib was the second mutant-selective BRAF inhibitor to enter into clinical testing. The clinical efficacy of dabrafenib appears to be similar to vemurafenib. In the BREAK-3 phase III trial, 250 metastatic melanoma patients with *BRAF^{V600}* mutations were randomized to treatment with dabrafenib or dacarbazine⁽⁵⁶⁾. The overall response rate was 50% for dabrafenib and 6% for dacarbazine, and dabrafenib treatment significantly improved progression-free survival (median, 5.1 vs 2.7 months; HR, 0.30; $P < .0001$). In this trial, dabrafenib did not achieve a statistically significant improvement in OS (HR, 0.61). However, in this trial, patients randomized to chemotherapy were allowed to cross over at the time of disease progression to treatment with dabrafenib, whereas the BRIM-3 study did not allow cross-over. Dabrafenib was approved for

the treatment of metastatic melanoma patients with a *BRAF*^{V600} mutation in 2013 (Table 41-7).

Both vemurafenib and dabrafenib are well tolerated by most patients. The most common side effects of the mutant BRAF inhibitors are rash, fever, fatigue, and arthralgias^(55, 56). Up to 25% of patients treated in early-phase clinical trials with vemurafenib, and a slightly lower percentage of patients treated with dabrafenib, developed cutaneous SCCs or keratoacanthomas, which are hyperproliferative skin lesions. Such lesions are generally removed surgically, and the BRAF inhibitors may be resumed safely without dose adjustment after appropriate treatment. Fevers, which occur in up to 30% of patients treated with dabrafenib, are generally controlled with dose interruptions and antipyretics, with treatment resumed safely after fevers resolve. For patients who develop frequent and severe fevers, dose reductions may provide relief, or the fevers can usually be controlled by concurrent treatment with steroids.

A key limitation to the use of vemurafenib and dabrafenib is their restriction to patients with a *BRAF*^{V600} mutation. A total of 10 metastatic melanoma patients without a *BRAF*^{V600} mutation were included in the phase I studies of these agents^(57, 58). None of those patients responded, and eight patients had disease progression at their initial restaging. Although it is possible that this could be simply due to the aggressive nature of this disease, preclinical testing has demonstrated that the mutant-selective BRAF inhibitors can increase the growth of cancer cells that do not have a *BRAF*^{V600} mutation⁽⁵⁹⁾. This is due to an unexpected effect of the inhibitors, known as paradoxical activation, which produces increased signaling through the RAS-RAF-MEK-ERK signaling pathway when there is no *BRAF*^{V600} mutation present. As a result, molecular testing for the *BRAF*^{V600} mutation is an absolute prerequisite for any patient in whom vemurafenib or dabrafenib is considered.

MEK Inhibitors

Although almost all metastatic melanoma patients with a *BRAF*^{V600} mutation derive some clinical benefit with BRAF inhibitor treatment, nearly all patients develop resistance. The median progression-free survival of both vemurafenib and dabrafenib is approximately 6 months, and 90% of patients develop resistance within 1 year. Analyses of both patient samples and cell lines with acquired resistance to the BRAF inhibitors have identified a number of resistance mechanisms⁽⁶⁰⁾. To date, all resistant tumors have retained the *BRAF*^{V600} mutation, and no new mutations in the coding region of the *BRAF* gene have been identified. However, both amplifications and splice variants of the *BRAF*^{V600} mutation have been identified in resistant tumors, as have

concurrent activating mutations in *NRAS* and *MEK1/2*. Each of these events reactivates signaling by MEK and downstream components of the RAS-RAF-MEK-ERK signaling pathway. These findings supported the rationale for determining the safety and efficacy of MEK inhibitors in *BRAF*^{V600} mutant melanomas.

Trametinib is a selective and potent inhibitor of MEK1 and MEK2. The safety and efficacy of trametinib were compared to chemotherapy (dacarbazine or paclitaxel) in 322 metastatic melanoma patients with *BRAF*^{V600} mutations in a phase III trial⁽⁶¹⁾. Trametinib resulted in improved overall response rate (22% vs 8%), progression-free survival (median, 4.8 vs 1.5 months; HR, 0.45; *P* < .001), and OS (HR, 0.54; *P* = .01). Trametinib is well tolerated, with side effects including rash, diarrhea, edema, and fatigue. Ocular events are a relatively rare but clinically important side effect of trametinib, including blurred vision, retinal pigment epithelium detachment, and retinal vein occlusion. Trametinib can also cause reversible cardiomyopathy. Single-agent trametinib was approved for the treatment of metastatic melanoma patients with a *BRAF*^{V600} mutation in 2013 (Table 41-7). Notably, trametinib was approved for patients who had not previously been treated with a selective BRAF inhibitor, because it fails to achieve clinical benefit in pretreated patients⁽⁶²⁾. Although no head-to-head clinical trials have compared single-agent trametinib to single-agent BRAF inhibitor therapy, it appears that the BRAF inhibitors have higher response rates and longer progression-free survival^(55, 61). Trametinib is an option for patients who cannot tolerate BRAF inhibitors.

Much more compelling data supports the use of MEK inhibitors in combination with BRAF inhibitors in *BRAF*^{V600} mutant melanoma patients. Phase I testing of dabrafenib and trametinib demonstrated that they could be combined safely at the maximally tolerated dose of each single agent⁽⁶³⁾. In fact, the combination had a much lower rate of cutaneous SCCs (7% vs 19%) and hyperkeratosis (9% vs 30%) than was observed with single-agent dabrafenib. This protective effect appears to be due to MEK inhibitor-induced blockade of dabrafenib's paradoxical activation of the RAS-RAF-MEK-ERK pathway in keratinocytes⁽⁶⁴⁾. The combination does have a higher rate of pyrexia (71%) than is observed with dabrafenib alone (26%). In a randomized phase II trial of 162 metastatic melanoma patients with *BRAF*^{V600} mutations who were treated with dabrafenib alone or in combination with trametinib, the combination achieved a significant improvement in progression-free survival (median, 9.4 vs 5.8 months; HR, 0.39; *P* < .001), and none of the patients treated with the combination of dabrafenib and trametinib had disease progression as their best response (76% overall response rate). Combined treatment with dabrafenib and trametinib was approved for metastatic melanoma

patients with a *BRAF*^{V600} mutation in 2014 (Table 41-7). Subsequent to this approval, phase III trials demonstrated that dabrafenib and trametinib produce significant improvements in progression-free survival versus single-agent dabrafenib and versus single-agent vemurafenib (^{65, 66}). Combined treatment with vemurafenib and cobimetinib, another MEK1/2 inhibitor, has also demonstrated superiority to single-agent vemurafenib treatment in a phase III trial (see Table 41-7) (⁶⁷). Although the clinical results with combined BRAF and MEK inhibition are impressive in patients who are BRAF inhibitor naïve, these combination regimens achieve clinical responses in only approximately 15% of patients who have already developed resistance to single-agent BRAF inhibitors (^{68, 69}).

MEK inhibitors have also been tested in selected melanoma patients without *BRAF*^{V600} mutations. Treatment with MEK162, also known as binimetinib, achieved clinical responses in 20% of metastatic melanoma patients with activating *NRAS* mutations in a phase II trial, and randomized clinical trials versus chemotherapy in this patient population are under way (⁷⁰). Preclinical studies have also identified candidate combinatorial strategies with MEK inhibitors to achieve increased efficacy in *NRAS*-mutant melanomas, a number of which are in early-phase clinical trials (⁷¹). Both preclinical studies and the clinical outcomes of a small number of patients enrolled in early-phase clinical trials also support that MEK inhibitors may be effective for patients with *BRAF* mutations that affect sites other than V600 (⁷²). Prospective clinical trials with MEK inhibitors in this population are ongoing.

KIT Inhibitors

Three different phase II clinical trials of the KIT inhibitor imatinib, which is approved for the treatment of gastrointestinal stromal tumor (GIST), in metastatic melanoma patients reported a combined clinical response rate of approximately 1% (²¹). However, these trials were performed without any molecular selection criteria, because they predated the discovery of frequent *KIT* mutations in mucosal, acral, and sun-damaged cutaneous melanomas (²⁰). Phase II studies of imatinib in metastatic melanoma patients with *KIT* mutations or amplifications have demonstrated much more promising results than were observed in unselected patients (⁷³⁻⁷⁵). The response rates reported in these trials range from 15% to 30%, with subgroup analyses demonstrating response rates of up to 50% in patients with the most common recurrent mutations detected in melanomas. Although these results are a marked improvement compared to those observed in unselected patients, the response rates are not as high as those

in GIST patients with *KIT* mutations treated with the same inhibitors. Studies are ongoing to identify the *KIT*-mutant melanoma patients who are most likely to benefit from KIT inhibitors and combinatorial strategies that are more effective.

Immunotherapy

Melanoma is a highly immunogenic tumor. In the last 20 years, immunotherapeutic approaches such as cytokine therapy, cancer vaccines, immune check-point inhibition, and adoptive T-cell transfer have been extensively studied in metastatic melanoma. In contrast to direct cytotoxic chemotherapy, immunotherapy aims to control cancer by stimulating the patient's own immune systems to attack it. Over time, it has been demonstrated that effective immunotherapies can achieve remarkably durable disease control and survival in melanoma, even in patients with very advanced disease. Such results appear to be achievable in an increasing number of patients as the key regulators of the antitumor immune response are identified, understood, and targeted.

Interleukin-2

Interleukin-2 (IL-2) is a growth factor normally secreted by CD4 helper cells that can activate effector CD8 T cells and natural killer (NK) cells. In nonrandomized studies, high-dose IL-2 (HD IL-2) therapy (600,000-720,000 IU/kg intravenously every 8 hours for up to a maximum of 14 doses per cycle for two cycles) achieved clinical responses in 16% of patients, including approximately 6% of patients who had complete responses (⁷⁶). Long-term follow-up showed that the majority of complete responders remained disease free for more than 10 years. Although it was never proven superior to another therapy in a randomized trial, HD IL-2 therapy was approved for the treatment of metastatic melanoma patients in 1998 based on this potential for durable disease control (see Table 41-7) (⁷⁷). Retrospective analyses demonstrated that higher response rates may be observed in patients with only cutaneous and/or subcutaneous metastases, whereas patients with brain metastases have very poor outcomes with this treatment (⁷⁸). High-dose IL-2 therapy is complicated by capillary leak syndrome that can cause hypotension, pulmonary edema, and renal failure; hepatic, gastrointestinal, endocrine, and cutaneous toxicities; arrhythmias; and psychiatric disturbances. Although these toxicities generally resolve quickly (within days) after stopping HD IL-2 therapy, the treatment-related mortality for HD IL-2 is 1% to 2%. Thus, safe administration requires adequate prescreening of patients to ensure adequate cardiac and pulmonary function,

as well as significant training and experience of the health care team.

Combinations of IL-2 with other therapeutic agents have been investigated. A randomized multicenter phase III trial of HD IL-2 with or without gp100 cancer vaccine in 185 metastatic melanoma patients demonstrated that the addition of gp100 significantly improved overall response rate (16% vs 6%) and progression-free survival (median, 2.2 vs 1.6 months, $P = .008$)⁽⁷⁹⁾. Patient treated with combination therapy also had a trend for improved OS, but this did not reach statistical significance (17.8 vs 11.1 months, $P = .06$).

Ipilimumab (Anti-Cytotoxic T Lymphocyte-Associated Antigen 4 Antibody)

Cytotoxic T lymphocyte-associated antigen 4 (CTLA4) is an inhibitory immune checkpoint molecule that is expressed on the surface of activated T cells and regulatory T cells. Ipilimumab is a fully human immunoglobulin (Ig) G1 anti-CTLA4 monoclonal antibody that binds to the T cells and enhances antitumor immunity. Two randomized phase III studies have demonstrated that ipilimumab improves OS in metastatic melanoma patients. In the first phase III study, previously treated patients with advanced melanoma were randomized to receive gp100 vaccine, ipilimumab, or ipilimumab with gp100 vaccine⁽⁸⁰⁾. Ipilimumab was given at 3 mg/kg every 3 weeks for a total of four treatments. The response rate was only 10.9% for ipilimumab and only 5.7% for ipilimumab with gp100. However, both regimens resulted in improved progression-free survival and OS compared to gp100 vaccine alone. Patient had a median survival of 10.0 months with single-agent ipilimumab (HR, 0.68; $P < .001$ vs gp100) and 10.1 months with ipilimumab plus gp100 (HR, 0.66; $P = .003$), in comparison to 6.4 months with gp100. Because treatment with ipilimumab alone demonstrated greater progression-free survival (HR, 0.64 vs gp100) than treatment with ipilimumab with gp100 (HR, 0.81), there was concern that gp100 could be having a detrimental effect on patient outcomes, as had been observed previously in other vaccine trials in melanoma⁽⁵¹⁾. A subsequent phase III trial randomized 502 treatment-naïve metastatic melanoma patients to treatment with dacarbazine alone or in combination with ipilimumab⁽⁸¹⁾. Ipilimumab was dosed at 10 mg/kg for four doses followed by maintenance therapy every 12 weeks. Both OS (median, 11.2 vs 9.1 months; HR, 0.72; $P < .001$) and progression-free survival (HR, 0.76; $P = .006$) were significantly improved in the patients who received ipilimumab. The overall response rate was 15.2% with ipilimumab plus dacarbazine and 10.3% with dacarbazine alone. Ipilimumab (3 mg/kg every 3 weeks for four doses) was subsequently approved for the treatment of metastatic melanoma patients in

2011 (see Table 41-7). Recently, long-term follow-up of almost 5,000 patients treated on clinical trials with ipilimumab demonstrated that the 3-year OS rate was 22% for all patients in the cohort (26% for treatment-naïve patients and 20% for previously treated patients), with Kaplan-Meier analysis suggesting that very few patients died from melanoma after this time point⁽⁸²⁾.

As noted earlier, the clinical response rate of ipilimumab is modest. In addition, the clinical responses seen with ipilimumab are often significantly delayed and can even develop after an initial increase in tumor size. In recognition of this potential for delayed but significant clinical benefit, immune-related response criteria (irRC) were developed to assess clinical responses in patients treated with immunotherapy⁽⁸³⁾. In irRC, new lesions do not necessarily define progression, and progressive disease must be confirmed in two consecutive observations at least 4 weeks apart. In addition to the potential for delayed responses, it also appears that re-initiation of ipilimumab can benefit some patients who experience disease progression after this therapy. In a study of 31 patients with initial clinical response or stable disease for at least 3 months with initial ipilimumab treatment that subsequently progressed, investigators demonstrated that re-induction of ipilimumab (3 mg/kg for four doses) led to clinical responses in up to 38% of patients and disease control in up to 75%⁽⁸⁴⁾. Thus, re-induction of ipilimumab is a reasonable therapeutic option for patients with disease progression who had disease control lasting at least 3 months from previous ipilimumab treatment. Ipilimumab can also provide clinical benefit in appropriately selected patients with brain metastases. A phase II trial in 72 patients with active brain metastases demonstrated that ipilimumab achieved disease control in up to 24% of patients with small, asymptomatic brain tumors that did not require steroids⁽⁸⁵⁾. However, disease control was only achieved in 5% of patients with tumors that required steroids to control symptoms and/or cerebral edema.

Immune-related adverse effects (irAEs) are frequently seen with ipilimumab. These effects include hypophysitis, rash, colitis, and hepatitis. Approximately 60% of patients treated with ipilimumab have irAEs, including up to 20% with grade 3 or 4 toxicities. Because high-grade irAEs can be life threatening, particularly autoimmune colitis leading to bowel perforation, early recognition of irAEs is critical to the safe administration of ipilimumab. Treatment of irAEs includes symptomatic and supportive care, as well as high-dose systemic steroids (1-2 mg/kg/d of prednisone or equivalent) depending on the severity of irAEs. Ipilimumab retreatment can be considered in patients with grade 1 or 2 irAEs once symptoms resolve. However, any grade 3 or 4 irAEs other than grade 3 skin toxicity are contraindications to further

ipilimumab treatment. Interestingly, systemic steroid use to control severe irAEs does not appear to affect tumor response to ipilimumab⁽⁸⁶⁾.

Anti–Programmed Death 1 Protein Antibodies

The programmed death 1 protein (PD-1) is another important immune checkpoint receptor expressed on the surface of activated T cells. PD-1 has two known ligands, PD-L1 (B7-H1) and PD-L2 (B7-DC); PD-L1 is broadly expressed on immune and nonhematopoietic cells including tumor cells, and the expression on tumor cells can be upregulated by IFN, which is predominantly produced by T cells. The ligation of PD-1 and PD-L1 inhibits T-cell proliferation and activation and induces apoptosis of antigen-specific T cells to prevent collateral tissue damage and autoimmune disease. The PD-1/PD-L1 pathway is hijacked by tumor cells to suppress antitumor immunity. Therefore, blocking the interaction of PD-1 and PD-L1 has been studied as a therapeutic approach for cancers.

Pembrolizumab

Pembrolizumab, a humanized anti-PD-1 IgG4 monoclonal antibody, was approved by the FDA in 2014 for metastatic melanoma patients with disease progression following ipilimumab (and BRAF inhibitor therapy if *BRAF*^{V600} mutation positive) (see Table 41-7). In a phase I study, 135 patients with advanced melanoma received pembrolizumab at a dose of 10 mg/kg every 2 or 3 weeks or 2 mg/kg every 3 weeks⁽⁸⁷⁾. The objective response rate was 38% across all dose cohorts, with the highest confirmed response of 52% in the 10 mg/kg every 2 weeks cohort, regardless of previous ipilimumab treatment. In patients with ipilimumab-refractory advanced melanoma, pembrolizumab has demonstrated a 26% clinical response rate⁽⁸⁸⁾. Notably, most clinical responses to pembrolizumab were ongoing at the time of those reports, and the median OS had yet to be reached. More recently, a randomized clinical phase III clinical trial demonstrated that pembrolizumab (2 mg/kg dosed either every 2 or 3 weeks for up to 2 years) achieved significant improvements in response rate (33% for both dosing regimens vs 12%, $P < .001$), progression-free survival (HR, 0.58; $P < .001$ for both dosing regimens), and OS (HR, 0.63; $P < .0005$ for every-2-week dosing; HR, 0.69; $P = .0036$) versus treatment with ipilimumab (3 mg/kg every 3 weeks for four cycles)⁽⁸⁹⁾.

In contrast to ipilimumab, less than 5% of patients treated with pembrolizumab experienced grade 3 or 4 irAEs, and only approximately 10% experience grade 3 or 4 toxicity of any kind⁽⁸⁹⁾. Fatigue (~20%), rash (~15%), pruritus (~15%), diarrhea (~15%), and hypothyroidism (~10%) are the most frequent toxicities observed, and they are generally not severe. While rare

with ipilimumab, treatment-related pneumonitis has been reported in 1% to 4% of the patients treated with pembrolizumab, usually grade 1 or 2.

Nivolumab

Nivolumab is another human anti-PD-1 IgG4 monoclonal antibody. In a phase I study, 296 previously treated patients with advanced solid cancers received nivolumab at a dose of 0.1 to 10 mg/kg every 2 weeks for up to 2 years⁽⁹⁰⁾. Objective responses were observed in 28% of 96 evaluable melanoma patients, and the responses were durable, lasting at least 1 year in 13 of 18 patients treated for 1 year or more. The most common adverse events were fatigue, decreased appetite, diarrhea, nausea, rash, and pruritus. Grade 3 or 4 drug-related adverse events occurred in 14% of patients. Pneumonitis developed in nine patients (3%) and was the cause of drug-related death in three patients (1%). Nivolumab was approved in 2014 for the treatment of metastatic melanoma patients previously treated with ipilimumab (and a BRAF inhibitor for patients with a *BRAF*^{V600} mutation) (see Table 41-7). Nivolumab has also been shown to be more effective than chemotherapy in treatment-naïve patients. In a randomized phase III study of 418 previously untreated metastatic melanoma patients, the 1-year OS rate was 72.9% with nivolumab and 42.1% with dacarbazine (HR, 0.42; $P < .001$)⁽⁹¹⁾. The response rates with nivolumab and dacarbazine were 40% and 14%, respectively, and the median progression-free survival times were 5.1 and 2.2 months, respectively (HR, 0.43; $P < .001$). Grade 3 or 4 treatment-related adverse events were also less common with nivolumab (11.7%) than with dacarbazine (17.6%).

Preclinical studies demonstrated that combined blockade of both CTLA4 and PD-1 was more effective than either alone⁽⁹²⁾. This strategy is now being evaluated in patients. A phase I study of concurrent ipilimumab and nivolumab found that the maximum-tolerated dose of the concurrent administration of both agents was 3 mg/kg of ipilimumab and 1 mg/kg of nivolumab⁽⁹³⁾. In the phase I trial, the overall response rate was 40%. Impressively, most of the responding patients experienced >80% tumor regression, and the median OS in the trial was 39.7 months. Although the regimen was very active, 53% of patients developed grade 3 or 4 adverse events, and 21% of patients discontinued therapy due to treatment-related toxicities. A subsequent phase III clinical trial comparing outcomes with ipilimumab (3 mg/kg every 3 weeks for four doses) with or without nivolumab (1 mg/kg every 3 weeks for four doses, then 3 mg/kg every 2 weeks for up to 2 years) showed that the combination resulted in higher response rates (61% vs 11%, $P < .001$), with 22% of patients achieving complete responses, and improved progression-free survival (HR, 0.40; $P < .001$)⁽⁹⁴⁾. The combination was

more toxic, with 54% of patients experiencing grade 3 or 4 toxicities (24% with single-agent ipilimumab). A randomized, three-arm, phase III study comparing single-agent nivolumab, single-agent ipilimumab, and concurrent nivolumab with ipilimumab showed similar outcomes with the combination therapy, with statistically superior outcomes to treatment with ipilimumab. Concurrent treatment with ipilimumab and nivolumab for *BRAF*^{V600} wild-type, unresectable or metastatic melanoma was approved by the FDA in 2015 (^{94a}).

Tumor-Infiltrating Lymphocytes

Adoptive cell transfer with autologous ex vivo–expanded tumor-infiltrating lymphocytes (TILs) is a promising therapy that builds on the initial development of HD IL-2. Tumor-infiltrating lymphocytes, which are isolated from a surgically resected tumor, are expanded with IL-2 ex vivo. If a sufficient number of TILs are generated in this process, then the patient is eligible to be infused with these TIL cells as therapy. Prior to this infusion, patients undergo lymphodepletion, and then after the TIL infusion, patients receive HD IL-2. There are a number of potential benefits of the lymphodepletion, including the reduction or elimination of immune suppressive lymphocytes (ie, regulatory T cells), increased availability of homeostatic cytokines such as IL-7 and IL-15 that promote the expansion and activation of TILs (^{95, 96}), and stimulation of toll-like receptor signaling (⁹⁷). In addition, the cytoreductive nature of lymphodepletion also results in the TILs having no competition for the IL-2 that is administered. In sum, these features promote the likelihood that the IL-2 treatment will support the growth and activity of T cells that can recognize and attack melanoma metastases. Preclinical and clinical studies support that more aggressive lymphodepletion regimens may result in improved outcomes with TIL treatment (^{96, 98}). For example, a retrospective analysis of TIL trials reported that patients who received 12 Gy or 2 Gy of total-body irradiation with lymphodepleting chemotherapy prior to TIL infusion had higher clinical response rates than patients who received lymphodepleting chemotherapy alone (72% vs 52% vs 49%) (⁹⁹). However, to date, no randomized trial has compared the safety and benefits of different conditioning regimens.

Overall, the clinical response rate of adoptive cell transfer with lymphodepletion and IL-2 is 40% to 50%. Many of these responses are durable, and 5-year OS rates are approximately 30% (⁹⁹). However, adoptive cell transfer is only available for patients who are capable of tolerating the significant toxicities caused by lymphodepletion and HD IL-2. In addition, a significant proportion of patients (30% to 40%) fail to have sufficient TIL expansion from their tumor harvests to allow treatment, and it is currently unknown if successful TIL growth portends a better disease biology

and/or improved outcomes with other therapies as well. In addition to planning randomized trials, multiple efforts are under way using genetically modified TILs, including with recombinant T-cell receptors that recognize tumor antigens or expressing chimeric antigen receptors fused to costimulatory molecules. Trials are also under way and planned to test the safety and efficacy of combining TIL with checkpoint inhibitors.

Biochemotherapy

Biochemotherapy refers to regimens that combine cytotoxic chemotherapy with immunotherapy. Although a variety of regimens exist, the chemotherapy background generally consists of cisplatin, vinblastine, and dacarbazine, whereas the immunotherapy component includes IFN α -2b and IL-2 (given as an infusion instead of boluses). Results of both randomized and nonrandomized clinical trials have demonstrated that biochemotherapy regimens can achieve response rates in 30% to 50% of patients, but at the cost of significantly increased toxicity versus either chemotherapy or immunotherapy alone. Retrospective analyses support that a subset of patients treated with biochemotherapy achieve long-term survival (ie, 15% to 17% OS at 5 and 10 years) (¹⁰⁰). However, multiple prospective randomized clinical trials failed to demonstrate significant improvements in survival compared to chemotherapy alone (⁵¹). Due to its high response rate and potential for long-term survival, biochemotherapy can be considered for selected patients, particularly patients without *BRAF*^{V600} mutations with rapidly progressive or symptomatic disease after progression on other effective therapies. Similar to HD IL-2 therapy, careful patient selection and an experienced health care team are necessary for safe administration of biochemotherapy.

Soft Tissue and Bone Sarcomas

J. Andrew Livingston
Anthony Conley

Shreyaskumar Patel

INCIDENCE

Sarcomas are a rare and heterogeneous group of tumors that arise from mesenchymal tissues. According to the estimates of the American Cancer Society, approximately 1.6 million people were estimated to be diagnosed with cancer in the United States in the year 2013, with only 14,420, or just less than 1% of cases, representing sarcomas ⁽¹⁾; 11,410 of these cases represent new soft tissue sarcomas and 3,010 represent bone sarcomas, with 4,390 and 1,440 deaths, respectively, resulting from these tumors ⁽¹⁾.

EPIDEMIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of sarcomas is not well understood. Multiple environmental factors including radiation and chemical exposures, trauma, and infection have been associated with the development of soft tissue and bone sarcomas. Both sporadic and inherited molecular and genetic aberrations have been identified in specific subsets of sarcoma and have been implicated in sarcomagenesis.

Several inherited familial cancer syndromes have been associated with a predisposition to development of soft tissue and bone sarcomas. The Li-Fraumeni syndrome resulting from a germline mutation of the *p53* tumor suppressor gene is associated with increased risk of soft tissue sarcomas and osteosarcoma among several other cancers in children and young adults ⁽²⁾.

Inherited retinoblastoma is also associated with the development of sarcomas, both osteosarcoma and soft tissue sarcoma ⁽²⁾. Neurofibromatosis type 1 is associated with an increased risk of development of sarcoma in a preexisting neurofibroma, resulting in a malignant peripheral nerve sheath tumor ⁽³⁾. Sarcomas have been associated with other cancer family syndromes including basal cell nevus syndrome, Werner syndrome, familial adenomatous polyposis, and Gardner syndrome, among others ⁽²⁾.

Recurrent cytogenetic abnormalities have been identified in many sarcomas and are thought to contribute to sarcomagenesis. Genetic profiling of bone and soft tissue sarcomas has expanded the characterization of mesenchymal tumors beyond translocation-positive/translocation-negative categorizations to identify three distinct groups: (1) genetically unstable sarcomas with complex karyotypes; (2) tumors with specific, recurrent genetic alterations such as translocations, deletions, or copy number variations; or (3) tumors with molecular aberrations such as amplifications, mutations, or loss of heterozygosity (Table 42-1). These alterations serve an important role in diagnosis as well as prognosis and have potential implications for therapy.

Molecular testing has become more widely used for diagnosis in soft tissue sarcoma, identifying specific abnormalities in certain histologic subtypes ⁽⁴⁾. For example the t(x;18) translocation is a specific marker for synovial sarcomas. The transcript formed from this translocation (*SYT-SSX*) can be detected using polymerase chain reaction (PCR) testing. In one study, the *SYT-SSX* transcript was positive in 84.5% of tumors where the diagnosis of synovial sarcoma was certain

based on histology and 24.3% of tumors in which synovial sarcoma was considered but not first in the differential diagnosis⁽⁶⁾. Another example is the *FUS-DDIT3* translocation in myxoid liposarcoma where the presence of *DDIT3* rearrangement confirms the diagnosis⁽⁶⁾. These data suggest that molecular pathology may also be a useful adjunct in the diagnosis of some sarcomas.

Specific translocations have also been investigated as prognostic biomarkers and potential therapeutic targets. For example, the *EWS-FLI1* transcript in Ewing sarcoma was previously identified as an independent prognostic factor⁽⁷⁾, but more recent studies have

not found an association potentially due to improved therapeutic regimens⁽⁸⁾. Alternatively, in alveolar rhabdomyosarcoma, translocation-negative tumors have better outcomes than translocation-positive tumors despite histologic appearance⁽⁹⁾. Although genomic profiling has increased our understanding of sarcomagenesis, to date no routine therapies have been identified to target specific translocations in sarcoma. However, the success of the targeted therapy imatinib in the treatment of gastrointestinal stromal tumors, directed at an oncogenic mutation in *KIT*, suggests a role for subtype-specific molecular therapies.

SOFT TISSUE SARCOMA

Soft tissues include fibrous, adipose, and vascular structures as well as muscles and tendons and are mesenchymal in origin. Soft tissue sarcomas are a heterogeneous group encompassing approximately 60 different subtypes, based on their resemblance to normal tissues rather than the tissue of origin.

Clinical Presentation

Soft tissue sarcomas can occur in any anatomic region. The majority of soft tissue sarcomas arise from the extremities (60%), followed by the trunk (30%) and the head and neck region (10%). The most common presenting symptom is a soft tissue mass or swelling. Pain is reported by only about one-third of patients at presentation. Therefore, because of the lack of symptoms, there is often a delay in the diagnosis. Patients with a soft tissue mass that is increasing in size, a mass >5 cm, or a mass that is deep to deep fascia, regardless of pain, should be referred for evaluation of a suspected soft tissue sarcoma ⁽¹⁰⁾.

Evaluation

Evaluation of a suspected soft tissue sarcoma begins with a comprehensive history and physical examination. Imaging evaluation is dependent on the site of disease. For soft tissue tumors of the extremities, head and neck, and pelvis, magnetic resonance imaging (MRI) is preferred. Soft tissue sarcomas found in the retroperitoneum and abdomen are generally best evaluated by computed tomography (CT). Positron emission tomography (PET) imaging can distinguish histologic grade to a degree based on tumor standardized uptake values (SUV) ⁽¹¹⁾. For both soft tissue sarcomas and bone sarcomas, PET imaging has a predictive role in determining response to chemotherapy and targeted agents such as imatinib, but it has also been shown to predict survival after initial cycle of therapy among patients receiving neoadjuvant chemotherapy for high-grade soft tissue sarcoma ^(12, 13).

A biopsy is essential to diagnosis, and the method of biopsy chosen should be the least invasive technique available to make a definitive diagnosis. A core-needle biopsy is sufficient; however, multiple cores should be obtained to improve diagnostic yield. If an open biopsy is performed, it should be planned such that the biopsy tract can be removed at the time of definitive surgical resection to reduce the risk of seeding and recurrence ⁽¹⁴⁾. An excisional biopsy may be used for small or superficial lesions; however, careful examination of margins and planning of the orientation of the resection should always be performed. Fine-needle

aspiration (FNA) is not recommended but can be useful in confirming recurrence, assuming that an experienced sarcoma cytopathologist is available ⁽¹⁵⁾.

Pathology

Sarcomas are classified primarily according to their tissue appearance, histologic grade, and sometimes the cell of origin. This can be difficult, as approximately 60 different histologic types of soft tissue sarcoma are recognized (Table 42-2). Histologic diagnosis is classified by the updated 2013 World Health Organization criteria ⁽¹⁶⁾.

Pathologists often separate sarcomas into three histologic grades using the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading system. Biological aggressiveness can be predicted based on histologic grade, and this spectrum varies among the histologic subtypes of sarcoma ⁽¹⁷⁾. Immunohistochemistry, cytogenetics, and molecular pathology can aid in making a diagnosis; however, some poorly differentiated spindle cell neoplasms cannot be categorized further.

Staging and Prognosis

The American Joint Committee on Cancer (AJCC) staging system may be used for soft tissue sarcomas (Table 42-3) ⁽¹⁸⁾. All soft tissue sarcoma subtypes are included except Kaposi sarcoma, dermatofibrosarcoma protuberans, infantile fibrosarcoma, and angiosarcoma. This system is designed to classify tumors of the extremities, trunk, head and neck, and retroperitoneum, but it was not designed for evaluation of sarcomas of the gastrointestinal (GI) tract. This system has its limitations because anatomic site and certain histologic subtypes (eg, small cell histologies) that are known to influence outcome are not taken into account ⁽¹⁹⁾.

Several clinicopathologic factors are important for treatment planning and prognosis assessment. These form the basis for the AJCC classification system and include tumor grade, size of the primary tumor, depth of invasion, and extent of disease ⁽¹⁷⁾. High-risk features for local recurrence or distant metastases are high-grade lesions, primary tumor >5 cm, and deep tumor location. Approximately 50% of patients with intermediate- and high-grade soft tissue sarcoma will develop metastatic disease requiring systemic therapy ⁽²⁰⁾. The 5-year overall survival for soft tissue sarcoma is around 50%, with local control and distant disease being the key determinants ⁽²¹⁾.

Treatment

Treatment of sarcoma requires a multidisciplinary approach with experienced medical, surgical, and

radiation oncologists, pathologists, and radiologists. An improved understanding of soft tissue sarcoma subtypes in regard to natural history, response to chemotherapy, and potential for targeted therapies has led to more subtype-specific treatment according to individual histology.

Treatment of Local Disease

Surgery

For local disease, surgical resection is the mainstay of treatment. Sarcomas tend to expand and compress tissue planes, which produce a pseudo-capsule comprising normal tissue interlaced with tumor tissue. Wide local excision with a margin of normal tissue surrounding the tumor is associated with lower local recurrence rates of approximately 10% to 30% (¹⁷). The ideal surgical margins should be 2 to 3 cm without tumor involvement. If positive margins are confirmed by pathology, re-excision to obtain negative margins is important when feasible to improve local control and relapse-free survival. For patients with borderline resectable tumors, consideration should be given to neoadjuvant therapy depending on the tumor histology and patient's performance status.

Adult sarcomas have a less than 4% prevalence of lymph node metastases (²²). For this reason, routine regional lymph node dissection is often not required. However, patients with synovial sarcoma, clear cell sarcoma, rhabdomyosarcoma, angiosarcoma, and epithelioid sarcomas have a higher incidence of lymph node metastases and should be evaluated closely for lymphadenopathy.

Improved surgical techniques and multimodality treatment have resulted in a decrease in radical resection of extremity tumors with a corresponding rise in limb-sparing procedures combining wide local resection with preoperative or postoperative chemotherapy and radiotherapy. Approximately 90% of patients with localized sarcomas of the extremities can safely undergo limb-sparing procedures to preserve limb function and adequately maintain local control (²³). A study conducted at the National Cancer Institute (NCI) showed no survival advantage to amputation over limb-sparing surgery with postoperative radiation (²⁴).

Radiation

Although radiation is not effective for the treatment of gross disease, it has been a useful adjunct to surgery in the treatment of microscopic local disease and for palliation of symptoms. Radiation therapy is commonly used in the preoperative or postoperative adjuvant setting. Because there are pros and cons as to the timing of radiation therapy, this topic remains controversial; appropriate discussion between radiation oncologists,

Table 42-3 Staging From the American Joint Committee on Cancer

Primary tumor (T)						
TX	Primary tumor cannot be assessed					
T0	No evidence of primary tumor					
T1	Tumor 5 cm or less in greatest dimension					
	T1a superficial tumor ^a

medical oncologists, and surgeons is required in planning the treatment of each patient.

Preoperative radiation has several advantages over postoperative radiation, including smaller radiation portals, conversion to a limb-sparing procedure, reduction of the extent of the surgical procedure, and lower radiation doses, which can be used because there are theoretically fewer radio-resistant hypoxic cells within the tumor and surgical removal can supplement the boost (²⁵). However, preoperative radiotherapy may lead to difficulty in assessing pathologic responses to preoperative chemotherapy and may also contribute to delayed wound healing. Several studies have shown improved local control rates with preoperative radiation, especially with larger tumors that were initially

considered unresectable (²⁶). The modality of choice is external beam radiotherapy (EBRT), and a dose of 50 Gy or more is often required to obtain local control. At these dose levels, the entire circumference of the extremity must not be irradiated in order to avoid lymphedema. A period of 4 to 6 weeks is needed following preoperative radiation to prevent wound complications. Following the surgical resection, close or positive margins could be treated with a radiation boost if feasible. Brachytherapy, EBRT, or intraoperative radiotherapy can be used by experienced clinicians in appropriate situations (²⁷).

Postoperative radiation therapy should be considered in patients with high-grade soft tissue sarcomas of the extremities with positive microscopic margins

(<1 mm from the inked margin). In this setting, adjuvant radiation improved the 5-year local control rate compared to the no RT group (74% vs 56%; *P* = .01) ⁽²⁸⁾. More recently, adjuvant intensity-modulated radiation therapy has been shown to reduce local recurrence as compared to conventional EBRT for primary soft tissue sarcoma of the extremity (hazard ratio [HR], 0.46; *P* = .02) ⁽²⁹⁾. The interval of time between surgery and initiation of radiation therapy is a controversial but legitimate concern. The most recent soft tissue sarcoma guidelines issued by the National Comprehensive Cancer Network (NCCN) suggest the interval should be no greater than 6 weeks ⁽³⁰⁾.

Radiation therapy is occasionally used as the sole treatment modality for palliation for some patients with soft tissue sarcomas. These patients are often those who have unresectable disease or who are not appropriate candidates for surgery and/or chemotherapy. There have been reports of 5-year survival rates ranging from 25% to 40% with radiation therapy alone and of local control rates of approximately 30%, depending on the primary tumor's size and biology ⁽³¹⁾.

Chemotherapy

Systemic therapy for soft tissue sarcomas is primarily used in the metastatic/advanced disease setting, whereas the role of chemotherapy in the neoadjuvant and adjuvant setting is less well established. Treatment relies primarily upon conventional chemotherapy agents, which are largely unchanged over the past two decades. In general, tumors with a higher grade are more likely to respond to chemotherapy; however, chemosensitivity varies based on histologic subtype (Table 42-4) ⁽³²⁾. An understanding of chemosensitivity and molecular aberrations based on subtype has led to histology-driven treatment algorithms for specific soft tissue sarcomas such as leiomyosarcoma, myxoid liposarcoma, and angiosarcomas (Fig. 42-1). This approach is particularly important in considering targeted therapies for specific subtypes that are considered chemoresistant such as alveolar soft parts sarcoma.

The two most active agents in the treatment of soft tissue sarcoma are doxorubicin and ifosfamide. Doxorubicin is most active at doses of ≥75 mg/m², with single-agent response rates of approximately 20% to 35% ⁽³³⁾. Ifosfamide has been shown to produce single-agent response rates similar to those of single-agent doxorubicin when used at doses of 10 g/m² or higher ⁽³⁴⁾. Ifosfamide has also been shown to have greater efficacy when administered as a 2- to 3-hour infusion as opposed to a 24-hour infusion ^(34, 35). Studies have shown that both doxorubicin and ifosfamide also exhibit a positive dose-response curve ^(33, 34). The response rate in soft tissue sarcoma patients whose disease failed doxorubicin-based therapy and who then received high-dose ifosfamide as a single agent was

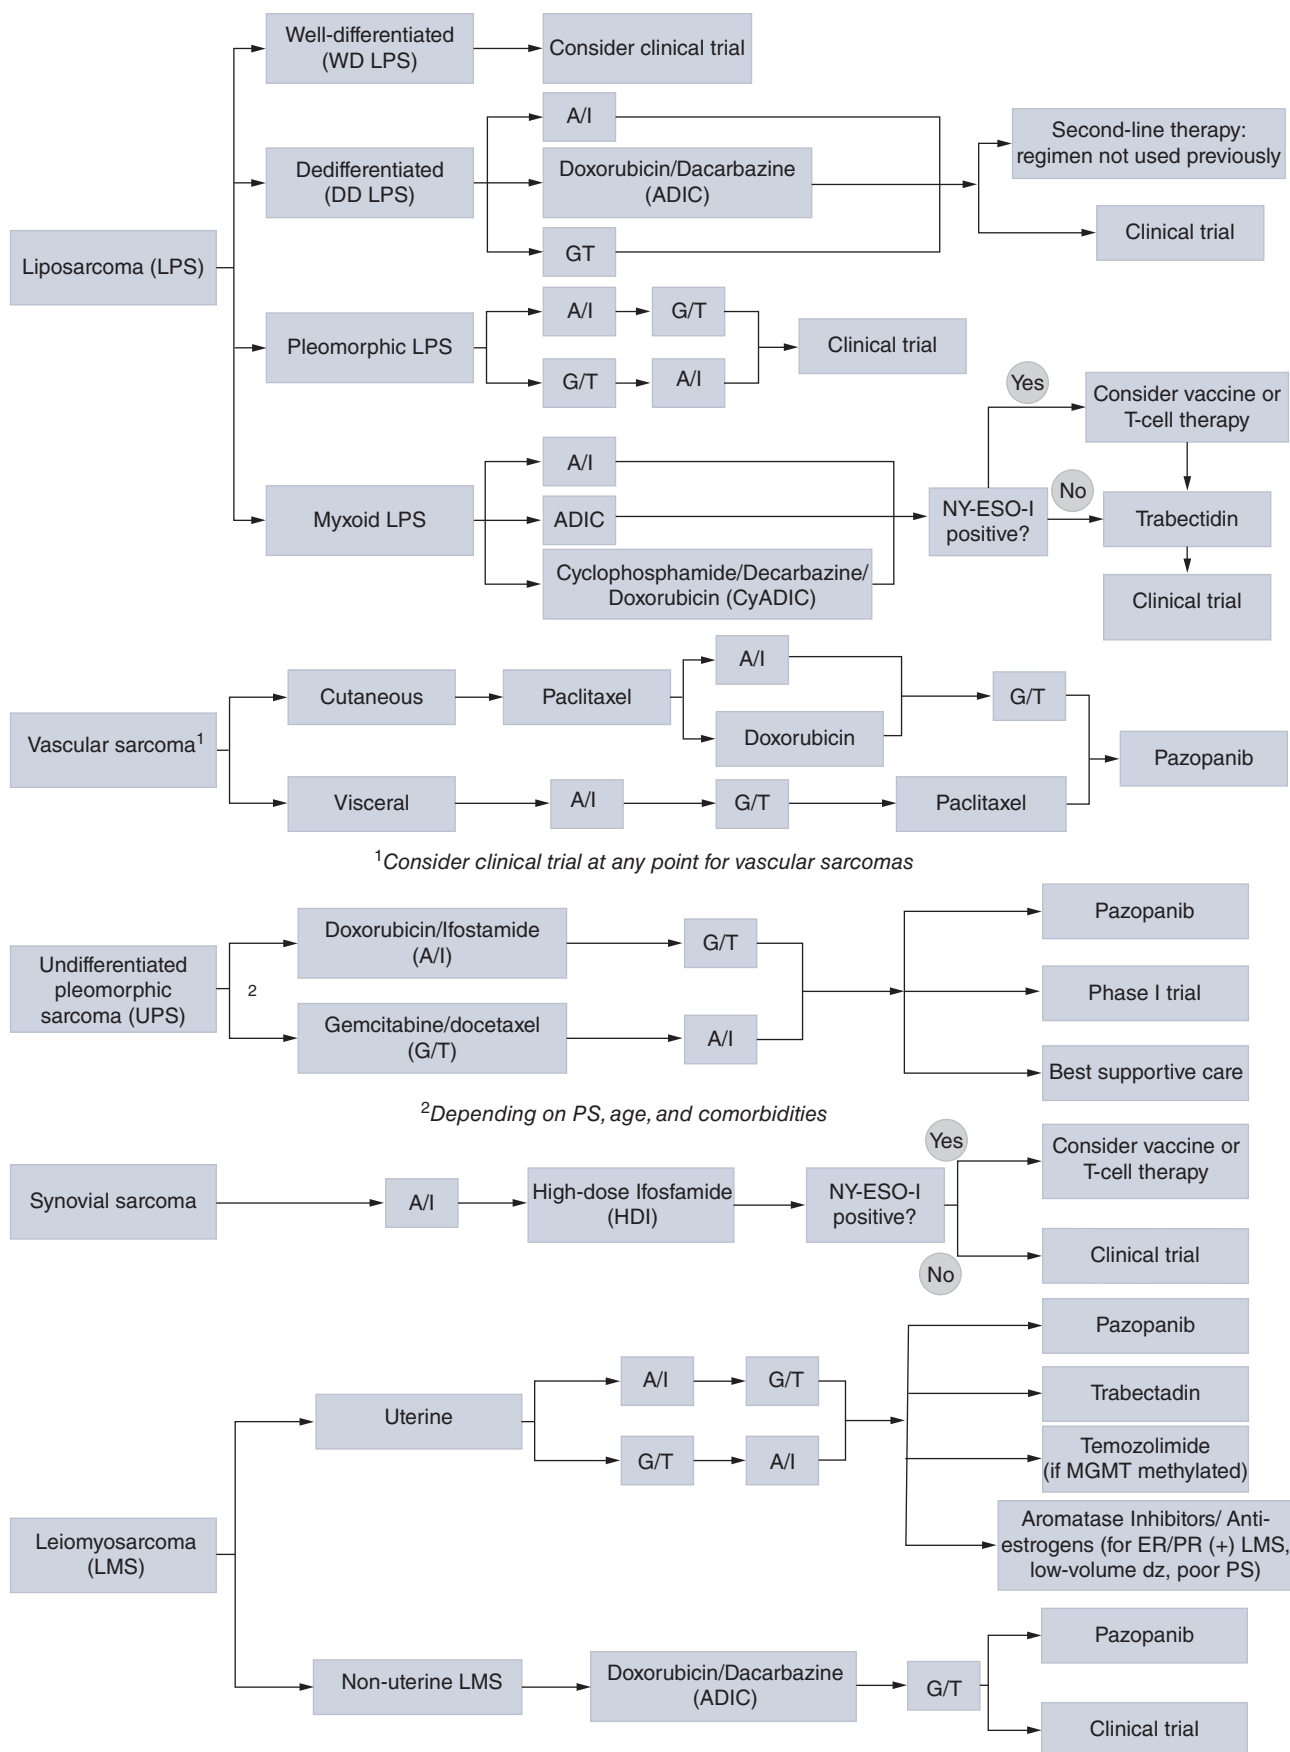

Table 42-4 Relative Chemosensitivity of Soft Tissue Sarcomas

Relative Chemosensitivity	Example
Highly sensitive (chemotherapy standard of care in management)	Ewing sarcoma family of tumors/PNET Embryonal and alveolar rhabdomyosarcoma
Sensitive to chemotherapy	Synovial sarcoma Small cell sarcoma Myxoid/round cell liposarcoma Uterine leiomyosarcoma
Moderate sensitivity to chemotherapy	Pleomorphic liposarcoma Myxofibrosarcoma Epithelioid sarcoma Pleomorphic rhabdomyosarcoma Leiomyosarcoma Malignant peripheral nerve sheath tumor (MPNST) Angiosarcoma Desmoplastic small round cell tumor (DSRCT)
Insensitive to chemotherapy	Dedifferentiated liposarcoma Clear cell sarcoma Endometrial stromal sarcoma
Chemoresistant (chemotherapy risk clearly outweighs benefit)	Gastrointestinal stromal tumor (GIST) Alveolar soft parts sarcoma (ASPS) Extraskeletal myxoid chondrosarcoma

PNET, primitive neuroectodermal tumor.

29% ⁽³⁴⁾. Therefore, high-dose ifosfamide as a single agent at doses of 14 g/m² is sometimes used as a salvage regimen at the University of Texas MD Anderson Cancer Center (MDACC) for selected histologies.

Combination therapy with dose-intense doxorubicin and ifosfamide has been shown to improve response rates and progression-free survival (PFS) and possibly overall survival ⁽³⁶⁾. The combination of doxorubicin (75 or 90 mg/m²) and ifosfamide (at 10 g/m²) was evaluated at MDACC in patients with soft tissue sarcomas and demonstrated a 75% response rate (95% confidence interval [CI], 59%-71%; complete response [CR], 12%) in patients with primary tumors of the extremities and a 68% response rate (95% CI, 56%-80%; CR, 12%) in patients with primary disease at any site ⁽³⁷⁾. The response rates according to histology were as follows: malignant fibrous histiocytoma, 69%; synovial sarcoma, 88%; unclassified sarcomas, 60%;

Visual Art: © 2015 the University of Texas MD Anderson Cancer Center

FIGURE 42-1 Approach to systemic therapies for advanced soft tissue sarcomas. A/I doxorubicin/ifosfamide; ADIC doxorubicin, dacarbazine; CyADIC, cyclophosphamide, doxorubicin, dacarbazine; ER, estrogen receptor; G/T gemcitabine/docetaxel; MGMT, O6-methylguanine-DNA methyltransferase; PR, progesterone receptor; PS, performance status.

non-GI leiomyosarcomas, 50%; liposarcomas, 56%; angiosarcomas, 83%; and neurogenic sarcomas, 40%; other miscellaneous histologies demonstrated objective response rates of 45%⁽³⁷⁾. In the large randomized phase III European Organization for Research and Treatment of Cancer (EORTC) 62012 trial comparing single-agent doxorubicin with doxorubicin in combination with ifosfamide, the combination group had a significantly higher response rate (26% vs 14%) and increased median PFS (7.4 vs 4.6 months) but also had an increase in grade 3 and 4 toxicities. Although overall survival at 1 year was increased in the combination group (60% vs 51%, $P = .076$), this failed to meet statistical significance⁽³⁸⁾. At our center, we continue to use combination dose-intense doxorubicin and ifosfamide in appropriately selected patients and preferentially in the neoadjuvant setting for large (≥ 5 cm), high-grade, resectable soft tissue sarcomas.

Dacarbazine has activity as a single agent, with response rates of 10% to 15%. The three-drug regimen MAID (mesna, doxorubicin [Adriamycin], ifosfamide, dacarbazine) has been studied and has shown response rates varying from 25% to 47%⁽³⁹⁾. When the MAID regimen was studied at MDACC, significant toxicities related to the addition of dacarbazine were seen⁽⁴⁰⁾. The combination of doxorubicin and dacarbazine (ADIC) is often used in extrauterine leiomyosarcoma or as a second-line regimen in other soft tissue sarcomas. In patients with advanced/metastatic leiomyosarcoma or liposarcoma treated with ADIC as first-line therapy, Response Evaluation Criteria in Solid Tumors (RECIST) response rates of 57% and 40% were observed, respectively⁽⁴¹⁾.

Gemcitabine alone or in combination with docetaxel is frequently used for the treatment of advanced, recurrent, or metastatic disease once patients fail doxorubicin- and ifosfamide-based therapy or in patients who may not tolerate intensive chemotherapy. An initial phase II study using gemcitabine as a single agent demonstrated a response rate of 18% (95% CI, 7%-29%), including many pretreated patients⁽⁴²⁾. The synergistic effect of docetaxel when added to gemcitabine was evaluated in a randomized phase II study, SARC002⁽⁴³⁾. By RECIST, response rates for the gemcitabine-docetaxel arm and gemcitabine arm was 16% and 8%, respectively. Furthermore, an improvement in median PFS (6.2 vs 3.0 months) and overall survival (17.9 vs 11.5 months) was noted in the gemcitabine-docetaxel arm compared to the gemcitabine arm. The two histologies most responsive to the gemcitabine-docetaxel arm were leiomyosarcoma and high-grade undifferentiated pleomorphic sarcoma.

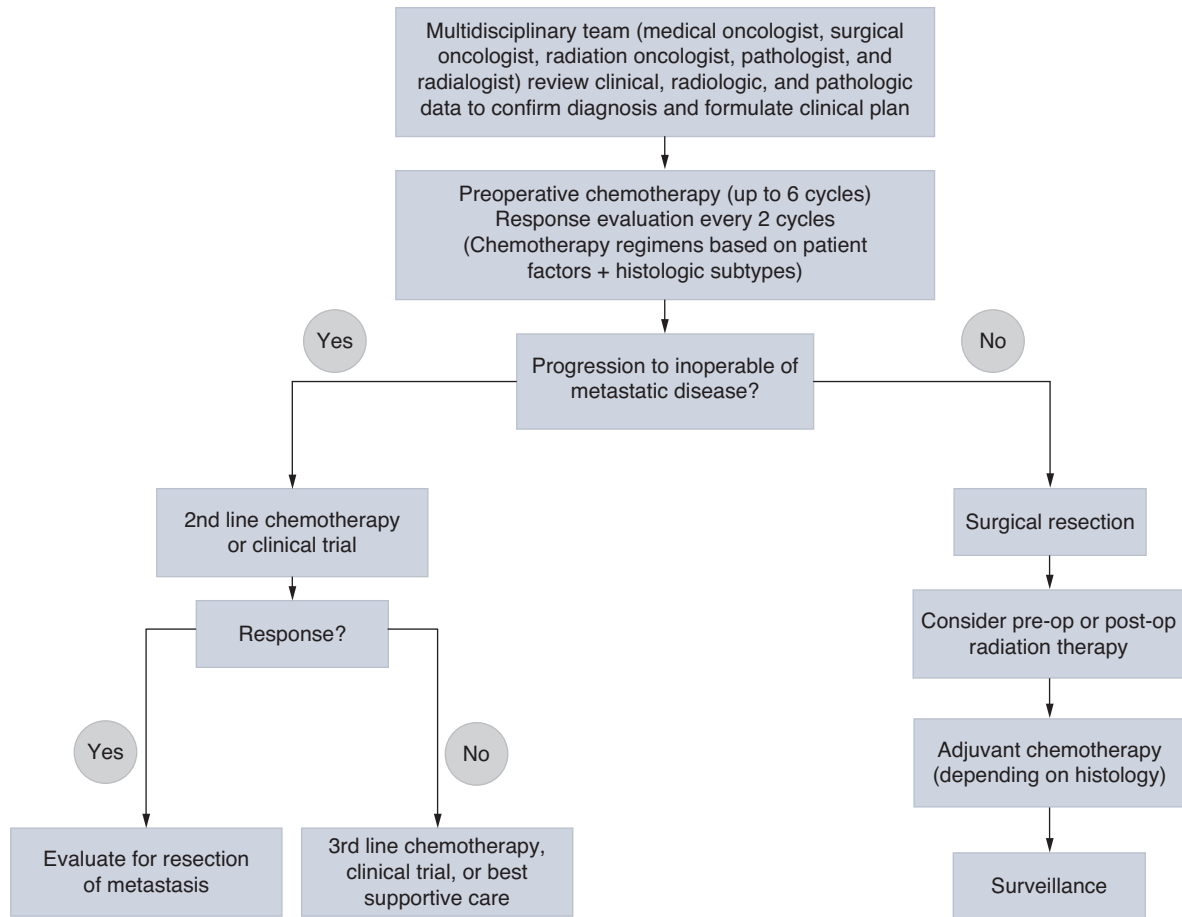

Trabectedin, a novel antitumor compound initially isolated from extracts of sea squirt *Ecteinascidia turbinata* through the NCI drug screening program in the 1960s, has shown activity in the second-line treatment of soft tissue sarcomas. The mechanism

of action of trabectedin is complex but is thought to involve displacement of transcription factors from their promoter⁽⁴⁴⁾. Additionally, sensitivity of myxoid liposarcoma, a translocation-related soft tissue sarcoma, has been shown to correlate with expression of the *FUS-DDIT3* fusion gene⁽⁴⁵⁾. Taken together, these factors suggest a role for trabectedin in translocation-related sarcomas and pose a potential mechanism of action. In a single-arm phase II trial of trabectedin as second- or third-line therapy in advanced soft tissue sarcoma, the overall response rate was 8%⁽⁴⁶⁾. However, many patients demonstrated prolonged disease stabilization, with 26% with stable disease >6 months with minimal toxicities. This benefit was greatest in leiomyosarcomas and translocation-related sarcomas. A retrospective review of eight phase II trials of trabectedin in translocation-related soft tissue sarcomas demonstrated encouraging results in regard to disease control, with greatest activity in myxoid liposarcoma⁽⁴⁷⁾. This has led to a current phase III trial of first-line therapy with trabectedin versus doxorubicin-based chemotherapy in translocation-related sarcomas. Currently, trabectedin is approved in Europe for second-line treatment of soft tissue sarcoma and has been granted orphan drug status by the US Food and Drug Administration.

Adjuvant/Neoadjuvant Chemotherapy

The goals of chemotherapy in the treatment of high-risk local disease are to eradicate micrometastasis, decrease risk of local recurrence, and downsize tumors to facilitate either limb-sparing procedures for extremity tumors or resection for tumors initially deemed unresectable (Fig. 40-2). At MDACC, preoperative chemotherapy is preferred in patients with high-risk (>5 cm or high-grade) tumors and in patients who are considered borderline resectable with chemosensitive soft tissue sarcoma subtypes.

Postoperative chemotherapy and its benefits continue to be controverted as trials of adjuvant therapy have yielded conflicting results. In the most recent update to the Sarcoma Meta-Analysis Collaboration (SMAC) conducted in 2008, the benefit of adjuvant chemotherapy was analyzed among 1,953 patients with soft tissue sarcoma across 18 trials⁽⁴⁸⁾. This update incorporated five trials evaluating doxorubicin and ifosfamide in combination, a regimen not previously represented in the initial SMAC analysis. This updated meta-analysis detected favorable odds ratios (ORs) of local recurrence and distant recurrence for chemotherapy. Although the absolute risk reduction (ARR) in distant recurrence with adjuvant doxorubicin-based chemotherapy for all studies was 9% (95% CI, 5%-14%; $P = .000$), the ARR with adjuvant doxorubicin-ifosfamide chemotherapy was 10% (95% CI, 1%-19%; $P = .03$)⁽⁴⁸⁾. By pooling the data, the number needed to treat (NNT) to prevent

Visual Art: © 2015 the University of Texas MD Anderson Cancer Center

FIGURE 42-2 Treatment approach for patients with stage III soft tissue sarcomas.

distant recurrence was 12. Although a survival benefit was not noted with single-agent doxorubicin, a statistically significant survival advantage was observed with the doxorubicin-ifosfamide combination. The OR for overall survival in the doxorubicin-ifosfamide cohort was 0.56 (95% CI, 0.36-0.85; $P = .01$). Combining all trials in the meta-analysis, the NNT to prevent one death was 17. A recent randomized controlled trial of adjuvant therapy with doxorubicin 75 mg/m² and ifosfamide 5 g/m² in patients with intermediate- or high-grade STS failed to demonstrate a benefit in overall survival (HR, 0.94; $P = .72$) or relapse-free survival (HR, 0.91; $P = .51$)⁽⁴⁹⁾. Although the data regarding adjuvant therapy are conflicting, within our institution, we continue to offer adjuvant therapy with doxorubicin in combination with ifosfamide to healthy patients with intact organ function who have high-risk disease (tumor size >5 cm, high-grade histology, and deep soft tissue involvement).

Targeted Therapy

As in other tumor types, increased knowledge of cancer genomics and identification of oncogenic driver

mutations in soft tissue sarcomas have led to much enthusiasm and investigation of molecular-based targeted therapies. A comprehensive review of targeted therapies under development for soft tissue sarcoma is beyond the scope of this chapter, and therefore, the focus will be on currently approved therapies. Targeting cKIT with the tyrosine kinase inhibitor (TKI) imatinib in gastrointestinal stromal tumors (GISTs) is perhaps the best-known and most successful example in sarcoma. Although targeted agents have shown promise in specific histologies, the multitargeted TKI pazopanib has shown activity across multiple subtypes of soft tissue sarcomas. Pazopanib is a small-molecule inhibitor with activity against VEGF1-3, PDGFRA, PDGFRB, and KIT. A phase II trial of pazopanib in advanced soft tissue sarcoma evaluating 12-week PFS as the primary end point showed benefit in leiomyosarcoma (44%), synovial sarcoma (49%), and other nonlipomatous soft tissue sarcoma (39%)⁽⁵⁰⁾. Subsequently, a placebo-controlled phase III trial of pazopanib in metastatic soft tissue sarcoma demonstrated a low response rate (partial response [PR], 6%) but significant improvement in PFS (4.6 months vs 1.6 months with placebo; HR, 0.31;

$P < .0001$)⁽⁵¹⁾. In a multivariate Cox model, favorable prognostic factors in patients treated with pazopanib were good performance status and low or intermediate tumor grade. Additional targeted therapies in soft tissue sarcoma are primarily being developed and studied in specific soft tissue sarcoma subtypes.

Metastatic Disease and Metastasectomy

Patients with metastatic disease involving multiple organs are generally incurable and considered appropriate for palliative systemic therapy as described earlier. The subset of patients with lung-only metastatic disease, especially with a greater than 12-month disease-free interval, have a favorable biology and prognosis and therefore should be considered for resection if feasible. This approach results in 3- to 5-year survival of up to 20%. Chemotherapy is the mainstay of therapy for patients with metastatic disease, although surgical resection of residual disease to render patients free of gross disease is often pursued. The sequencing of chemotherapy is similar to that of isolated local disease. In a study conducted at MDACC, patients with metastatic disease showed a 57% response rate to doxorubicin (75-90 mg/m²) and ifosfamide (10 g/m²)⁽³⁷⁾. If patients fail this regimen, the choice of treatment depends on the histology of the tumor and the performance status of the patient.

Specific Soft Tissue Sarcomas

Vascular Sarcomas

Vascular sarcomas are tumors that originate from or differentiate toward the endothelium with varying malignant potential. Although epithelioid hemangioendotheliomas have an intermediate malignant potential and indolent clinical course, angiosarcomas, at the other end of the spectrum, have a highly malignant biologic behavior with early propensity for distant metastasis and dismal outcomes. These tumors also differ in their response to chemotherapy and targeted therapy and, therefore, are discussed separately below.

Epithelioid hemangioendotheliomas (EHE) are considered to be of intermediate malignant potential with development of metastasis and recurrence. They typically are associated with a blood vessel, usually a medium sized or large vein. Epithelioid hemangioendothelioma most commonly occurs in the soft tissues, but liver, lung, and bone may be sites of primary involvement. In over 42% of patients with hepatic EHE, symptoms are often absent and the lesions are discovered incidentally. Some patients experience constitutional symptoms such as fatigue, anorexia, nausea and poor exercise tolerance. Most cases of EHE

affecting soft tissues are localized, whereas multifocality is more common with EHE involving liver or lung, and these patients develop metastatic disease during the course of their illness. Multifocal or metastatic disease does not equate to mortality, and many patients can survive long term with metastatic disease. Sixty-three percent of patients with liver EHE and less than half of patients with metastatic EHE of soft tissues die from their disease.

Localized EHE of soft tissue should be treated with surgical resection with adequate margins. Following resection, these tumors can recur locally in about 12% of patients⁽⁵²⁾. Preoperative radiation therapy should be considered in patients where good margins are unlikely, and postoperative radiation therapy should be considered in cases where the margins are positive and no preoperative radiation was administered. Localized EHE does not require the use of chemotherapy or targeted therapies.

Metastatic EHE of soft tissue may be followed without therapy until there is evidence of progressive disease on serial imaging over a 3-month period. When systemic therapy is needed, conventional chemotherapy and antiangiogenic therapy may be considered. Systemic therapy options include gemcitabine, taxanes, and doxorubicin. Targeted therapy with bevacizumab (PR, 29%; stable disease, 57%; and progressive disease, 14%)⁽⁵³⁾, sorafenib (30.7% without progression at 9 months)⁽⁵⁴⁾, and interferon α -2b⁽⁵⁵⁾ has been reported to have utility in patients with metastatic EHE.

Angiosarcomas are highly malignant tumors with endothelial differentiation with a propensity for recurrence and distant metastasis. These tumors are extremely rare, representing <2% of all sarcomas, and can develop de novo or in the setting of prior radiation therapy or chronic lymphedema. Due to their endothelial location, these tumors are particularly well poised for early dissemination and development of metastasis. Angiosarcoma has a propensity for cutaneous involvement, and 60% of cases have skin or soft tissue involvement. Other sites of visceral involvement include spleen, liver, lung, pleura, heart, and GI tract. Clinical behavior and response to therapy can vary from one site to another, with cardiac angiosarcomas carrying the worst prognosis.

Even when these tumors are nonmetastatic, multifocality is often present locally, resulting in high recurrence rates. Therefore, it is critical to approach localized disease with a multidisciplinary approach that combines chemotherapy, radiation, and surgery to produce better outcomes⁽⁵⁶⁾. At our institution, we prefer to treat these patients with neoadjuvant chemotherapy followed by surgery and radiation. Chemotherapy can utilize either doxorubicin-based or taxane-based approaches, both of which have

excellent outcomes, and the choice of the regimen depends on the primary location of disease, histologic subtype, performance status of the patient, and potential for toxicity. For cutaneous angiosarcoma, taxanes are as good as doxorubicin-based approaches, but for visceral angiosarcoma, doxorubicin-based approaches may have better activity.

Patients with metastatic disease can be treated with single-agent or multiagent chemotherapy. Monotherapy with doxorubicin (response rate, 29%-33%; PFS, 3-5 months) and paclitaxel (response rate, 18%-89%; PFS, 4-5 months) appears to have significant activity in patients with angiosarcomas⁽⁵⁷⁻⁶¹⁾. Based on a retrospective study of 117 patients with metastatic angiosarcoma, weekly paclitaxel (response rate, 53%) may have comparable efficacy to doxorubicin as a single agent in patients with cutaneous angiosarcoma⁽⁵⁷⁾. Doxorubicin may have advantages over paclitaxel in visceral angiosarcomas. Gemcitabine also appears to have single-agent activity (response rate, 64%; PFS, 7 months)⁽⁶²⁾, but this drug is more commonly used in combination with taxanes.

The most commonly used combination therapies in angiosarcoma are doxorubicin-ifosfamide and gemcitabine-docetaxel. The doxorubicin-ifosfamide combination is preferred for visceral angiosarcomas and has better durability than any other treatment for angiosarcoma, with a median PFS of 5.4 months⁽⁵⁹⁾. The gemcitabine-docetaxel combination appears to have good activity both in the visceral and cutaneous angiosarcomas.

Antiangiogenic therapies with activity in angiosarcomas include bevacizumab (PR, 9%; stable disease, 48%; median PFS, 12 weeks)⁽⁵³⁾, sunitinib⁽⁶³⁾, and sorafenib (CR, 3%; PR, 11%; stable disease, 57%; median PFS, 3.2 months)⁽⁶⁴⁾. Although responses with targeted therapies appear to be low compared to conventional chemotherapy, this may be a result of using an unselected study population for treatment.

Leiomyosarcoma

Leiomyosarcoma (LMS) is a common soft tissue sarcoma subtype and can arise anywhere in the body. The site of origin and grade are important prognostic factors and also guide treatment. Patients with vascular origin LMS have a worse prognosis compared with nonvascular LMS patients. Additionally, patients with uterine LMS tend to fare better compared with extrauterine LMS patients, although this may be in part due to a higher rate of complete resection in uterine LMS⁽⁶⁵⁾. Leiomyosarcoma is responsive to multiple chemotherapeutic agents used in soft tissue sarcoma but has been shown to be less responsive to ifosfamide-containing regimens than single-agent doxorubicin⁽⁶⁶⁾. Gemcitabine is active in LMS. A subtype-specific phase II trial of gemcitabine versus

gemcitabine in combination with docetaxel in metastatic or relapsed LMS⁽⁶⁷⁾ showed significant response rates with both single-agent gemcitabine and the combination (19% vs 24%, respectively) in patients with uterine LMS. In the non-uterine LMS subgroup, combination therapy resulted in higher objective response rates (14% vs 5%) and prolonged PFS (6.3 vs 3.8 months). Hormonal treatment may be considered for patients with uterine LMS. In the largest retrospective study of aromatase inhibitors in uterine LMS, response rates included PR in 9% and stable disease in 32%. Patients with hormone receptor-positive disease demonstrated better PFS⁽⁶⁸⁾. The treatment algorithm for advanced LMS should take into account the site of origin (uterine vs extrauterine), hormone expression in uterine LMS, and O⁶-methylguanine-DNA methyltransferase (MGMT) methylation status (see Fig. 42-1).

Liposarcoma

Liposarcomas represent the second most common soft tissue sarcoma. There are several histologic subtypes of liposarcoma with unique clinical and biological features. Myxoid liposarcoma represents the most common variant of liposarcoma. Other subsets include well-differentiated, dedifferentiated, and pleomorphic subtypes. Myxoid liposarcomas often occur in the third through fifth decades of life and generally develop in the extremities. Although regarded a low-grade tumor, local recurrence and distant metastasis occur in about 30% of patients. Sites of metastasis include lungs and soft tissue regions such as the axilla, retroperitoneum, the pleural lining, and even the pericardium. A rare variant of myxoid liposarcoma, round cell liposarcoma, is considered to be a more malignant variant of a spectrum of this disease. An increase in round cell percentage correlates to metastasis and poor survival in myxoid liposarcomas⁽⁶⁹⁾. The balanced translocation t(12;16)(q13;p11) results in the oncoprotein FUS-DDIT3, which is pathognomonic for myxoid liposarcoma^(70,71). The product of this arrangement is thought to contribute to the oncogenesis through transcription of angiogenic, inflammatory, and adipocytic maturation factors resulting in myxoid liposarcoma⁽⁷²⁾. Treatment options for myxoid liposarcoma depend on the location and size of the lesion. Whereas surgery and radiation are more feasible for extremity locations, retroperitoneal involvement is less amenable to surgery for curative intent. Importantly, myxoid liposarcoma is considered a chemosensitive disease. Reports from MDACC using doxorubicin-based chemotherapy yield response rates of 44%. Trabectedin has been shown to be active in myxoid liposarcoma across multiple trials^(45,73). Aside from binding to the minor groove of DNA and forming covalent adducts and displacement of transcription factors, this agent is thought to promote differentiation of myxoid

liposarcoma lipoblasts. Surgery is the mainstay of treatment for well-differentiated/dedifferentiated liposarcoma; however, recurrence rates are high, especially in the retroperitoneum. Benefit from chemotherapy has been reported to be minimal, with objective response rates of approximately 12% (⁷⁴). In a recent review of 89 patients with dedifferentiated liposarcoma of the retroperitoneum treated at MDACC, response rates were higher (23% by RECIST) with a clinical benefit rate (PR + stable disease >6 months) of 37%, suggesting a potential role for chemotherapy in select patients with unresectable or borderline resectable disease.

Alveolar Soft Parts Sarcoma

Alveolar soft parts sarcoma (ASPS) is a rare soft tissue sarcoma subtype predominantly affecting adolescents and young adults and accounting for <1% of all soft tissue sarcomas. Although the disease course is indolent with a prolonged natural history, ASPSs have a high rate of metastasis and a median overall survival of approximately 90 months. Although lung metastases are most common, ASPS can also metastasize to the brain, an otherwise uncommon site for sarcoma. In a review of our institutional experience with ASPS, 65% of patients presented with stage IV disease. Among those with localized disease at presentation, 5-year overall survival was 88%, whereas those who presented with metastatic disease had a median overall survival of 40 months and 5-year overall survival of 20% (⁷⁵). Despite its propensity for metastasis, ASPS is resistant to conventional chemotherapy. Highly vascular, these tumors are characterized by an unbalanced translocation t(X;17)(p11;q25) resulting in the ASPL-TFE3 fusion protein and overexpression of *MET*, leading to angiogenesis. Cediranib, a highly potent vascular endothelial growth factor (VEGF) inhibitor, has recently shown promise in the treatment of ASPS. In a single-arm phase II study of 43 patients, cediranib demonstrated an overall response rate of 35% and a disease control rate of 84% at 6 months (⁷⁶). Sunitinib, a multitargeted small-molecule inhibitor including VEGF, has also been shown to be active in ASPS (⁷⁷).

Follow-Up Management

The major goals of follow-up surveillance and management should be early identification of potentially curable recurrences, identification of treatment-related complications, and patient reassurance. Surveillance of patients treated for soft tissue sarcomas is based on known prognostic factors, outcomes in individual subsets of patients, and patterns of tumor recurrence.

For patients with low-risk T1 primaries who have undergone treatment with curative intent and are free of any gross evidence of disease, follow-up should

include a history and physical, cross-sectional imaging of the tumor bed to evaluate for local recurrence, and routine chest x-rays for surveillance of metastatic disease (⁷⁸). For tumors of the head and neck and extremities, MRI is appropriate; for tumors of the chest cavity, abdomen, and retroperitoneum, CT scans are appropriate (⁷⁸). The routine use of chest CT for evaluation of metastatic disease in soft tissue sarcomas has been studied and found not to be cost effective. The NCCN guidelines recommend follow-up with annual scanning of the primary site for at least 5 years; however, often these patients are seen every 3 to 4 months in the immediate postoperative period for the first 2 years, then every 4 to 6 months for the next 2 years, and yearly thereafter.

Patients with high-risk T2 (>5 cm) soft tissue sarcomas are at a greater risk for distant lung metastases. In patients with high-risk tumors who have undergone treatment with curative intent and are free of any gross evidence of disease, follow-up should include a history and physical, cross-sectional imaging of the tumor bed, and routine chest x-rays for surveillance of metastatic disease (⁷⁸). These patients are followed in the same manner as low-risk patients, with follow-up visits with the above studies every 3 months for the first 1 to 2 years, then visits every 4 months for the next 1 to 2 years, followed by visits every 6 months for 1 to 2 years, and yearly visits thereafter (⁷⁸). As for local recurrence surveillance, the cross-sectional imaging is omitted after 5 years, because most local recurrences appear within 5 years of initial treatment (⁷⁸).

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors are the most common mesenchymal tumors of the GI tract (⁷⁹). Previously, they were often designated smooth muscle tumors of the GI tract—specifically, GI LMS, leiomyoblastoma, LMS, and leiomyomas. Investigators discovered that GISTs express the KIT (CD-117) receptor tyrosine kinase and possibly originate from the interstitial cell of Cajal, the intestinal pacemaker cell responsible for peristalsis (⁸⁰). These tumors most commonly arise in the stomach (60%-70%), small intestine (20%-30%), colon and rectum (5%), and esophagus (<5%), although they can arise anywhere in the GI tract or omentum/peritoneum. The liver, peritoneum, and abdominal wall are the most common sites of metastatic disease; however, there are reports of associated central nervous system (CNS), lymph node, lung, and bone metastasis (⁸¹). The incidence of GIST is equal in men and women; it generally peaks between the fourth and sixth decades of life, and patients are more commonly Caucasian. Presenting symptoms often represent the site of tumor origin but may be vague, including abdominal pain, anorexia, weight loss, and dyspepsia.

Historically, the mainstay of treatment for GIST was surgical resection. Conventional chemotherapy or radiotherapy has not been effective in the treatment of GIST. The identification of specific oncogenic driver mutations involving the c-KIT protein has led to the development and approval of multiple TKIs that have greatly improved the prognosis of patients with metastatic GIST. Previously, median overall survival was approximately 18 months. In the era of imatinib, this has improved to around 5 years⁽⁸²⁾.

Molecular profiling of patients with GIST has now become standard of care, as the mutational status has important implications in regard to diagnosis, prognosis, and guiding treatment decisions. Approximately 70% to 80% of GISTs harbor a *KIT* gene mutation, with another 5% to 8% with *PDGFRA* mutations, and the remaining 12% to 15% deemed wild-type GIST⁽⁸³⁾. Wild-type GIST constitutes a heterogeneous grouping, with additional mutations identified in succinate dehydrogenase (*SDH*) and *BRAF* V600E, among others. Deletions in exon 11 are the most common *KIT* mutation and portend a more aggressive disease course with shorter overall survival and higher risk of recurrence. Internal tandem repeats involving exon 11, however, are associated with gastric GIST and tend to be more indolent. Exon 9 mutations have been associated with GIST of the small intestine and a clinically aggressive course. *PDGFRA* mutations can occur in multiple exons (12, 14, and 18) and are observed primarily in gastric GIST.

Imatinib mesylate, an oral TKI that selectively inhibits BCR-ABL, KIT, and PDGFR, is approved for adjuvant therapy and for unresectable/metastatic GIST. Early trials with imatinib showed objective response rates of 53% to 69% and significant improvement in 5-year overall survival of about 50%^(82, 84). These trial results led to two phase III trials (EORTC 62005 and Southwest Oncology Group [SWOG] S0033) that were designed to compare imatinib at two dose levels (400 mg/d vs 800 mg/d)^(85, 86). In both studies, the higher dose arm failed to show a statistically significant difference in response or overall survival as compared to the once-daily dosing schedule. Gastrointestinal stromal tumors with exon 11 mutations are the most responsive to imatinib therapy, whereas those with exon 9 mutations tend to be more resistant. Patients with exon 9 mutations demonstrated shorter PFS and overall survival as compared to those with exon 11 mutations when treated with imatinib⁽⁸⁷⁾. Patients with exon 9 mutations may benefit from an increased dose of imatinib (800 mg daily). Patients with non-KIT non-PDGFR mutated or wild-type GIST rarely show significant or sustained response to treatment. The optimal duration of imatinib therapy is not known. In one study, investigators randomized patients who had control of disease at 3 years with imatinib to either

continue or discontinue treatment⁽⁸⁸⁾. The 2-year PFS was 80% in the continuous treatment cohort compared with 16% in the treatment interruption group. Relapse in the continuous treatment group was thus attributed to resistance.

Imatinib has also shown efficacy in the adjuvant setting⁽⁸⁹⁾. As in the metastatic setting, the optimal duration of adjuvant imatinib therapy has not been well established. A randomized trial comparing 1 year versus 3 years of adjuvant imatinib therapy for *KIT*-positive resected GIST showed benefit to longer duration of adjuvant therapy⁽⁹⁰⁾. Patients receiving 36 months of adjuvant imatinib had longer recurrence-free survival (5-year recurrence-free survival, 65.6% vs 47.9%; HR, 0.46; $P < .001$) and improved 5-year overall survival (92% vs 81.7%; HR, 0.45; $P = .02$). The benefit of extending therapy beyond 3 years is not known.

Approximately 10% of GIST patients have primary resistance to imatinib, with higher rates seen in exon 9 mutated and wild-type GIST. Secondary resistance is often due to new mutations in the *KIT* gene involving exon 13 or exon 17⁽⁹¹⁾. Sunitinib, a multikinase inhibitor that targets VEGF, appears to have activity in patients with primary resistance and secondary *KIT* mutations^(92, 93). The overall objective response rate, however, was less than 10%. Several additional targeted therapies targeting the KIT and PDGFR pathways have also been evaluated. Nilotinib, a second-generation TKI, was evaluated as third-line therapy following imatinib and sunitinib and showed a low response rate of 3%⁽⁹⁴⁾. Regorafenib, a multitargeted TKI, has shown better efficacy in patients after failure of both imatinib and sunitinib. In a phase II trial, an objective response rate of 12% and clinical benefit rate (PR or stable disease >16 weeks) of 79% were observed in patients, leading to a current phase III trial⁽⁹⁵⁾.

Response evaluation in GIST uses the Choi criteria rather than the standard RECIST measures used in most other solid tumors. Positron emission tomography imaging may also be used and was initially noted to show treatment response at an earlier time point compared to standard CT imaging⁽¹²⁾. Certain molecular events, such as apoptosis, occur early on and may partially explain the rationale behind early PET response related to imatinib⁽⁹⁶⁾. Our institution also demonstrated that RECIST criteria may underestimate early tumor response seen in GIST. Patients who respond to imatinib clinically may show a decrease in tumor size and/or a decrease in tumor radiodensity by CT radiography (Fig. 42-3). Further analysis of patients treated with imatinib at MDACC revealed that, when tumor density is taken into account, sensitivity of CT imaging is comparable to PET response^(97, 98). This data culminated in the development of the Choi criteria of response assessment (Table 42-5). These criteria

FIGURE 42-3 Gastrointestinal stromal tumor response to imatinib therapy on computed tomography and positron emission tomography imaging. (Used with permission from Dr. Haesun Choi, Department of Diagnostic Radiology, The University of Texas MD Anderson Cancer Center.)

have been prospectively validated and are considered in response assessment in current trials of GIST. It is our experience that decisions to discontinue therapy should not be based solely on CT radiography or PET imaging but instead should also take into consideration the patient’s overall clinical condition.

In summary, the front-line therapy for patients with newly diagnosed, metastatic GIST is imatinib at 400 mg daily. Patients with exon 9 mutations should initiate therapy with imatinib at 800 mg daily. Imatinib should be continued indefinitely or until progression, as defined by Choi criteria. Computed tomography imaging is used to assess response initially at 2 months and then at 3-month intervals for at least the first 2 years. At the time of progression, we check the plasma imatinib level, and if tolerable,

we increase the dose of imatinib to a total of 800 mg daily. If or when this strategy fails, we proceed to second-line therapy sunitinib and subsequent third-line therapy with regorafenib. For patients with isolated or resectable metastatic disease, surgery and/or hepatic artery embolization or radiofrequency ablation is offered if feasible. For resectable GIST patients with high-risk features, such as a high mitotic count and/or large tumor size, adjuvant imatinib for at least 3 years should be administered to increase recurrence-free survival. The optimal duration of imatinib use in the adjuvant setting beyond 3 years remains unknown.

BONE SARCOMA

Bone sarcomas are rare tumors, making up less than 0.2% of all cancers. In 2013, an estimated 3,010 new cases of bone sarcomas were diagnosed in the United States, and 1,440 deaths were attributed to this group of diseases (1). The most common malignant tumor of bone is osteosarcoma followed by chondrosarcoma and then the Ewing sarcoma/primitive neuroectodermal tumor (PNET) family of tumors. Malignant fibrous histiocytoma, fibrosarcoma, chordoma, and giant cell tumor of bone are rare bone tumors and account for <5% of all primary malignant bone tumors. The Ewing sarcoma/PNET family of tumors tend to occur more frequently in children and adolescents, whereas osteosarcoma has a biphasic pattern of incidence that peaks in adolescents, with the growth of long bones, and in the elderly, with tumors arising in association with Paget disease or previously radiated tissues. Chondrosarcomas are usually seen in patients after the fifth decade of life, but they can also occur in younger patients, where the tumors tend to be of a higher grade malignancy. Features of common bone tumors are listed in Table 42-6.

Clinical Presentation

The clinical presentation of any bone tumor depends on its location. Most osteosarcomas arise in the metaphyseal region of long bones, specifically the distal femur, proximal tibia, and proximal humerus. Approximately 55% of osteosarcomas occur around the knee joint. Chondrosarcomas can also arise in any bone of the body; however, they generally occur in the pelvis and other flat bones. Ewing sarcoma/PNET tumors tend to occur in the diaphyseal portion of the long bones and in flat bones of the body (eg, the pelvis and scapula).

The most common presenting symptom is pain and swelling or a mass. Patients who have pelvic tumors may have neurologic impairment and severe pain, typically because these tumors are often not recognized

Table 42-5 Choi Response Criteria

Response	Response Definition
Complete response (CR)	Disappearance of all disease No new lesions
Partial response (PR)	A decrease in size of >10% OR a decrease in CT density (HU) >15% No new lesions No obvious progression of nonmeasurable disease
Stable disease (SD)	Does not meet the criteria for CR, PR, or PD No symptomatic deterioration attributed to tumor progression
Progression of disease (PD)	An increase in unidimensional tumor size of >10% AND did not meet criteria for PR by CT density Any new lesions, including new tumor nodules in a previous cystic tumor

CT, computed tomography; HU, Hounsfield unit.

Table 42-6 Features of Common Bone Tumors

Type	Frequency	Age Distribution	Gender	Common Sites	Radiologic Features	Pathologic Features
Osteosarcoma	45%	10-20 years	M > F	Metaphysis	Sunburst calcifications	Spindle cells, osteoid matrix
MFH	8%	20-80 years	M > F	Long bones	Radiolucent with ill-defined margins	Pleomorphic spindle cells, NO osteoid
Chondrosarcoma	22%	20-80 years	M > F	Pelvis/shoulder girdles	Lobulated appearance	Lobules, chondroid matrix
Ewing/PNET	15%	10-20 years	F > M	Diaphyses	Lytic with soft tissue component	Small round blue cells

F, female; M, male; MFH, malignant fibrous histiocytoma; PNET, primitive neuroectodermal tumor.

until late in the disease course. In the case of Ewing sarcoma, patients often present with constitutional symptoms of night sweats and fevers.

Evaluation

Evaluation of suspected bone sarcoma should begin with a careful history, physical examination, and routine laboratory tests, followed by imaging directed to the given complaint. The imaging of any bone tumor should begin with a plain film of the involved area. X-ray images are often helpful in the diagnosis

of bone sarcomas; for example, osteosarcoma often has a “sunburst” appearance of calcification on x-ray imaging, which is virtually diagnostic (Fig. 42-4). The amount of calcification associated with osteosarcoma depends on the histologic subtype (eg, osteoblastic osteosarcoma usually has very dense calcification, whereas telangiectatic osteosarcoma is primarily lytic). Chondrosarcoma also has a distinct appearance on x-ray imaging, with destruction of the bone and endosteal scalloping of the bony cortex and a chondroid matrix, which appears lobulated (See Fig. 42-4). Ewing sarcoma has a typical “onion-skin” appearance

FIGURE 42-4 X-ray imaging of osteosarcoma, Ewing sarcoma, and chondrosarcoma. **A.** The typical “sunburst” appearance of osteosarcoma. **B.** The “onion-skin” appearance often seen in Ewing sarcoma. **C.** The lobulated appearance of chondrosarcoma.

on x-ray imaging (See Fig. 42-4). Additional initial imaging should include a CT scan and/or MRI of the primary lesion to further evaluate involvement of the neurovascular structures, surrounding soft tissues, and adjacent joints and to better evaluate any associated soft tissue mass.

Biopsy of bone sarcomas is critical to the diagnosis, and careful planning is essential. When patients are diagnosed with bone sarcoma or the diagnosis is suspected, it is important to have a multidisciplinary team approach with physicians who are experienced in the treatment of bone sarcomas. Core-needle biopsy has been shown to be accurate in making a diagnosis in up to 91% of cases⁽⁹⁹⁾. An open biopsy should be performed only when core-needle biopsy is nondiagnostic. Current guidelines recommend either a core or open biopsy to confirm the diagnosis prior to any surgical procedure. When surgery is ultimately performed, care should be taken to assure that the biopsy tract is completely resected.

Complete staging should include chest x-ray, CT scan of the chest, and bone scan to evaluate for metastatic disease. Chest imaging is warranted in all patients, because the most common site of metastasis from bone sarcoma is the lungs. A bone scan should be included in the workup for metastatic disease in patients with bone sarcoma to evaluate for distant bone metastases or skip metastases. For patients with Ewing sarcoma, an MRI of the spine should be performed, because there is a risk of bone marrow metastases. We do not routinely obtain bone marrow biopsy in the staging evaluation of Ewing sarcoma. Marrow involvement has been shown to highly correlate with bone metastasis⁽¹⁰⁰⁾.

Positron emission tomography/CT is being used more frequently in the initial diagnostic evaluation, staging, and response assessment for bone sarcomas. However, fluorodeoxyglucose (FDG) uptake alone is not adequate for characterization of primary bone

tumors; morphologic evaluation is key⁽¹⁰¹⁾. Positron emission tomography/CT imaging can also play an important role in response assessment because bone sarcomas do not demonstrate typical RECIST responses to chemotherapy (Fig. 42-5). Multiple studies have reported the utility of PET/CT in evaluating chemotherapy response in osteosarcoma and Ewing family tumors^(102, 103). In one study of osteosarcoma, a 25% to 50% reduction of SUV following 1 week of neoadjuvant chemotherapy has been shown to correlate with >90% tumor necrosis on pathologic evaluation⁽¹⁰⁴⁾. At our center, we routinely use PET/CT in the evaluation and response assessment for osteosarcoma and Ewing family tumors.

Pathology

There are multiple histologic subtypes of bone sarcoma, with the most common cytogenetic and molecular aberrations summarized in Table 42-7. Osteosarcoma can be broken down into two major categories: conventional osteosarcoma and variant osteosarcoma (Fig. 42-6). Conventional osteosarcoma comprises approximately 60% to 75% of all osteosarcomas, whereas the 11 variants comprise the other 35% to 40%⁽¹⁰⁵⁾. Conventional osteosarcoma includes osteoblastic osteosarcoma, chondroblastic osteosarcoma, and fibroblastic osteosarcoma. These classifications are made based on the histologic features of the tumor, such as the amount of matrix present within the tumor and whether bone or cartilage is predominant. The classification of the osteosarcoma variants relies more on the clinical correlation, such as the site of disease (ie, jaw, skull, or pelvis), the setting in which the disease presents (ie, postradiation, Paget disease, multifocal, and retinoblastoma), and the morphology, such as telangiectatic, small cell, malignant fibrous histiocytoma (MFH) of bone, dedifferentiated chondrosarcoma, and surface lesions such as parosteal, periosteal, and high-grade surface osteosarcoma.

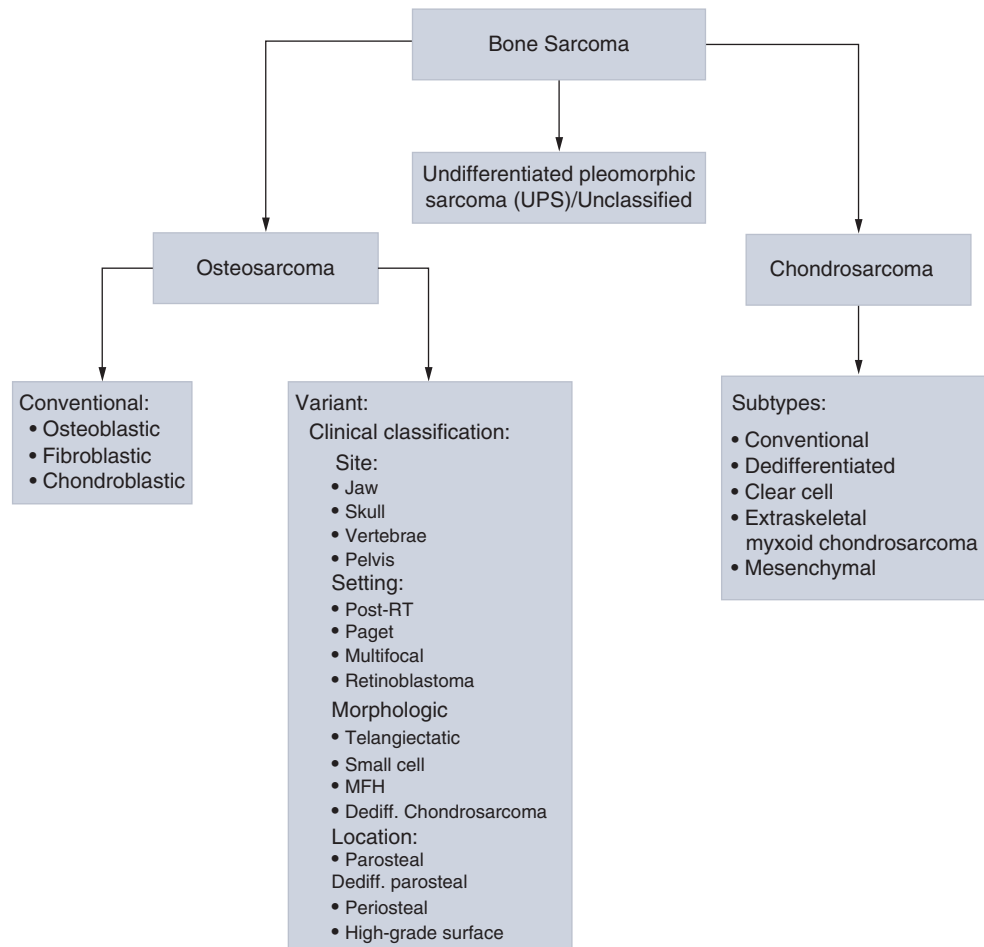

FIGURE 42-6 Pathologic classification of bone sarcomas. Dediff, dedifferentiated; MFH, malignant fibrous histiocytoma; RT, radiotherapy. (Visual Art: © 2015 the University of Texas MD Anderson Cancer Center).

High-grade osteosarcomas demonstrate significant genomic instability and therefore possess complex and heterogeneous chromosomal alterations. Copy number loss or gain in multiple chromosomes as well as amplifications in the *MDM2* gene, *CDK4*, *MYC*, and *VEGF* have been described. To date, sequencing of osteosarcomas has yet to identify effective molecular targets⁽¹⁰⁶⁾.

Malignant fibrous histiocytoma of bone is similar to MFH of soft tissue histologically and often appears to constitute the high-grade component of dedifferentiated chondrosarcoma. Malignant fibrous histiocytoma is thought to be part of a spectrum of osteosarcoma where the spindle cells do not produce osteoid visible by light microscopy; however, it may become possible to visualize these at some time in the future, especially following chemotherapy in responding tumors.

Chondrosarcomas are malignant tumors of bone characterized by cartilaginous proliferation. These tumors produce chondroid matrix and can arise from benign processes such as enchondroma. Chondrosarcoma is characterized by the permeation of cartilage into the bone marrow. This process is virtually pathognomonic for chondrosarcoma. Dedifferentiated chondrosarcoma is a unique subset of chondrosarcomas typified by a low-grade conventional chondrosarcoma juxtaposed with a high-grade soft tissue component. Several less common variants exist including mesenchymal chondrosarcoma and clear cell chondrosarcoma. Next-generation sequencing has identified somatic mutations in isocitrate dehydrogenase 1 and 2 (*IDH1/2*) in central conventional chondrosarcomas and dedifferentiated chondrosarcomas⁽¹⁰⁷⁾. This finding may aid in distinguishing chondrosarcoma from chondroblastic osteosarcoma and could serve as a unique therapeutic target⁽¹⁰⁸⁾.

Ewing sarcoma family of tumors (ESFT) represent a completely separate histology and are grouped with the PNETs due to their similarities in histology, immunohistochemical staining, and molecular genetics. This family of tumors includes Ewing tumors of bone, extraosseous Ewing tumors, PNETs, and Askin tumors (PNET of the chest wall). These tumors are often referred to as “small round blue cell tumors” because, under the microscope, the cells contain scanty cytoplasm and round to oval nuclei with fine chromatin that are tightly packed together. The ESFTs possess recurrent translocations involving the *EWS* gene, with identification of an *EWS* translocation considered pathognomonic in the diagnosis of ESFT. The translocation t(11;22)(q24;q12) *EWS-FLI-1* fusion was the first described and most common translocation. Several additional translocations have also been identified (see Table 42-7).

Bone sarcomas are classified as either high- or low-grade lesions, similar to the three-tier grading system of soft tissue sarcomas. Grading is an important factor

that helps to determine the overall stage and prognosis. Finally, the pathologist should be provided with the diagnostic imaging and x-ray findings because these provide important information to assist in making a final diagnosis in bone sarcomas.

Staging and Prognosis

There are two widely accepted staging systems, that of the AJCC and that of the Musculoskeletal Tumor Society^(109, 110). In a comparison of these systems, there was no significant difference between them, and neither had any notable advantage⁽¹¹¹⁾. At MDACC, instead of routinely using a staging system, we prefer to emphasize prognostic factors (eg, size of the primary, location and extent of bone involvement, soft tissue involvement, histologic grade, and presence or absence of distant metastases). The prognosis of patients with bone sarcomas largely depends on the specific histology, grade, location, and presence of metastatic disease. The most important and well-established prognostic factor for patients with bone sarcoma is the percentage of tumor necrosis achieved with preoperative chemotherapy.

Treatment

The treatment of bone sarcomas is best accomplished by a multidisciplinary team comprising medical oncologists, surgical oncologists, pathologists, and radiation oncologists working together to provide comprehensive care. The treatment required depends on the tumor type, location, and extent of disease. Treatment algorithms for high-grade bone sarcomas and Ewing sarcoma are shown in Figs. 42-7 and 42-8.

Osteosarcoma

Osteosarcoma is the prototype of most other bone sarcomas. Chemotherapy is the mainstay of treatment for osteosarcoma, which is considered a systemic disease, because most patients have micrometastatic disease at presentation. This is evidenced by the historic long-term survival rate of <20% in patients treated with surgery alone as compared to the nearly 70% cure rate among patients with localized osteosarcoma of an extremity treated with aggressive combination chemotherapy followed by adjuvant surgery⁽¹¹²⁾.

At MDACC, adolescent and adult patients with conventional high-grade osteosarcoma of an extremity receive treatment consisting of preoperative chemotherapy followed by limb-sparing surgery, followed by postoperative chemotherapy (see Fig. 42-7). The postoperative therapy is tailored based on the knowledge of the percent necrosis found in the pathologic

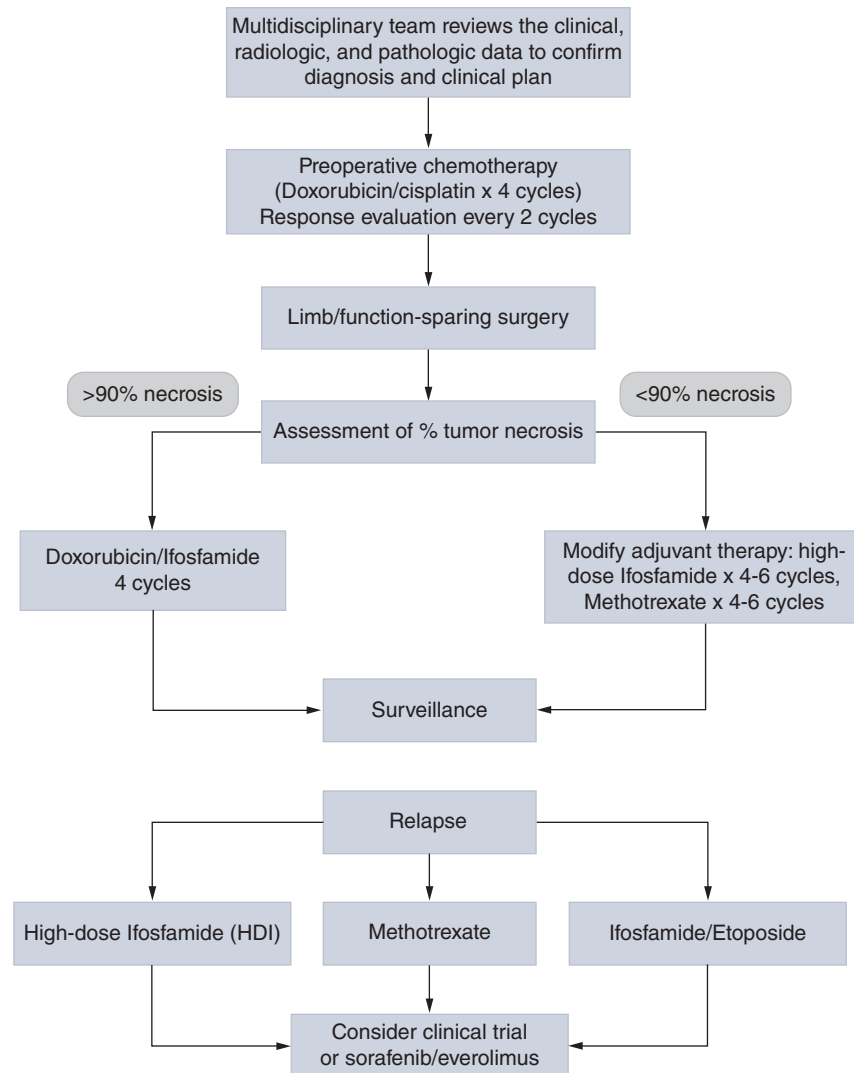

FIGURE 42-7 Treatment approach for high-grade primary bone sarcomas. (Visual Art: © 2015 the University of Texas MD Anderson Cancer Center).

specimen after surgery. This approach is based on a series of patients treated within our center in which tailored postoperative therapy demonstrated improved survival and differs from the current standard treatment of pediatric osteosarcoma ⁽¹¹³⁾.

The most active agents for the treatment of osteosarcoma are cisplatin, doxorubicin, ifosfamide, and high-dose methotrexate ⁽³⁴⁾. Intra-arterial administration of cisplatin (120 mg/m²) in combination with doxorubicin (90 mg/m² continuous infusion over 96 hours) given preoperatively has been studied by investigators at MDACC ⁽¹¹²⁾. Imaging of osteosarcoma has limited utility in response assessment; the percentage of tumor necrosis is the single most important predictor of long-term disease-free and overall survival ⁽¹¹⁴⁾. Generally, patients with ≥90% tumor necrosis after preoperative chemotherapy have a 5-year continuous disease-free survival of approximately 80% ⁽¹¹²⁾.

The 5-year continuous disease-free survival of patients with <90% tumor necrosis after preoperative chemotherapy is significantly worse, ranging from 13% up to 67% depending on the postoperative chemotherapy regimen ⁽¹¹²⁾. To address this, we analyzed a consecutive series of 123 patients with osteosarcoma of the extremity treated within our center who were divided into three cohorts based on the time period in which they were treated and the postoperative chemotherapy given. All patients received preoperative doxorubicin and cisplatin induction. Patients received the sequential addition of high-dose methotrexate (8 g/m²) and then methotrexate plus ifosfamide postoperatively in the second and third groups depending on the time period in which they were treated. Among patients with ≥90% tumor necrosis, relapse-free survival was not significantly different among the three groups. In patients with poor response, with <90% tumor necrosis, the

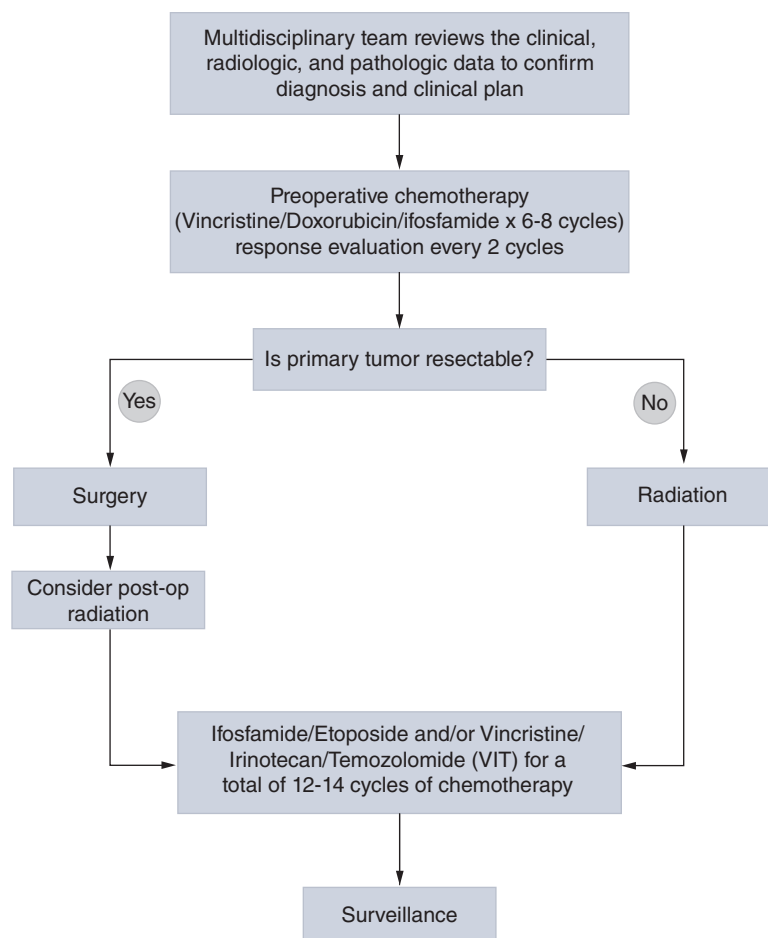

FIGURE 42-8 Treatment approach for patients with Ewing sarcoma/primitive neuroectodermal tumor and mesenchymal chondrosarcoma. (Visual Art: © 2015 the University of Texas MD Anderson Cancer Center).

addition of methotrexate and then methotrexate plus ifosfamide improved the 5-year relapse-free survival from 13% to 34% and 67%, respectively⁽¹¹³⁾.

The role of postoperative switch therapy or intensified therapy among patients guided by histologic response to preoperative chemotherapy remains controversial. In the EURAMOS-1 study, 618 patients with high-grade osteosarcoma who received preoperative methotrexate, doxorubicin, and cisplatin (MAP) with $\geq 10\%$ viable tumor at surgery were randomized 1:1 after surgery to receive either continuation of MAP or intensification with the addition of ifosfamide and etoposide to the same MAP backbone (MAPIE)⁽¹¹⁵⁾. Intensification with MAPIE failed to show an advantage in terms of event-free survival (HR, 1.01) and overall survival (HR, 0.99) and was associated with additional toxicity at a median follow up of 4.5 years.

For patients who achieve $\geq 90\%$ tumor necrosis with four cycles of doxorubicin and cisplatin preoperatively, we recommend four additional cycles of doxorubicin (75 mg/m^2) combined with ifosfamide (10 g/m^2). For those with $< 90\%$ tumor necrosis after preoperative

doxorubicin and cisplatin, we favor six cycles of high-dose ifosfamide and six cycles of high-dose methotrexate given sequentially.

Patients with high-grade osteosarcomas of other sites are treated in a similar fashion; however, their overall outcome appears to be worse than that of patients with extremity tumors. This may be due in part to poor sensitivity to the chemotherapy agents and also to difficulties in achieving a negative surgical margin of resection owing to anatomic constraints. Patients with low-grade and variant osteosarcomas—such as well-differentiated intramedullary osteosarcoma or parosteal osteosarcoma and jaw osteosarcoma, typically arising in the mandible, which have a lower tendency to produce distant metastases—are treated with surgical resection with negative margins alone without routine use of adjuvant chemotherapy. If surgical resection with negative margins cannot be achieved in osteosarcoma of the jaw, preoperative chemotherapy should be considered. Patients with intermediate-grade periosteal osteosarcoma should also receive preoperative chemotherapy.

Malignant fibrous histiocytoma of bone is treated according to the same basic principles as conventional osteosarcoma. Studies performed at MDACC showed that with preoperative doxorubicin and cisplatin, approximately 50% of the patients with localized MFH of bone had percent tumor necrosis of $\geq 90\%$ (¹¹⁶). The median survival was 23 months for all patients who received this preoperative regimen, with the patients who achieved $\geq 90\%$ having a median survival of 66 months and patients with $< 90\%$ necrosis having a median survival of 20 months. The European Osteosarcoma Intergroup had similar results in studies using doxorubicin and cisplatin preoperatively and postoperatively, with 5-year PFS and overall survival rates of 56% and 59%, respectively (¹¹⁷).

Extraskeletal osteosarcomas, chondrosarcomas, and Ewing sarcomas are treated in a similar fashion as soft tissue sarcomas. In our experience at the MDACC, extraskeletal osteosarcomas are not as responsive to chemotherapy as osseous osteosarcomas and do not respond to cisplatin or high-dose methotrexate, unlike their skeletal counterparts (¹¹⁸).

Metastatic and Recurrent Disease

Approximately 10% to 20% of patients with osteosarcoma present with metastatic disease. Lung is the most common site of metastasis in osteosarcoma; however, osteosarcoma can also metastasize to almost any bone in the body. Lymph node metastases are rare. Patients who have resectable pulmonary metastases are treated with curative intent with primary chemotherapy, as described earlier, followed by surgical resection of all lesions either at the same time or in staged operations. With this approach, patients have a 15% to 30% chance of long-term disease-free survival and potential cure. Patients with bone metastasis have a poorer prognosis, with therapy usually directed at palliation.

Relapse is seen in about 30% of patients presenting with localized disease and up to 80% of patients who present with primary metastatic disease. Patients with relapsed or recurrent disease are approached similarly to patients with primary metastatic disease with chemotherapy and/or resection when possible. Several agents have demonstrated some activity in relapsed or refractory osteosarcoma including gemcitabine alone or in combination with docetaxel; ifosfamide or cyclophosphamide in combination with etoposide; as well as others. Targeted therapies are under investigation in osteosarcoma. The multikinase inhibitor sorafenib demonstrated benefit in a phase II trial of relapsed osteosarcoma, with a PFS of 46% at 4 months and clinical benefit rate of 29% (¹¹⁹). Subsequently, a phase II trial of sorafenib and everolimus demonstrated 45% PFS at 6 months, but failed to meet its prespecified end point of 50% PFS at 6 months (¹²⁰).

Chondrosarcoma

Chondrosarcomas are resistant to most chemotherapeutic agents used for the treatment of bone sarcomas. Surgical resection is the primary treatment modality, regardless of the grade of the tumor. Conventional chondrosarcoma patients with unresectable/metastatic disease should be enrolled onto clinical trials, and genomic profiling should be considered for potential target identification. Unlike other chondrosarcoma subtypes, mesenchymal chondrosarcoma and dedifferentiated chondrosarcoma should be treated with multimodality therapy.

Dedifferentiated chondrosarcoma is associated with low-grade chondrosarcoma, and foci of high-grade soft tissue sarcoma may resemble osteosarcoma of MFH of bone and are often thought of as variants of osteosarcoma (¹²¹). These tumors can respond to doxorubicin/cisplatin-based chemotherapy and are treated in the same manner as conventional osteosarcomas (¹²²), although tumor necrosis at resection is less than optimal compared to conventional chondrosarcomas. Patients with refractory/recurrent disease should be considered for clinical trials and molecular testing. Approximately 60% of dedifferentiated chondrosarcomas harbor mutations in the *IDH1* gene, which makes IDH oncometabolite inhibitors an attractive option to consider (¹²³). Mesenchymal chondrosarcomas are a rare variant that present in the jaw, spinal column, and ribs with lytic lesions on x-ray. The histology consists of a bimorphic appearance of benign to low-grade cartilaginous components with poorly differentiated small cell components (¹²⁴). The majority of these tumors harbor a unique *HEY1-NCOA2* fusion, which is thought to affect Notch signaling (¹²⁵). Mesenchymal chondrosarcomas do respond to chemotherapy; a recent series of 54 patients with localized disease treated with combination chemotherapy demonstrated a reduced risk of fracture (HR, 0.482; 95% CI, 0.213-0.996; $P = .046$) and death (HR, 0.445; 95% CI, 0.256-0.774; $P = .004$) (¹²⁶). This disease is treated in a similar fashion as Ewing sarcoma, discussed in the next section. In our experience, responsive tumors typically exhibit more calcification with an associated decrease in FDG avidity (when PET/CT is used for response assessment), and they are less apt to show decreases in tumor size, as opposed to Ewing sarcomas, which typically exhibit dramatic tumor size reduction. This makes RECIST a less reliable tool for adequate response assessment of mesenchymal chondrosarcoma.

Ewing Sarcoma

Like osteosarcoma, Ewing sarcoma and the PNET family of tumors are treated primarily with chemotherapy

prior to surgery, because patients with localized disease most likely have occult metastasis at the time of diagnosis. These tumors are extremely responsive to the following chemotherapeutic agents: doxorubicin, dactinomycin, ifosfamide, cyclophosphamide, vincristine, and etoposide. The most commonly used combinations are vincristine, doxorubicin, and cyclophosphamide (VAC); ifosfamide and etoposide (IE); and vincristine, doxorubicin, and ifosfamide (VAI). Multiple trials have shown that with these combinations of chemotherapy, survival rates greater than 50% can be achieved^(127, 128). At MDACC, we usually give vincristine (up to 2 mg) with doxorubicin (75-90 mg/m²) and ifosfamide (10 g/m²) as our preoperative chemotherapy regimen. This is followed by surgical resection, if possible, or radiation therapy. Ewing sarcoma is very radiosensitive; often, when surgical resection is not an option or positive margins remain, consolidative radiation therapy is used. Studies show good survival results in patients who have consolidative radiation therapy when needed⁽¹²⁹⁾. After definitive resection, tumor necrosis is assessed and postoperative therapy modified as needed (see Fig. 42-8). A recent retrospective review of 66 patients from our institution treated with chemotherapy and R0 resection identified histologic response (necrosis $\leq 95\%$), radiographic response by RECIST, and metastasis to be independent predictors of outcome⁽¹³⁰⁾. Based on these data, additional study is needed to determine the role of adjuvant radiation in patients with poor histologic response after preoperative chemotherapy and R0 resection.

Metastatic/Recurrent Disease

Metastatic or recurrent Ewing sarcoma is treated in a similar manner as metastatic or recurrent disease in osteosarcoma. Patients who have metastatic disease in their lungs at the time of presentation are treated as outlined earlier, with curative intent. Patients with recurrent or metastatic disease after primary therapy are treated on the basis of their disease-free interval. If there is a long interval (>12 months), a retreat of previous chemotherapeutic regimens, preferably at higher dose intensity (eg, high-dose ifosfamide), is reasonable. For patients with a shorter interval between therapy and recurrence or metastasis, investigational therapies are appropriate.

Targeted therapy for metastatic ESFT has recently focused on inhibition of the insulin-like growth factor 1 receptor (IGF1R). This tyrosine kinase receptor is expressed on the cell surface of Ewing sarcoma cells and is thought to play a key role in the pathogenesis of Ewing sarcoma⁽¹³¹⁾. Single-agent studies with IGF1R antibodies have only shown modest activity, with objective response rates ranging from 6% to 14%^(132, 133). To date, efforts focused on targeting the *ETS* tumor-specific gene fusions have been unsuccessful.

Giant Cell Tumor of Bone

Giant cell tumor of bone is another rare primary tumor of bone. Although considered benign, these tumors have a propensity for local recurrence to metastasize to lung. Tumors most commonly involve the epiphyses of long bones and usually result in pain, swelling, and decreased range of motion. Giant cell tumors appear as lytic, eccentrically located lesions in the epiphyses of a long bone on x-ray imaging. The primary treatment of giant cell tumors of bone consists of surgical intervention, either wide excision or intralesional curettage and cementation. Radiation therapy can be used as primary treatment or following surgery and has been shown to improve local control and disease-free survival, but has also been associated with an increased risk of malignant transformation⁽¹³⁴⁾. When the primary location precludes surgical resection due to morbidity or patients develop distant metastatic disease, consideration is given to systemic therapy⁽¹³⁵⁾. At MDACC, we have previously treated patients with interferon α -2b therapy with either 3 million units subcutaneously every day for 6 to 12 months or 10 million units subcutaneously every Monday, Wednesday, and Friday for 6 to 12 months⁽¹³⁶⁾. Clinicians should be aware, however, that these tumors respond gradually and can even grow initially on treatment and that often responses are not fully appreciated until after interferon therapy has been completed. More recently, denosumab, an antibody to the RANK ligand, which inhibits osteoclastic function and increases calcification, has been shown to improve pain in patients with recurrent or metastatic giant cell tumor. In a phase II study of denosumab in unresectable or recurrent giant cell tumor, treatment with denosumab resulted in tumor response in 86% of evaluable patients (defined as elimination of $>90\%$ of giant cells or no radiographic progression of target lesion for up to 25 weeks)⁽¹³⁵⁾. For patients with unresectable disease, we currently employ a combination of embolization, interferon, and denosumab on a case-by-case basis.

Follow-Up Management

Regular and long-term follow-up is essential. Patients are followed at MDACC with x-rays and physical examination every 3 months for the first 2 years, every 4 months for the next 2 years, every 6 months for the next 2 years, and then yearly thereafter. Surveillance includes high-quality chest imaging with either chest x-ray or chest CT in high-risk patients, plain films of the primary tumor site to evaluate for recurrence and stability of any prosthesis, and routine laboratories. Bone scans and/or PET/CT scans are useful in patients with specific symptoms or history of bony metastasis. Monitoring should also include an assessment of

the potential late effects of chemotherapy including anthracycline-induced cardiomyopathy, nephrotoxicity, neuropathy, and secondary malignancies.

THYROID CANCER

Introduction

Thyroid cancer is the most common endocrine malignancy. It has the highest incidence in the United States and is increasing worldwide. In 2014, approximately 63,000 new cases of thyroid carcinoma were diagnosed in the United States, accounting for 4% of all new malignant disease. Three of four all new thyroid cancer diagnoses are made in women, corresponding to the threefold higher rates seen in women between 2007 and 2011 (¹). Thyroid cancer occurs less frequently in children compared to adults, with a peak incidence of around 50 years. Despite this, overall long-term survival remains favorable (²). Histologic types (Table 43-1) include those that derive from the follicular epithelial cells (papillary and follicular), which account for the majority of thyroid cancers, and from the parafollicular C cells (medullary) (²). Other thyroid tumors, including primary lymphomas of the thyroid, which are usually metastases from other primary sites, are also encountered, although rarely.

EVALUATION OF SOLITARY THYROID NODULES

Introduction

Thyroid cancer usually presents as a nodule identified on physical examination or discovered incidentally on imaging studies performed for unrelated reasons. However,

most thyroid nodules are benign, with about 10% to 15% found to be malignant on biopsy (³). The main diagnostic challenge is accurately differentiating benign from malignant disease in order to ensure appropriate definitive therapy and avoid unnecessary treatments.

Diagnosis

Clinically palpable nodules are found in approximately 5% of the population (⁴). Benign and malignant nodules are almost always clinically indistinguishable. Features indicating increased likelihood of carcinoma are summarized in Table 43-2. Initial evaluation and management of patients presenting with thyroid nodules is detailed in Fig. 43-1.

Thyroid ultrasonography with fine-needle aspiration (FNA) and cytologic examination is the modality of choice for evaluating nodules with suspicious characteristics (⁵). Papillary, medullary, and anaplastic carcinomas can be readily diagnosed by FNA or biopsy, but distinguishing benign from malignant follicular lesions proves more difficult. Histologic examination showing capsular or vascular invasion is necessary to classify a lesion as malignant. Because follicular adenoma and carcinoma cannot be differentiated cytologically, they are grouped as “indeterminate or suspicious follicular neoplasms.” The rate of carcinoma for suspicious follicular neoplasms is about 20%. The incidence of malignancy increases with larger nodule size, male sex, and increasing age. Testing for molecular markers should be considered for patients with indeterminate or suspicious follicular neoplasm on cytology. Fifteen

Table 43-1 Types of Thyroid Cancer

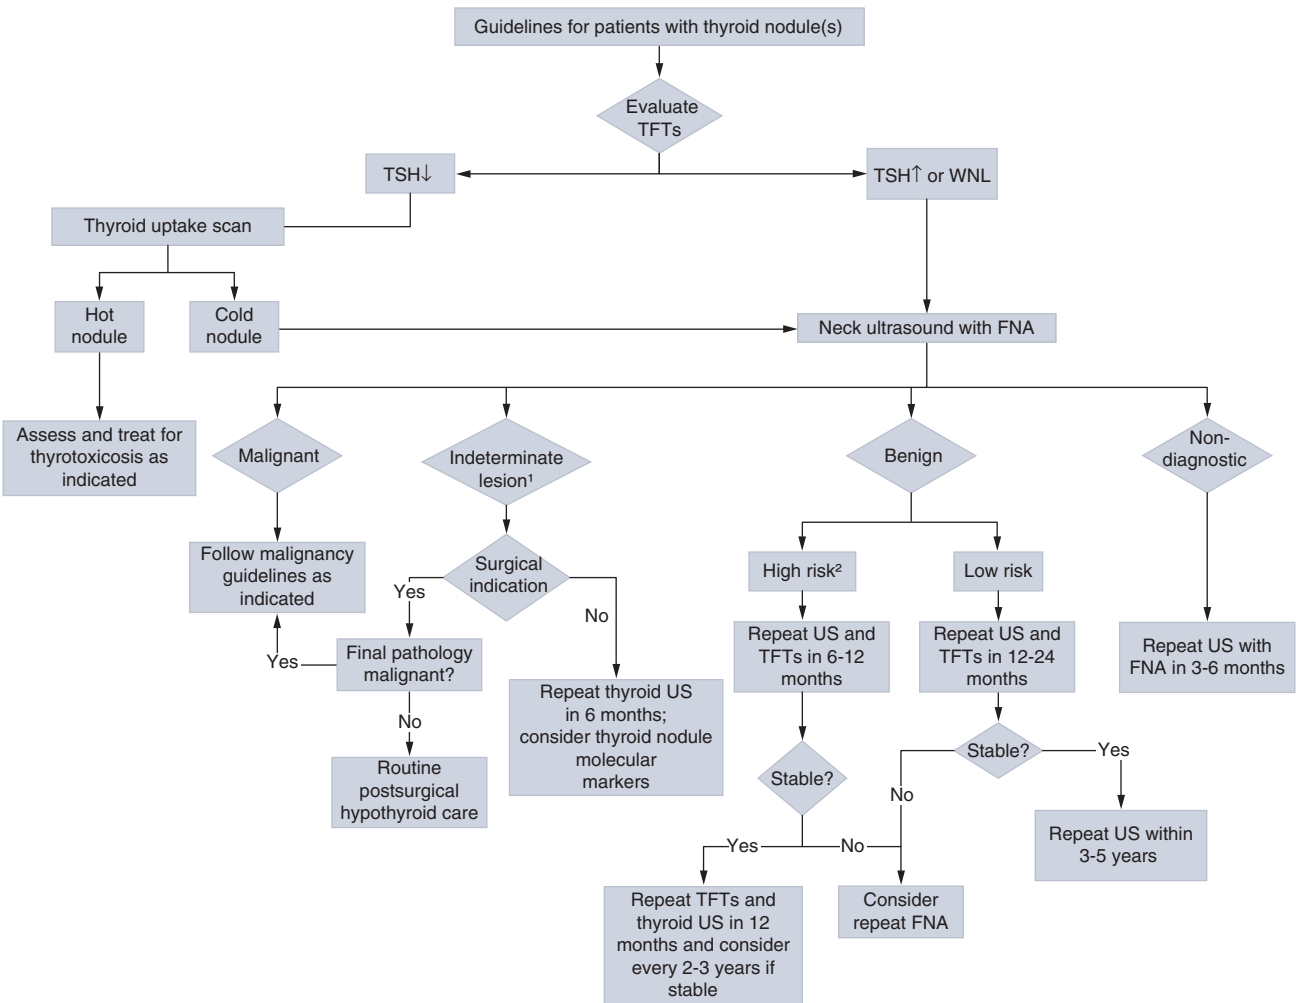

Type	Frequency	Prognosis (10-year overall survival)
Originating from follicular cells		
Papillary	80%	93%
Follicular	11%	85%
Hürthle cell	3%	76%
Anaplastic (undifferentiated)	2%	14%
Originating from C cells		
Medullary	4%	75%

Data from Hundahl SA, Fleming ID, Fremgen AM, Menck HR. A National Cancer Data Base report on 53,856 cases of thyroid carcinoma treated in the U.S., 1985-1995. *Cancer*. 1998;83(12):2638-2648.

Table 43-2 Clinical Features Associated With Increased Risk of Malignancy

Age <20 years
Presence of cervical lymphadenopathy
History of radiation to the head and neck during childhood
Family history of medullary thyroid cancer or MEN types 2A and 2B
Hard fixed nodule
Recent nodule growth
Hoarseness of voice (indicating invasion of recurrent laryngeal nerve)

MEN, multiple endocrine neoplasia.

¹Includes: suspicious for papillary, follicular neoplasm or lesion, Hürthle cell neoplasm, or lesion or atypical cells of undetermined significance.

²History of radiation exposure to the head and neck or family history of thyroid cancer.

FIGURE 43-1 Evaluation of thyroid nodules. FNA, fine-needle aspiration; TFT, thyroid function test; TSH, thyroid-stimulating hormone; US, ultrasound; WNL, within normal limits.

to 25% of the time, the FNA will yield “inadequate diagnostic material,” and this necessitates repeat aspiration. The majority (85%-95%) of thyroid nodules are benign. Radionuclide scans usually show malignant lesions as hypofunctioning or “cold,” although 85% of “cold” nodules are still benign.

DIFFERENTIATED THYROID CANCER

Introduction

Differentiated thyroid cancer (DTC) includes papillary, follicular, and poorly differentiated histology types and composes about 90% of all thyroid cancers (⁶). The factors associated with increased risk of thyroid carcinoma are summarized in Table 43-3.

Traditionally, exposure to ionizing radiation, family history, and genetic syndromes have been the main risks associated with DTC (^{7,8}). However, a recent meta-analysis of 21 observational studies suggests an association with obesity (adjusted relative risk [RR], 1.33; 95% confidence interval [CI], 1.24-1.42) (⁹). On average, thyroid tumors are recognized ten years following radiation exposure, but can be seen as long as 30 years. Malignancy occurs in up to 30% of cases with head or neck irradiation. Exposure to external sources of radiation after the Chernobyl nuclear accident led to a 3- to 75-fold increase in the incidence of papillary thyroid carcinoma (PTC) in fallout regions, especially in younger children (⁷). Familial PTC is reported in 5% of all patients with PTC and may portend a more aggressive disease course (^{9a}). Additionally, DTC has also been associated with other tumors, particularly breast and renal cancer (¹⁰).

Pathogenesis

Understanding the follicular cell tumorigenesis pathways is central to the development of novel therapies

Table 43-3 Risk Factors Associated With Differentiated Thyroid Carcinoma

Exposure to ionizing radiation, especially during childhood
Familial adenomatous polyposis (Gardner syndrome)
Carney complex
Werner syndrome
Cowden syndrome (phosphatase and tensin homolog [PTEN]-hamartoma tumor syndrome)
Pendred syndrome
Familial papillary thyroid cancer

to treat thyroid cancer. The MAPK pathway is the main oncogenic propagator of PTC. *BRAF* and *Ras* genes in this pathway normally code for growth and function in normal and tumor cells. Chromosomal rearrangements of the gene encoding the transmembrane tyrosine kinase receptors *ret* and *trk* have been implicated as an early step in the development of these tumors. Mutations in either *BRAF* (40%-60%) or *Ras* (10%-15%) or *RET/PTC* rearrangements (10%-15%) are present in most DTCs (^{11,12}) (Fig. 43-2).

Activating *ret* mutations may be the result of ionizing radiation and were the most common mutations found in the Chernobyl radiation-induced thyroid carcinomas (^{13,14}). *BRAF* mutation has been implicated in more aggressive disease and greater mortality from PTC (¹⁵). In addition, when present in combination with *BRAF*, a recent novel driver, telomerase reverse transcriptase (*TERT*) mutation, which is implicated in advanced thyroid cancer, results in the most aggressive PTC with the highest recurrence rate (^{16,17}). Of follicular thyroid cancers, 30% are driven by Pax8-peroxisome proliferator-activating receptor (*PPAR*)- γ rearrangements, and 10% to 15% are driven by *Ras* mutations (¹²).

Thyroid tumors are dependent upon angiogenesis, which is important for tumor cell growth, promotion and development of metastases (¹⁸). Vascular endothelial growth factor (VEGF), an important proangiogenic factor, binds to VEGF receptors. This then activates MAP-kinase signalling and promotes further tumor growth. Vascular endothelial growth factor receptors play a contributory role in the development and progression of thyroid cancer (¹¹).

Diagnosis

Thyroid cancer is subdivided into well-differentiated neoplasms characterized by slow growth and high curability and a small group of poorly differentiated

FIGURE 43-3 Classic histology for papillary thyroid carcinoma.

tumors with poor outcome. There are four major sub-types of thyroid cancer which are based on morphology and biological behavior. This classification is advantageous as it relates morphology to methods of treatment and prognosis.

Histologic characteristics of conventional PTCs include numerous papillae lined by cuboidal to low columnar follicular cells with enlarged irregular nuclei with longitudinal grooves, intranuclear cytoplasmic pseudoinclusions, and solitary or multiple marginally placed micronucleoli⁽¹⁹⁾ (Fig. 43-3). Follicular variant of PTC and other PTC variants are also recognized. Follicular tumors, although frequently encapsulated, can exhibit vascular and capsular invasion microscopically; it is this invasion that, when identified histopathologically, distinguishes benign neoplasms from malignant follicular neoplasms (Fig. 43-4). Hürthle cell carcinomas are considered a type of follicular cancer. Tall cell

FIGURE 43-4 Follicular carcinoma with invasion of capsule. Capsular and vascular invasion distinguish benign neoplasms from carcinoma.

variants, columnar cell variants, Hürthle cell variant, and insular type are histologic subtypes that may portend a worse prognosis.

Staging

The TNM (tumor, node, metastasis) method may be most useful for prediction of disease-free survival and is generally used in our institution. Tumor size and presence of extrathyroidal invasion carry prognostic importance and thus should consistently be included in the pathologist's synoptic report. Anaplastic thyroid carcinoma by convention is always stage IV (Tables 43-4 and 43-5).

Management

Surgical Management

Preoperative ultrasound of the entire neck (not just of the thyroid) is indicated to help identify the presence of nodal metastases and help the surgeon to perform the appropriate surgery. Total thyroidectomy is the preferred initial surgical procedure for most patients with DTC at our institution (Fig. 43-5). Arguments for total thyroidectomy rather than lobectomy are that: (1) papillary foci are seen in bilateral lobes in 60% to 85% of patients⁽²⁰⁾ and (2) 5% to 10% of recurrences of PTC after a unilateral lobectomy arise in the contralateral lobe⁽²¹⁾. A third reason that supports total thyroidectomy is that treatment with radioiodine and the specificity of serum thyroglobulin (Tg) concentrations as a tumor marker become most efficacious.

Consideration for lobectomy is reasonable in patients with no or low risk with localized small tumors⁽⁵⁾. Neck dissection should be performed on patients with identifiable nodal disease, because their presence impacts recurrence. Calcium and parathyroid hormone levels should be monitored postoperatively due to the risk of hypoparathyroidism from either vascular damage intraoperatively or inadvertent removal.

Postoperative Iodine-131 Therapy (Radioactive Iodine Treatment)

Iodine-131 (¹³¹I) is used as adjuvant therapy for thyroid carcinoma; iodine is preferentially taken up and trapped by the thyroid follicular cells and malignant counterparts. Iodine-131 destroys cells of follicular origin by first becoming concentrated in the cell where β rays are released, and the high-energy electrons spewed induce radiation cytotoxicity; simultaneously, γ rays are released that allow for detection of the emission by a camera. Therefore, postoperative examination with radioiodine scanning allows the identification of

Table 43-4 Staging of Thyroid Carcinoma

Primary Tumor (T)	
Note: all categories may be subdivided into (a) solitary tumor and (b) multifocal tumor (the largest determines the classification).	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension limited to the thyroid
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension limited to the thyroid
T3	Tumor more than 4 cm in greatest dimension limited to the thyroid or any tumor with minimal extrathyroid extension (eg, extension to sternothyroid muscle or perithyroid soft tissues)
T4a	Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
T4b	Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels
All anaplastic carcinomas are considered T4 tumors	
T4a	Intrathyroidal anaplastic carcinoma—surgically resectable
T4b	Extrathyroidal anaplastic carcinoma—surgically unresectable
Regional Lymph Nodes (N)	
Regional lymph nodes are those of the central compartment as well as lateral cervical and upper mediastinal lymph nodes.	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

residual regional or distant foci of disease, and radioiodine can be used therapeutically to ablate such tumor deposits. The rationale for using ^{131}I as adjuvant therapy is as follows: (1) it destroys any residual microscopic foci of disease, (2) it increases specificity of subsequent ^{131}I scanning for detection of recurrent or metastatic disease by elimination of uptake by residual normal tissue, and (3) it improves the value of measurements of serum Tg as a serum marker; hence, any elevation in Tg would be representative of recurrent or metastatic disease and not residual normal thyroid tissue (^{5, 6}). Combined retrospective data suggest that radioiodine ablation reduces long-term, disease-specific mortality in patients with primary tumors >4 cm in diameter or larger, those with multicentric disease, or those in whom there is evidence of soft tissue invasion at presentation (^{22, 23}). Low-risk patients (Fig. 43-5) may not benefit from radioiodine, and selective use is advocated in these patients. The use of postoperative Tg measured 1 to 2 months after surgery is a useful

tool to gauge residual or metastatic disease. Undetectable stimulated or unstimulated Tg indicates very low likelihood of residual disease. Nonstimulated Tg levels <5 ng/mL or stimulated Tg levels <10 ng/mL are also reassuring (²⁴). However, the decision to give ^{131}I should not rely solely on the level of Tg.

Postoperatively, patients who require ^{131}I therapy should be started on liothyronine (synthetic T_3) at 25 mg twice daily and discontinued 2 weeks prior to the radioiodine scan. Lower doses are given to elderly patients and patients with coronary artery disease. During this time, patients should avoid foods rich in iodine. Urinary iodine concentrations can be checked to assess total-body iodine content prior to the radioiodine therapy. For maximum radioiodine uptake, the thyroid-stimulating hormone (TSH) should be allowed rise to >30 $\mu\text{IU/mL}$ because this facilitates uptake of iodine by follicular cells. Increased iodide stores decrease radioiodine uptake. For patients in whom a preoperative contrast computed tomography (CT) was

Table 43-5 Stage Grouping for Thyroid Carcinoma

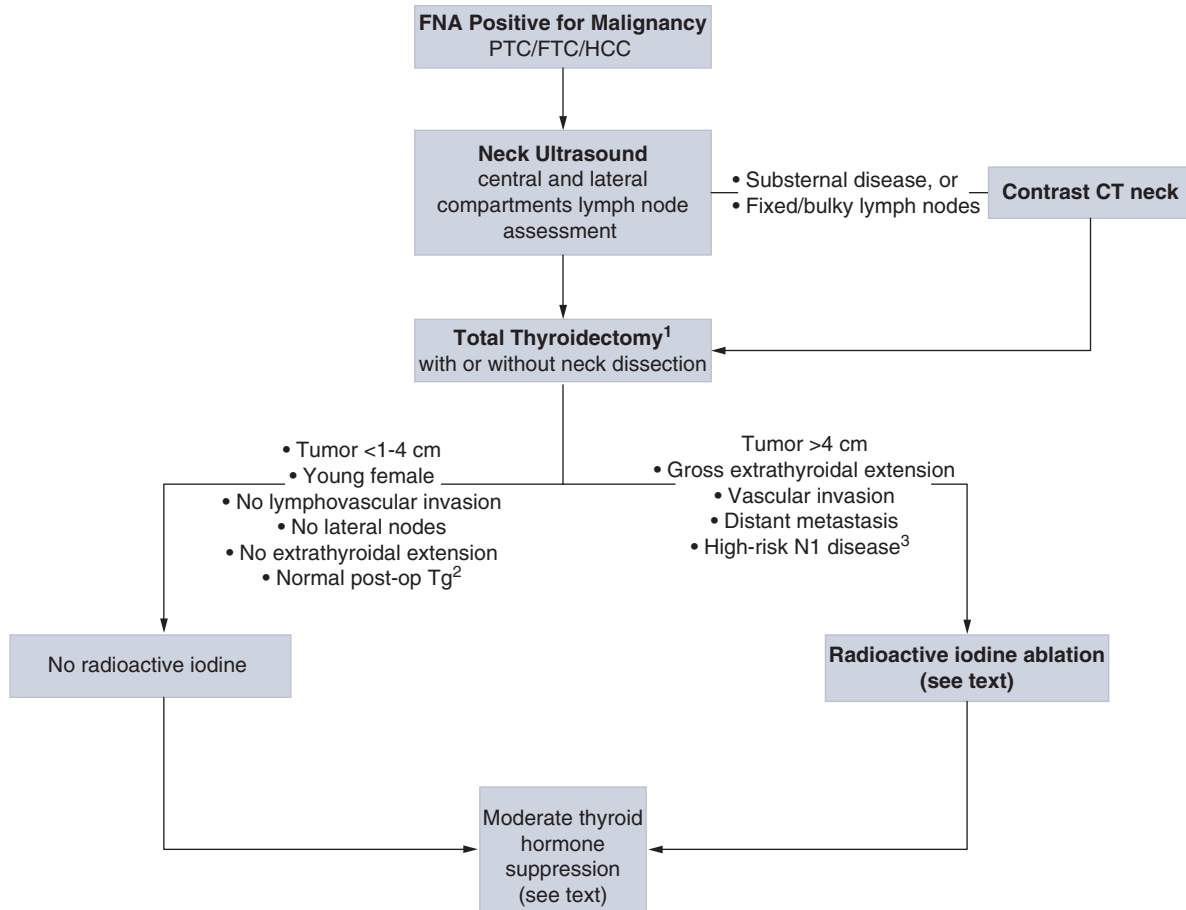

Separate stage groupings are recommended for papillary or follicular, medullary, and anaplastic (undifferentiated) carcinomas.			
Papillary or Follicular (<45 Years)			
Stage I	Any T	Any N	M0
Stage II	Any T	Any N	M1
Papillary or Follicular (≥45 Years)

done, radioiodine therapy should be avoided for at least 3 months. A pretreatment scan using a 2- to 5-mCi ^{123}I or ^{131}I radioiodine scan for localization of uptake prior to ablation is recommended but not mandatory. Twenty-four to 96 hours after dosing, a whole-body scan showing <5% uptake is presumed to be normal residual tissue. An uptake of more than 5% indicates excessive thyroid tissue and warrants consideration for further surgical resection. The dose of radioactive iodine is determined by extent of residual disease: 30 to 100 mCi for adjuvant ablation, approximately 150 mCi for nodal disease, and 200 mCi or more for metastatic disease outside the lungs (²⁴). A posttreatment scan is performed to assess for further uptake of radioactive iodine that was not previously seen on the pretreatment scan (ie, regional or distant metastases). The posttreatment scan is a more sensitive technique to detect

metastatic disease, because the ability to demonstrate radioactive iodine-avid lesions is directly proportional to the amount of radioactive iodine given (Fig. 43-6).

Short-term complications, although rare, include radiation thyroiditis, neck edema, sialoadenitis, and tumor hemorrhage. These occur more often in the presence of bulky disease. Long-term complications, which increase with cumulative doses, include xerostomia, nasolacrimal duct obstruction (²⁵), pulmonary fibrosis (if pulmonary metastasis is present and treated at high doses), and secondary malignancies such as acute myelogenous leukemia (²⁶). There are no reports of congenital abnormalities in children conceived after radioactive iodine treatment; however, most physicians recommend waiting for 6 months before conceiving. Radioactive iodine should not be given to pregnant women due to the potential teratogenic effects for the

¹Consider lobectomy for small tumors <4 cm; no history of radiation; no gross extrathyroidal extension; no cervical lymph node disease; age <4; no family history.

fetus's growth and thyroid development; all women of childbearing age must have a negative pregnancy test prior to treatment.

Thyroid Hormone Therapy

Thyroid hormone replacement targeting TSH suppression has been shown to increase disease-free survival two- to threefold, especially in high-risk patients. It minimizes potential TSH-stimulated growth of thyroid cancer cells. Oversuppression of TSH to undetectable levels can present morbid consequences including osteopenia, atrial fibrillation, and possible cardiac hypertrophy. Moderate TSH suppression (subnormal but not undetectable) during follow-up was associated with better outcomes in all stages, including those with distant metastatic disease ⁽²⁷⁾.

For high risk patients, moderate TSH suppression continued for the first 3 years after initial diagnosis may be indicated.

External Beam Radiotherapy

External beam radiotherapy (EBRT) has a limited role in the treatment of PTC. Our institutional review of post-operative conformal EBRT in high-risk DTC patients showed durable locoregional control in those with residual microscopic disease after initial surgery. However, patients with gross residual disease had significantly worse outcomes, and EBRT in these instances should be avoided ⁽²⁸⁾. Guidelines recommend consideration for EBRT in patients >45 years old with gross non-iodine-avid macroscopic disease in whom further surgery would not be beneficial ⁽⁵⁾.

FIGURE 43-6 Whole-body scan with iodine-131 (^{131}I) showing multiple metastatic deposits in the neck and lungs, with physiologic uptake in the salivary gland, stomach, intestines, and bladder.

Management After Initial Therapy

Imaging

Following initial therapy, patients with DTC need lifelong monitoring using both clinical and radiographic data. In high-risk patients, follow-up radioiodine scan 12 months after initial radioiodine ablation should be considered for reassessment of disease burden. The TSH should be allowed to

increase to a value >30 $\mu\text{IU/mL}$ by either withdrawal of thyroid hormone or using recombinant human TSH (rhTSH). Thyrotropin alfa, an rhTSH, administered as two injections on 2 consecutive days may be used in lieu of standard thyroid hormone withdrawal to increase thyrotropin concentrations and for adequate stimulation of both radioiodine uptake for scanning and serum Tg concentrations. The use of rhTSH is of particular benefit in the patient in whom endogenous TSH levels cannot rise due to hypopituitarism or in whom the clinician prefers to avoid prolonged hypothyroidism and its resultant complications due to concurrent medical problems. Radioiodine scanning beyond this first follow-up scan needs to be individualized and is no longer routine for all thyroid cancer patients including high-risk patients.

Ultrasonography of the neck (thyroid bed and cervical neck compartments) with FNA of suspicious accessible lesions is used 6 to 12 months postoperatively as part of routine follow-up.

Other non-radioiodine imaging techniques include CT of the neck and chest, chest radiographs, fluorodeoxyglucose (FDG) positron emission tomography (PET) or PET, and magnetic resonance imaging (MRI). Magnetic resonance imaging and CT of the neck play important roles in the detection of recurrent disease; they are not as sensitive as ultrasound but are much less operator dependent. Chest CT shows both micronodular and macronodular pulmonary metastases. Fluorodeoxyglucose-PET/CT imaging is useful in patients with a Tg >10 ng/mL who have negative radioiodine imaging but is not routinely used in follow-up of other thyroid cancer patients (⁵). Patients with DTC with little to no iodine activity generally have higher glucose metabolism and positivity on FDG-PET scans. Lack of iodine uptake denotes tumor dedifferentiation. Although PET is sensitive in detecting metastatic disease, it is not specific for thyroid cancer, and caution should be exercised when evaluating recurrent disease (Fig. 43-7). The use of CT imaging in conjunction with FDG-PET improves the sensitivity for small subcentimeter metastatic disease seen with DTC.

Monitoring Serum Thyroglobulin

Thyroglobulin is a unique protein synthesized only by the thyroid follicular cells (both benign and differentiated malignant tissue) and, therefore, is a good biochemical test to assess for the presence of residual, recurrent, or metastatic disease. Dedifferentiated tumors lose the ability to secrete Tg, and it cannot be used as a tumor marker. Following total thyroidectomy with or without radioiodine ablation, the Tg falls to its nadir usually within 3 months, but may take as long as 2 years. Subsequent Tg

FIGURE 43-7 Positron emission tomography (PET) scan showing posterior pharyngeal metastatic papillary thyroid carcinoma. Thyroglobulin level was 35 ng/mL, and radioiodine whole-body scan was negative for disease.

measurements (stimulated or unstimulated) are used to monitor for disease recurrence and should be repeated in the same laboratory to avoid erroneous misinterpretations of interassay variability (²⁹). Simultaneously Tg and Tg antibody (TgAb) should always be measured together because TgAb can falsely lower the Tg concentrations in immunometric assays. These antibodies, which are present in approximately 25% of patients, interfere with the assay's ability to bind to Tg. Thyroglobulin measurements by radioimmunoassay or liquid chromatography tandem mass spectrometry are more resistant to interference by TgAb and are used when antibody presence is detected. The median time to TgAb disappearance after total thyroidectomy and radioiodine ablation is about 3 years (³⁰). Therefore, increases in TgAb after the nadir has been reached should alert the clinician to the possibility of recurrent disease. Although in general the diagnostic accuracy of serum Tg is higher after TSH stimulation than during thyroxine treatment, an unstimulated Tg measured by second-generation assays may be used to follow up patients with stimulated Tg of

<2 ng/mL with no evidence of recurrent disease on imaging (³¹).

Metastatic Disease

Distant metastases are evident in about 15% of patients with DTC. Half of these patients have notable metastases at the time of initial presentation (¹²). The most common sites of metastasis, in decreasing order of frequency, are the lungs, bones, and other soft tissues (Figs. 43-8A, 43-8B, and 43-9). Older patients have a higher risk for distant metastases. For resectable locoregional and isolated metastasis, surgery is preferred.

In those with iodine-avid unresectable disease or distant metastasis, ¹³¹I treatment should be recommended, and higher doses (150-200 mCi) are typically used. Although this treatment may be repeated 6 to 12 months later, caution and careful monitoring for side effects should be exercised. Moderate TSH suppression should also be continued in these patients. Metastases at different sites require management by multimodality approaches. Bone lesions may be surgically resected or treated with ¹³¹I treatment or EBRT (³²). In follicular thyroid carcinoma, where the lesions are highly vascular, arterial embolization has been used anecdotally with successful reduction in pain at our institution. In addition, intravenous bisphosphonates (pamidronate or zoledronic acid) and denosumab are prescribed for painful bony metastases with some success. Experience at our institution also showed improved median survival for patients with one or more brain metastases after surgical resection. Stereotactic radiosurgery is also an option. We suggest a multidisciplinary approach and discussion with the surgeon, radiation oncologist, and endocrinologist about the risks and benefits of each modality in the management of metastatic disease.

Systemic Therapy

In patients with progressive metastatic disease that does not respond to standard therapy, long-term overall survival is <10%. For this subset of patients, the understanding of the molecular model for thyroid cancer and the discovery of targeted therapies have led to a new era of treatment (¹²). Consequently, over the last 5 years, two tyrosine kinase inhibitors (TKIs), sorafenib (2013) and lenvatinib (2015), have been approved by the US Food and Drug Administration (FDA) for the treatment of locally recurrent or metastatic, progressive DTC refractory to radioactive iodine treatment. Previously recommended cytotoxic therapies with agents such as doxorubicin have had poor outcomes with significant toxicities (¹²). The TKIs target intercellular signaling pathways (MAPK

FIGURE 43-8 A. A woman with metastatic follicular thyroid carcinoma to left humerus. B. Radiograph of metastatic follicular thyroid carcinoma to left humerus in the same patient.

pathway in the tumor cells) but also play a role in the surrounding tumor vasculature (¹²). Trials evaluating the efficacy of the approved drugs have shown better progression-free survival (PFS) than in the placebo groups (5 months with sorafenib and 14.7 months

with lenvatinib) (^{33,34}). The recently approved TKI lenvatinib had an overall response rate of 64.8% versus 1.5% in the placebo group (odds ratio, 28.87; 95% CI, 12.46-66.86). However, it is important to note the deleterious effects of these drugs, most commonly hypertension, gastrointestinal effects such as diarrhea, altered taste and stomatitis, palmar-plantar erythrodysesthesia syndrome (hand and foot syndrome), and weight loss.

Indications for therapy include patients with progressive or symptomatic unresectable disease that is refractory to ¹³¹I treatment. Patients with asymptomatic stable or very slowly progressive disease on thyroid hormone suppression may be closely monitored. Prior to initiation of therapy, a comprehensive evaluation to ascertain appropriate selection of patients should be conducted. This should include a candid discussion with the patient and family about the benefits and risks of these agents. Furthermore due to the life-threatening adverse effects of these drugs, only clinicians who are well versed with use of these agents should initiate and monitor these patients. We have previously published an adverse event monitoring tool used at our institution to guide clinicians initiating patients on these agents (³⁵).

FIGURE 43-9 Patient with multiple metastatic deposits of papillary thyroid carcinoma to the skin.

Differentiated Thyroid Carcinoma in Children

As in adults, PTC followed by follicular thyroid cancer occur most frequently in children. Exposure to radiation is the major risk factor. It is not unusual for children with PTC to present with multifocal disease with lymph node involvement, extrathyroidal extension, and pulmonary metastasis (³⁶). Despite this, children overall have high cure rates, with 10-year survival of almost 100%. Those diagnosed before the age of 10 years, however, seem to have a higher risk of recurrence and death. The treatment of thyroid cancer in children mirrors that of adults. Total thyroidectomy (rarely lobectomy) with nodal dissection done at a high-volume center due to higher complication rates is recommended (³⁶). Postoperative universal radioiodine therapy is no longer advocated, and careful selection based on risk of recurrence, residual or distant disease remaining after surgery, and Tg levels is used to determine the need for therapy (³⁶). Moderate TSH suppression (0.1-0.5 $\mu\text{IU/mL}$) with relaxation when there is no evidence of recurrent disease is suggested. Lifelong surveillance is essential in monitoring children for recurrent disease because recurrence may occur 20 to 30 years later. For the few children with progressive radioiodine-refractory DTC, referral to a center with pediatric endocrine neoplasia expertise for consideration for systemic therapy is recommended.

MEDULLARY THYROID CARCINOMA

Introduction

Medullary thyroid carcinomas (MTCs) are derived from C cells (calcitonin-secreting cells) that are part of neural crest origin (see Table 43-1). The majority—80% of patients with MTC have sporadic disease. The other 20% have an inherited form that occurs as an autosomal dominant trait as part of the multiple endocrine neoplasia (MEN) clinical syndromes, MEN type 2A or type 2B or familial MTC (³⁷). In MEN 2A, MTC occurs in association with pheochromocytoma and multigland parathyroid tumors; MTC is usually the first manifested disease of the three components of this syndrome. In MEN 2B, MTC occurs in association with pheochromocytoma and mucosal neuromas (Figs. 43-10A and 43-10B) or neurofibromas and marfanoid habitus. Familial MTC is a variant of MEN 2A where only MTC is clinically evident (³⁸). Most patients with sporadic MTC present in the fifth or sixth decade of life with a male-to-female ratio of 1.4:1.

FIGURE 43-10 A. Patient with multiple endocrine neoplasia (MEN) type 2B, with typical thickening of the palpebrum. Note also the ganglioneuroma on the left superior eyelid. B. Multiple ganglioneuromas on the tongue of a patient with MEN type 2B.

Clinical Features and Diagnosis

The most common clinical presentation of sporadic MTC is a solitary thyroid mass found incidentally during routine examination. Other symptoms such as secretory diarrhea and facial flushing may also be seen with hormone overproduction. Fine-needle aspiration should be performed for suspicious nodules, and once MTC is suspected, calcium, calcitonin, and

FIGURE 43-11 Gross specimen of thyroid gland containing medullary thyroid carcinoma.

carcinoembryonic antigen (CEA) levels should be obtained, with screening for pheochromocytoma and a thorough history and physical examination also performed. Because about 6% of patients with sporadic MTC carry a germline *RET* mutation, genetic counseling and testing are offered to all patients with newly diagnosed apparent sporadic disease⁽³⁹⁾. If pheochromocytoma is confirmed, appropriate control of catecholamine hypersecretion and removal should precede thyroid surgery.

Medullary thyroid cancer occurs as a solid mass or cluster of C-cell hyperplasia interspersed between normal thyroid follicles and can be visualized with calcitonin immunostaining. (Fig. 43-11). It appears as variable amounts of fibrosis as well as deposits of amyloid in 60% to 80% of tumors. Notably, even the smallest visible tumors can be associated with metastases.

Metastases to cervical and mediastinal lymph nodes are found in about 50% of the patients at the time of initial presentation. Distant metastases to the lungs, liver, bones, and adrenal glands most commonly occur late in the course of the disease (Fig. 43-12).

FIGURE 43-12 Gross specimen of liver containing metastatic lesions of medullary thyroid carcinoma.

Inherited Medullary Thyroid Cancer

Inherited syndromes of MTC are all transmitted in an autosomal dominant form. In kindreds with inherited MTC, prospective family screening is essential due to the 90% to 95% penetrance of the disease⁽⁴⁰⁾. In these cases, MTC is usually present by the third to fourth decade of life. The mutation is detected in *RET* and can be identified in 98% of affected family members with appropriate screening. Patients with MEN 2B tend to exhibit more locally aggressive MTC⁽⁴⁰⁾. Screening with *RET* testing is recommended at age <6 months for familial MTC, and MEN 2A screening is recommended by 5 years of age⁽³⁸⁾.

Analysis of the *RET* gene should include the most common sites of mutation, exons 10 and 11, and if no mutation is found, testing should proceed with exons 13 to 16^(38, 41). Appropriate genetic counseling must be a part of the initial evaluation, including the possibilities of errors in testing, the potential for discrimination, and changes that may occur in quality of life.

Management

Surgery

In MTC, there is a high propensity for bilateral disease in both the sporadic and familial forms, and therefore, the usual treatment is total thyroidectomy with central neck compartment dissection in all patients. In unilateral sporadic disease, if the primary tumor is greater than 1 cm or central compartment disease is present, strong consideration should be given to ipsilateral modified radical neck or mediastinal dissections, or both⁽⁴¹⁾. Bilateral neck dissections are usually performed in many institutions, including our own. Hypoparathyroidism and recurrent laryngeal nerve damage are the most frequently encountered complications in both children and adults. We recommend referral to centers with high volume and experienced surgeons to decrease these complications.

For carriers of a familial *RET* mutation, current guidelines recommend prophylactic total thyroidectomy by age 5 years or when the mutation is identified for adults, particularly for those with codon 609, 611, 618, 620, 630, or 634 *RET* mutations. For MEN 2B patients and patients with codon 883 *RET*, 918 *RET*, or compound heterozygous (V804M + E805K, V804M + Y806C, or V804M + S904C) *RET* mutations, prophylactic thyroidectomy is recommended in the first year of life or at diagnosis^(38, 41). For patients with less lethal MTC codon 768, 790, 791, 804, and 891 *RET* mutations, surgery can be delayed if stringent criteria are met and good follow-up is adhered to⁽⁵⁾.

There is no role for thyroid hormone suppression therapy; hence, the goal should be to maintain the TSH and free thyroxine (T_4) concentrations within

normal levels. There is also no role of radioactive iodine therapy in the treatment of MTC, and therefore, thyroid hormone replacement may be started immediately after surgery.

External Beam Radiotherapy

External beam radiotherapy should be considered for patients who are at high risk for locoregional recurrence, due to improved relapse-free rate⁽⁴²⁾. In general, 20 fractions totaling 40 Gy are given to the cervical, supraclavicular, and upper mediastinal lymph nodes over 4 weeks; subsequent booster doses of 10 Gy are then given to the thyroid bed, especially if there was gross residual disease⁽⁴¹⁾. External beam radiotherapy can also be given to treat painful skeletal metastases.

Monitoring and Follow-Up

Biochemical testing with serum calcitonin and CEA is used in the routine follow-up of patients with MTC. About 3 months postoperatively, these markers should be within the normal ranges (a nadir of 6 months has been reported). Patients with palpable recurrent/residual disease, in general, will have stimulated calcitonin levels of at least 10 pg/mL except for tumors that are dedifferentiated and no longer secrete calcitonin (these tumors usually secrete CEA). Values of serum calcitonin >100 pg/mL are indicative of residual neck disease or distant metastases particularly in the liver, and these patients should be aggressively assessed clinically and radiographically⁽⁴¹⁾. Because of MTC's propensity for neck, mediastinal, and liver metastasis, diagnostic imaging should include ultrasonography of the neck, CT of the chest, and MRI of the liver. Routine use of PET, metaiodobenzylguanidine (MIBG), and bone scans is not recommended.

Recurrent or Persistent Disease

Patients with stable and asymptomatic recurrent disease can be monitored closely without therapy. Once the disease is progressive, symptomatic treatment is recommended. For those with locoregional disease without metastases, surgery is preferred. Similar to metastatic DTC, treatment of individual metastatic sites causing symptoms or problems can be addressed individually (see earlier "Differentiated Thyroid Carcinoma" section). As with DTC, recently the FDA has approved two TKIs, vandetanib (2011) and cabozantinib (2012), for progressive metastatic MTC. Initiation of these therapies should be done by clinicians who are well versed with use of these agents and are able to monitor these patients closely.

ANAPLASTIC THYROID CARCINOMA

Introduction

Anaplastic thyroid carcinoma (ATC) is a locally and systemically aggressive undifferentiated tumor with a disease-specific mortality rate approaching 100%. More than 90% of patients are over the age of 50 years, and more females than males are affected.

Diagnosis

Anaplastic thyroid carcinoma most commonly presents as rapid growth of a thyroid mass. A history of long-standing thyroid enlargement is noted in about 80% of the patients. Fine-needle aspiration or surgical biopsy can usually establish the diagnosis. Preoperative imaging (CT of brain to pelvis including FDG-PET) to assess extent of disease and planning for surgery and/or radiation therapy is recommended but should not delay therapy. Vocal cord paralysis is common in patients with ATC and should be assessed. Anaplastic thyroid carcinoma frequently arises from preexisting well-differentiated thyroid carcinoma, which supports the opinion that some ATCs develop by dedifferentiation from well-differentiated DTC (Fig. 43-13). Immunohistochemical staining for Tg, TTF1, and paired box protein Pax 8 (PAX8) should be used to aid in identifying better-differentiated sections⁽⁴³⁾. However, because undifferentiated carcinoma cells lose their ability to synthesize Tg, Tg immunoreactivity in ATCs may be absent. Although various mutations are found in ATC including *TP53* and β -catenin (*CTNNB1*), *RAS*, *BRAF*, *PIK3CA*, and others, molecular testing is currently not required for diagnosis or management^(43, 44).

FIGURE 43-13 Hematoxylin and eosin staining of thyroid illustrating papillary thyroid carcinoma (black arrows) in transition to anaplastic thyroid carcinoma (white arrows).

Median survival is about 5 months, with 1-year survival of 20% ⁽⁴⁴⁾. Better survival rates are seen only in patients with well-localized anaplastic tumors. Favorable prognostic features seem to be age <60 years, tumor size less than 5 cm, extent of surgery, radiotherapy, chemotherapy, coexisting DTC, and absence of distant metastases ⁽⁴⁴⁾.

Therapy

Treatment is generally palliative in nature because ATC is rarely cured and almost always fatal. Death occurs from upper airway obstruction and suffocation in half of patients and complications of therapy or distant metastases in the others. A multidisciplinary thyroid cancer team approach is needed in the management of these patients. The potential risks and benefits of all treatment modalities including palliative care should be discussed with the patient and family.

For primary lesions with no distant metastases for which effective resection can be safely achieved, then surgery is recommended as first-line treatment followed by adjuvant conformal radiotherapy with or without chemotherapy. In the presence of distant metastases, primary tumor resection should be considered to avoid invasion of surrounding structures. For unresectable lesions, neoadjuvant conformal radiotherapy with or without chemotherapy should be considered first because this may render the tumor resectable ⁽⁴³⁾. Patients with poor performance status should be offered palliative doses of radiotherapy if tolerable. The chemotherapeutic agents doxorubicin, paclitaxel or docetaxel, and cisplatin are the currently recommended agents ^(45, 46). Combretastatin, an antimicrotubule agent, and TKIs including sorafenib, gefitinib, and imatinib have also been used with varied responses ⁽⁴³⁾. However, because no systemic therapies are known to improve survival or quality of life in advanced ATC, patients seeking an aggressive approach should be considered for participation in clinical trials.

PARATHYROID CARCINOMA

Introduction

Parathyroid carcinoma is a rare endocrine malignancy, with a prevalence of 0.005% of all cancers ⁽⁴⁷⁾. The etiology of parathyroid carcinoma remains largely unknown. No well-recognized risk factors have been identified. Predisposing factors identified with some cases are outlined in Table 43-6. Parathyroid carcinoma also occurs sporadically or as part of a genetic syndrome. Patients with parathyroid carcinoma are about a decade younger than patients with benign hyperparathyroidism. The disease occurs with similar frequency in both sexes.

Table 43-6 Risk Factors and Syndromes Associated With Parathyroid Carcinoma

Predisposing factors
Prior diagnosis of thyroid cancer
Prior hyperfunctioning parathyroid gland
Secondary and tertiary hyperparathyroidism resulting from chronic renal failure and dialysis
Radiation exposure to the head and neck region
Genetic syndromes
Multiple endocrine neoplasia type 1
Familial isolated hyperparathyroidism
Hereditary hyperparathyroidism-jaw tumor syndrome

Clinical Features

Hypercalcemia is common and ranges from mild to severe and may manifest with peripheral target organ complications such as kidney stones and osteoporosis. Parathyroid hormone levels are generally greater than five times normal, and patients may present with a discrete neck mass. However, parathyroid cancer is an uncommon cause of primary hyperparathyroidism. The presence of severe hypercalcemia (>12 mg/dL), extremely elevated parathyroid hormone, and a palpable neck mass should raise the suspicion for parathyroid cancer ⁽⁴⁸⁾.

Diagnosis

The presence of personal or family history of associated conditions and the constellation of clinical features described earlier significantly increase the likelihood of parathyroid cancer. Confirming the diagnosis prior to histologic confirmation remains challenging. Imaging modalities routinely used to aid diagnosis include parathyroid ultrasonography and technetium-99m sestamibi. Chest CT and bone scintigraphy may also be useful for initial staging ⁽⁴⁹⁾. FNA is not routinely recommended due to the risk of seeding the tumor and lack of sufficient sample to definitely make a diagnosis. Screening for mutations in the *CDC73* gene, which encodes parafibromin, a protein that inhibits mitogenic function, is considered an integral part of the diagnostic workup of patients with sporadic or familial parathyroid cancer. Patients with familial hyperparathyroidism are also considered at high risk for *CDC73* mutation and should also be screened.

Pathology

Histopathologic diagnosis following the World Health Organization (WHO) criteria is defined by the presence

of capsular invasion and soft tissue invasion or histologic evidence of vascular invasion with or without invasion of vital organs or presence of locoregional or distant metastasis⁽⁵⁰⁾. The classic histopathologic criteria initially described by Schantz and Castleman, including the presence of a trabecular or lobular pattern, mitotic figures, thick fibrous bands, and capsular or blood vessel invasion, are also still used today⁽⁵¹⁾ (Fig. 43-14).

However, in some cases, the histopathologic diagnosis still remains quite challenging, and some highly differentiated tumors without distinct nuclear atypia or classic histopathologic criteria are initially considered to be adenomas but are later reclassified when recurrence or metastases appear. Immunohistochemical staining for parafibromin may increase the diagnostic accuracy, and although not widely used, we have used this at our institution for various cases. Mutations in the *CDC73* gene are seen not only in the majority of patients with hyperparathyroidism-jaw tumor syndrome but also in cases of sporadic and familial parathyroid cancer^(52,53). Fifteen percent of the parathyroid tumors associated with HPT-JT are carcinomas⁽⁵⁴⁾. On the contrary, mutations in *MEN1* seldom result in parathyroid carcinoma. To improve the accuracy of diagnosis of malignant parathyroid disease, pathologic specimens of suspected cases should be reviewed by

experienced pathologists. We are currently exploring the role of molecular profiling of parathyroid cancer in prognostication and also to identify targetable mutations that could result in novel targeted therapies.

To date, there no currently agreed upon staging criteria for parathyroid carcinoma.

The 5-year survival rate has improved over the years to approximately 85%, and the 10-year survival rate is approximately 50%⁽⁴⁷⁾. Death usually results from hypercalcemia and its associated complications.

Management

Because of its rarity and unpredictable clinical course, a multidisciplinary approach to caring for the patient with parathyroid carcinoma that involves the endocrinologist, surgeon, oncologist, and radiotherapist offers the best chance for cure.

Preoperative suspicion and intraoperative identification of malignancy and appropriate initial surgery are critical in the therapy for parathyroid carcinoma. Comprehensive resection of the tumor along with the ipsilateral lobe of the thyroid and abnormal or involved adjacent tissues (the so-called “en bloc” resection) is indicated⁽⁵⁵⁾. Every effort should be made to maintain the integrity of the capsule to prevent seeding of tumor, because this will contribute to recurrence. Because this tumor does not typically metastasize to lymph nodes, routine lymph node dissection is not indicated unless involved by tumor. For recurrences, a wide excision of locally recurrent tumor and an aggressive surgical resection of metastases whenever possible are recommended. Although these repeat operations are not always curative, they usually offer palliation for the marked hypercalcemia (the cause of true morbidity in these patients) for a considerable although variable period. Nevertheless, surgical resection, where possible, remains the most effective treatment for both primary and recurrent disease.

Radiotherapy has not become the standard of care in patients with parathyroid carcinoma because it is difficult to prove its efficacy with such small numbers of patients being treated in reported series⁽⁵⁶⁾. It may be considered in select patients at high risk of local relapse (those with gross or local invasion or tumor spillage intraoperatively) or those left with gross disease.

Chemotherapeutic agents, as of yet, do not seem to be efficacious in this disease. We have had success with sorafenib in a patient with metastatic disease who has shown sustained improvements in hypercalcemia⁽⁵⁷⁾.

Morbidity and mortality are generally caused by the effects of unremitting hypercalcemia rather than tumor growth. Medical treatments, especially in patients with unresectable disease, such as bisphosphonates, denosumab, or calcimimetics, offer only

FIGURE 43-14 Parathyroid gland carcinoma.

temporary and palliative control of hypercalcemia. Lifetime surveillance of serum calcium and parathyroid hormone levels is essential because of the protracted and unpredictable course of malignant parathyroid disease.

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Introduction

The term pheochromocytoma refers to a neoplasm derived from chromaffin cells. Although the majority of these tumors occur in the adrenal medulla, about 15% to 20% of cases arises from sympathetic or parasympathetic ganglia and are known as paragangliomas. Pheochromocytomas and paragangliomas are rare, with an estimated incidence of 0.95 per 100,000 person-years⁽⁵⁸⁾, and they have a slight female predominance (54% female)⁽⁵⁹⁾. Although pheochromocytoma is a possible cause of secondary hypertension, it represents less than 1% of cases. Nonetheless, it is important to consider this diagnosis in the proper clinical setting because it is potentially curable. Furthermore, failure to treat or improper treatment can lead to serious complications or death (Fig. 43-15).

The rule of 10 is a classic teaching in regard to pheochromocytoma. This rule states that among pheochromocytomas, 10% are bilateral, 10% are extra-adrenal, 10% are familial, and 10% are malignant. However, this does not capture our current understanding. Data now suggest that nearly 25% of apparently sporadic pheochromocytomas are hereditary and associated with germline mutations such as *RET*, *VHL*, *SDHD*, and *SDHB*⁽⁶⁰⁾. These are patients who were thought to have sporadic disease but have a higher risk of bilateral disease, malignancy, or extra-adrenal disease on the basis of their germline mutation.

FIGURE 43-15 Adrenal gland with pheochromocytoma.

Table 43-7 Signs and Symptoms of Pheochromocytoma (list not all inclusive)

Hypertension	Anxiety
Headache	Constipation
Sweating	Nausea
Palpitations	Insulin resistance
Pallor	Orthostasis
Flushing	Weight loss

Clinical Features

The presentation of pheochromocytomas and paragangliomas ranges from incidental discovery to cardiovascular shock and death. A classic presentation is described as the five Ps. These five Ps are spells of pressure (hypertension), pain (headache), palpitations, perspiration, and pallor. Although none of these signs and symptoms is universally present, it is reasonable to screen patients with hypertension and symptomatology suggestive of hyperadrenergic episodes. The spells can last from minutes to hours and may be triggered by exercise, stress, micturition, Valsalva maneuver, or anesthesia induction (Table 43-7).

Additional findings include hyperglycemia (due to suppression of insulin release), orthostasis/volume depletion (due to vasoconstriction), and constipation/abdominal distention (due to inhibition of gut motility). Rarely, there is co-secretion of other hormones resulting in distinct endocrine syndromes. These include vasoactive intestinal peptide causing Verner Morrison syndrome, adrenocorticotrophic hormone (ACTH) causing Cushing syndrome, growth hormone-releasing hormone causing acromegaly, and parathyroid hormone-related protein causing hypercalcemia⁽⁶¹⁾ (Figs. 43-16 and 43-17).

Diagnosis

Laboratory

Biochemical testing is the cornerstone of diagnosis. At our institution, plasma-free metanephrines and 24-hour urine fractionated metanephrines are the two most commonly used laboratory tests to diagnose pheochromocytoma or paraganglioma. The high sensitivity and specificity of these tests are the main reasons they are preferred over alternatives such as plasma or urinary catecholamines, urinary total metanephrines, or urinary vanillylmandelic acid. For low-risk patients, however, the 24-hour urine fractionated metanephrines may be preferable in order to reduce the number of false-positive results. Of course, note should be taken of any drugs or other factors that may cause false-positive results^(62, 63) (Table 43-8).

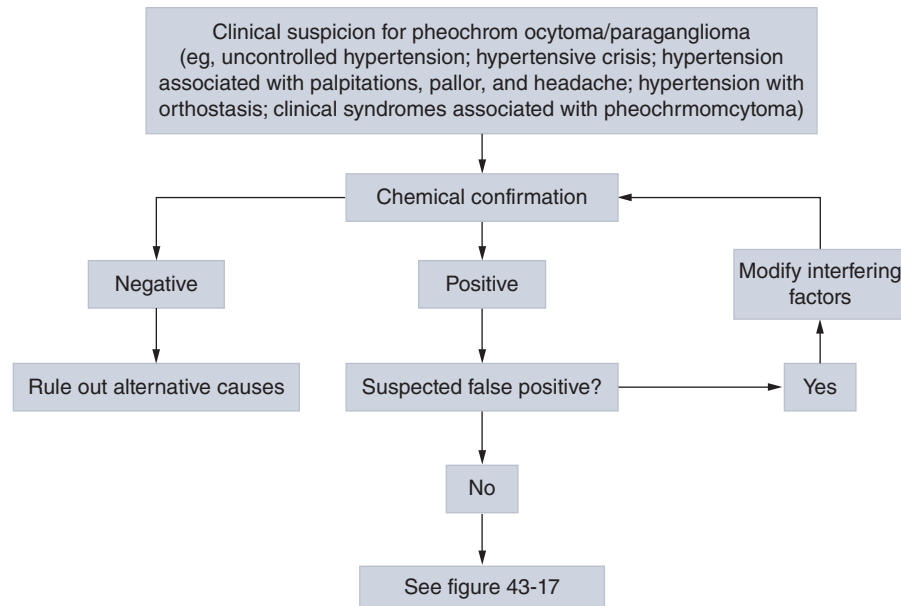

FIGURE 43-16 Biochemical confirmation of pheochromocytoma or paraganglioma.

Even in patients without signs or symptoms of pheochromocytoma or paraganglioma, testing is suggested in the following situations: (1) features or family history suggestive of syndromes associated with pheochromocytoma listed in [Table 43-9](#); (2) personal history of pheochromocytoma; or (3) adrenal incidentalomas.

Imaging

Imaging is not recommended for screening in the absence of biochemical evidence of pheochromocytoma or paraganglioma. However, once biochemical confirmation of the diagnosis is obtained, the next step is localization with imaging studies. Because the majority of pheochromocytomas and paragangliomas are located in the adrenal gland or elsewhere in the abdomen, cross-sectional imaging (CT or MRI) of the abdomen with attention to the adrenal glands has the highest yield. If an adrenal mass is not seen, the paraspinal region and urinary bladder should be carefully examined. Less commonly, extra-adrenal tumors may be located in the head and neck region.

There are certain imaging characteristics considered typical of pheochromocytoma or paraganglioma. Although helpful when present, their absence cannot be used to exclude the possibility that a mass is a pheochromocytoma or paraganglioma. On CT scan, they are usually heterogeneous with a density of greater than 10 Hounsfield units (HU) and delayed washout of contrast. On MRI, they are also usually heterogeneous and hyperintense on T2-weighted images with no dropout of signal on opposed phase imaging ⁽⁶⁴⁾. Functional imaging, such as MIBG scintigraphy or PET

scan, may be useful when cross-sectional imaging is nonlocalizing despite a high clinical suspicion. Because these tests are more often used to complement cross-sectional imaging when there is suspicion of metastases, they will be discussed in the section on malignant pheochromocytomas and paraganglioma ([Figs. 43-18](#) and [43-19](#)).

Genetics

Because pheochromocytoma and paraganglioma are associated with multiple familial syndromes (the majority of which are inherited in an autosomal dominant fashion), it is important to consider genetic testing. Features associated with familial cases include young age at diagnosis, positive family history, bilateral or multiple adrenal pheochromocytomas, and any paraganglioma. The syndromes in which pheochromocytomas or paragangliomas are seen include MEN type 2, familial paraganglioma syndromes, neurofibromatosis type 1, von Hippel-Lindau syndrome, Carney triad, and Carney-Stratakis syndrome ⁽⁶⁵⁾ (see [Table 43-9](#)).

Although some suggest genetic testing only in those with features suggesting a familial syndrome, others advocate more widespread testing due to a reported incidence of somatic mutations in more than 20% of patients with apparently sporadic disease. At our institution, genetic testing is performed on all patients with pheochromocytoma or paraganglioma. In any case, patients should always meet with a knowledgeable genetic counselor to discuss the risks and benefits prior to and after any familial testing. When a decision is

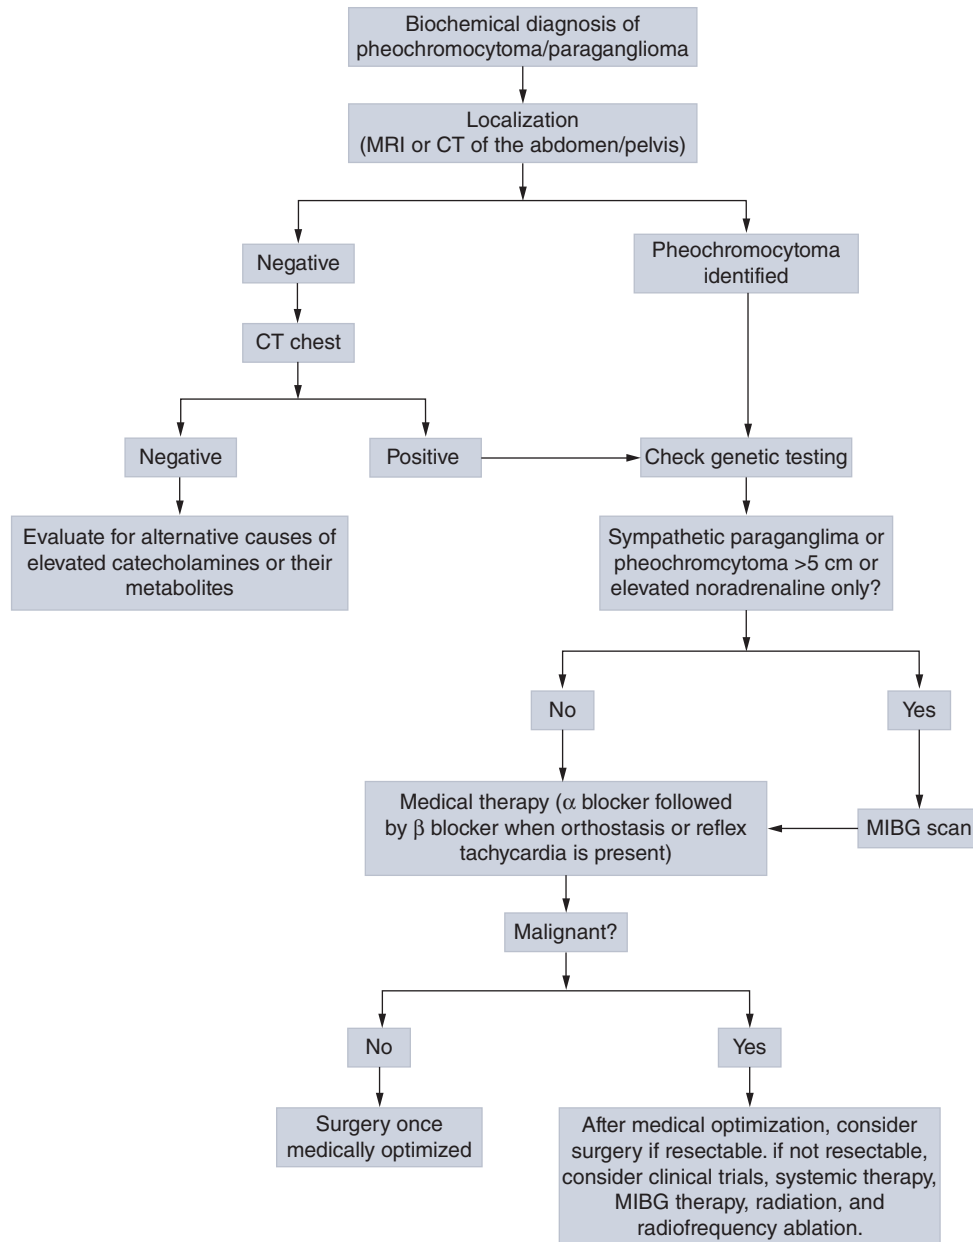

FIGURE 43-17 Algorithm for clinical approach to pheochromocytoma or paraganglioma following biochemical confirmation. CT, computed tomography; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging.

made to test, it is recommended that genetic testing be performed taking into account the most likely diagnoses rather than checking all mutations at once ^(60, 65, 66).

Therapy

Medical

Although surgery is the treatment of choice for pheochromocytoma or paraganglioma, patients must be medically optimized prior to surgery to reduce the risk of perioperative mortality. Preparation for surgery includes management of hypertension along with

volume expansion. The first step is initiating α blockade with either a nonspecific α -blocker (phenoxybenzamine) or a selective α -1 blocker (eg, doxazosin, prazosin, or terazosin) ⁽⁶⁷⁾. The dose is titrated until adequate control of hypertension is achieved without inducing severe orthostatic hypotension. Once the patient starts to develop orthostasis or reflex tachycardia, β blockade should be initiated. A high-sodium diet starting at the same time as α blockade is helpful for some patients to promote volume expansion. Medical optimization prior to surgery may be accomplished in 1 to 2 weeks. However, each patient is unique, and preparation may take longer for some patients.

Table 43-8 Potential Sources of False-Positive Laboratory Results for Pheochromocytoma

Related to time of collection
<ul style="list-style-type: none"> - Posture (fewer false positives if done supine after resting in a dark, quiet room for 30 minutes) - Nonfasting state - Exercise - Stress - Cold exposure - Hypoglycemia
Dietary or habits
<ul style="list-style-type: none"> - Caffeine - Nicotine - Alcohol - Ingestion of foods high in tyramine - Cocaine
Medications listed here are those most frequently encountered (many are test dependent)
<ul style="list-style-type: none"> - Tricyclic antidepressants (most other antidepressants can also interfere to a lesser degree) - Phenoxybenzamine - Labetalol - Acetaminophen - Amphetamines - Ephedrine - L-Dopa - Mesalamine - Sulfasalazine

Table 43-9 Syndromes Associated With Pheochromocytoma

Syndrome	Gene	Inheritance	Clinical Findings
MEN2a	<i>RET</i>	Autosomal dominant	Primary hyperparathyroidism, medullary thyroid carcinoma, Hirschsprung disease
MEN2b	<i>RET</i>	Autosomal dominant	Primary hyperparathyroidism, medullary thyroid carcinoma, mucosal ganglioneuromas, Marfanoid body habitus
Neurofibromatosis type 1	<i>NF1</i>	Autosomal dominant	Café-au-lait spots, axillary/inguinal freckling, neurofibromas, Lisch nodules, scoliosis, malignant nerve sheath tumors
von Hippel–Lindau syndrome	<i>VHL</i>	Autosomal dominant	Hemangiomas or the CNS, retinal angiomas, renal cell cancer, pancreatic neuroendocrine tumors, endolymphatic sac tumors
Carney triad	Unknown	Unknown	Gastrointestinal stromal tumors, pulmonary chondromas
Carney–Stratakis dyad	<i>SDHx</i>	Autosomal dominant	Gastrointestinal stromal tumors
Familial paraganglioma syndromes			
Paraganglioma syndrome 1	<i>SDHD</i>	Autosomal dominant	Head and neck parasympathetic paragangliomas (parent of origin effect—paternal)
Paraganglioma syndrome 2	<i>SDHAF2</i>	Autosomal dominant	Head and neck parasympathetic paragangliomas (parent of origin effect—paternal)
Paraganglioma syndrome 3	<i>SDHC</i>	Autosomal dominant	Head and neck parasympathetic paragangliomas
Paraganglioma syndrome 4	<i>SDHB</i>	Autosomal dominant	Renal cell cancer, papillary thyroid cancer, paragangliomas located in the chest/abdomen/pelvis

CNS, central nervous system; MEN, multiple endocrine neoplasia.

Data from Waguespack SG, Rich T, Grubbs E, et al. A current review of the etiology, diagnosis, and treatment of pediatric pheochromocytoma and paraganglioma. *J Clin Endocrinol Metab.* 2010;95(5):2023–2037; and Jimenez C, Cote G, Arnold A, Gagel RF. Review: should patients with apparently sporadic pheochromocytomas or paragangliomas be screened for hereditary syndromes? *J Clin Endocrinol Metab.* 2006;91(8):2851–2858.

FIGURE 43-18 This is a patient with multiple endocrine neoplasia type 2A and bilateral adrenal pheochromocytomas. The computed tomography (CT) scan (*left*) and CT angiogram (*right*) show a 1.6-cm pheochromocytoma in the medial limb of the right adrenal gland (*white arrowheads*) and a 4.6-cm pheochromocytoma in the left adrenal gland (*white arrows*).

Keep in mind that it is of utmost importance to avoid β -blockers before achieving adequate α blockade because lone β blockade leaves α receptors unopposed and open for activation by circulating catecholamines. This situation could potentially promote a hypertensive crisis. Although it is not currently the standard of care, calcium channel blockers have also been effective in the preoperative management of these patients (⁶⁷).

Surgical

Surgical resection following appropriate medical therapy is the primary mode of treatment for benign pheochromocytoma or paraganglioma. For smaller tumors, minimally invasive surgeries can reduce blood loss and hospital length of stay. As a result, the preferred procedures are laparoscopic or posterior retroperitoneoscopic adrenalectomy (⁶⁸). However, in some cases,

FIGURE 43-19 This is a patient with bilateral adrenal pheochromocytomas. These images are coronal views from a single photon emission computed tomography on the left and a metaiodobenzylguanidine scan on the right. They show increased uptake in the periphery of a cystic right-sided adrenal pheochromocytoma (*white arrows*) as well as a smaller left-sided adrenal pheochromocytoma (*white arrowhead*).

a larger tumor or a lack of local surgical experience with these techniques may make an open procedure preferable.

Close hemodynamic monitoring with pre- and intraoperative volume repletion is important to avoid hypotension following tumor resection. Short-acting intravenous vasodilators (eg, nitroprusside, nitroglycerine, phentolamine) may be needed intraoperatively to decrease the risk of precipitating a hypertensive crisis during tumor manipulation. Intravenous fluids should contain dextrose because patients are prone to hypoglycemia as a result of rebound insulin secretion following the precipitous drop in catecholamine levels after successful tumor resection. In patients who have pheochromocytoma associated with a germline mutation or bilateral adrenal disease, cortical-sparing adrenalectomy is the procedure of choice to minimize the risk of lifelong adrenal insufficiency. However, these patients require long-term follow-up because recurrence may develop many years after their primary surgery, and some may develop adrenal insufficiency despite a cortical-sparing technique^(69,70).

MALIGNANT PHEOCHROMOCYTOMA

Introduction

Unfortunately, there are no reliable clinical or pathologic features of the primary tumor that have been shown to consistently identify malignant pheochromocytoma or paraganglioma. As a result, the diagnosis can only be made after the discovery of metastatic disease. The most common sites of metastasis are the axial skeleton, followed by the liver, lymph nodes, lungs, and peritoneum. Although a generally quoted statistic is that 10% of pheochromocytomas are malignant, this is not true for all patients. In hereditary forms, rates less than 10% have been seen in patients with germline *RET* and *VHL* mutations. In contrast, rates in excess of 80% have been reported in patients with a germline *SDHB* mutation⁽⁷¹⁾.

In a large retrospective review, it was found that almost half of patients with malignant pheochromocytoma or paraganglioma are diagnosed with metachronous metastases (ie, they were thought to have benign disease until they were later found to have metastatic disease). This review identified tumor size (>5 cm) and site of primary tumor (infradiaphragmatic para-aortic paraganglia or the mediastinum) as being associated with a higher incidence of malignancy. However, there were no criteria that reliably excluded the possibility of malignancy⁽⁷²⁾, and newly noted metastatic

disease can be found up to 20 years after resection of an apparently benign pheochromocytoma^(73,74). It is for these reasons that lifelong surveillance of patients with seemingly benign pheochromocytoma or paraganglioma is always recommended.

Diagnosis

Because the diagnosis is made based on identification of metastatic disease, a combination of laboratory testing, imaging, and pathologic confirmation is generally relied upon. Typical staging studies include cross-sectional imaging (ie, CT or MRI) of the chest, abdomen, and pelvis. In the setting of malignant pheochromocytoma or paraganglioma, functional studies may be used to complement cross-sectional imaging. For example, MIBG scintigraphy has been used since 1981 to localize pheochromocytoma⁽⁷⁵⁾. Its usefulness is based on the fact that MIBG structurally resembles norepinephrine and is stored in the catecholamine-storage vesicles. For patients in whom dedifferentiation has occurred as well as patients with an *SDHB* mutation, PET scans using FDG have been a useful adjunct to cross-sectional imaging. Furthermore, 6-[¹⁸F]fluorodopamine PET scanning may have a role in the future but is not widely available^(75,76) (Fig. 43-20).

Given the rarity of this entity, precise data do not exist regarding prognosis. However, in a series of 10 patients with malignant pheochromocytomas, the

FIGURE 43-20 Metaiodobenzylguanidine scan showing uptake in recurrent malignant pheochromocytoma in the right adrenal bed (white arrow) as well as metastatic disease in the T2 vertebral body (white arrowhead).

5-year survival was reported as 20%, and all patients died within 10 years (⁷⁷).

Therapy

Medical/Surgical

Medical therapy is recommended following the same process as for benign tumors. For patients whose disease is potentially curable, surgery via an open approach is the preferred strategy. In patients for whom surgical cure is not feasible, palliative surgery may be recommended as needed for improved control of catecholamine secretion or for the prevention of complications related to the location of the disease. Because skeletal metastases are commonly seen, it is important to consider antiresorptive therapy to reduce the risk of skeletal-related events and associated morbidity (⁷⁸).

Radiation and Radiofrequency Ablation

If there is evidence of MIBG avidity, it can be used as a carrier for ¹³¹I delivery as targeted therapy. Although it is not widely available, it has shown efficacy in selected patients. Unfortunately, patients with MIBG-avid lesions will sometimes have additional nonavid lesions. Furthermore, the dose of radiation is limited by bone marrow toxicity. As a result, it is generally given with palliative intent (^{79, 80}).

External beam radiation can also be used for symptomatic relief of metastases not amenable to surgical resection. Retrospective studies have demonstrated improvement in symptoms but no dramatic response of the tumor on imaging (⁸¹). Radiofrequency ablation (RFA) has also been attempted in a limited number of patients with metastatic pheochromocytoma and can be considered as part of the treatment armamentarium (⁸²).

Chemotherapy

Traditional cytotoxic chemotherapy has been used with some success. Because these tumors are rare, there are no trials that definitively identify the most effective regimen. The regimens most often used are CVD (cyclophosphamide, vincristine, and dacarbazine) and CVAD (cyclophosphamide, vincristine, doxorubicin, and dacarbazine). In a retrospective review at a large cancer center, the response rate was 33%. Furthermore, the patients who responded to chemotherapy had a better overall survival compared with those who were nonresponders (6.4 vs 3.7 years) (⁸³). Although initial reports using a multityrosine kinase inhibitor (sunitinib) suggested partial short-term responses in a very small number of patients, data regarding the long-term efficacy and validation of these findings are still lacking (^{84, 85}).

ADRENOCORTICAL CARCINOMA

Introduction

Adrenocortical carcinoma (ACC) is a rare malignancy with significant morbidity and mortality. A review of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database found the majority of patients (87%) were Caucasian and diagnosis occurred at an average age of 51 years. A bimodal distribution of incidence was seen in the first and fourth decades of life. The age-adjusted annual incidence was 0.72 per million in the United States, and there was a slight female predominance (54%) (⁸⁶).

A review at our institution found that 42% of cases were hormonally productive, but there have been reports as high as two-thirds of cases. The majority of cases (55%) were associated with hypercortisolemia, and smaller numbers were associated with hyperaldosteronism or hyperandrogenism. Furthermore, the production of multiple hormones was present in almost 20% of these patients (⁸⁷). The various syndromes seen with functioning adrenal cancers are presented in Table 43-10. Of course, ACC can also present as a non-functioning tumor with only nonspecific symptoms of abdominal discomfort or pain, indigestion, or site-specific symptoms based on the location of metastatic disease.

Diagnosis

Laboratory

The suggested hormonal evaluation includes morning serum cortisol, ACTH, plasma renin activity, plasma aldosterone concentration, plasma free metanephrines, and 24-hour urine free cortisol. Additionally, total testosterone, dehydroepiandrosterone sulfate (DHEAS), and estradiol may be obtained if there is clinical suspicion of increased sex hormone secretion (ie, virilizing or feminizing features) (Fig. 43-21).

Imaging

Computed tomography or MRI of the chest, abdomen, and pelvis is generally the first step in staging. On CT, ACC is usually a large, heterogeneous mass with attenuation values greater than 10 HU showing heterogeneous contrast enhancement, poor contrast washout, and necrosis. Special attention should be devoted to assessment for metastatic disease in the lungs, liver, bones, and regional lymph nodes. The MRI appearance of ACC is also heterogeneous and hyperintense on T2-weighted images. As seen on CT, contrast enhancement on MRI is heterogeneous with poor washout. Of note, MRI is particularly useful in assessing for tumor

Table 43-10 Clinical Syndromes Associated With Functional Adrenocortical Carcinoma (ACC)

Clinical Syndrome	Suggestive Clinical Features	Suggested Laboratory Workup
Cushing syndrome	Obesity, moon facies, purple striae, cervical fat pads, easy bruising, myopathy, hypertension, diabetes mellitus	Plasma electrolytes, plasma glucose, adrenocorticotrophic hormone (ACTH), cortisol, 24-h urine free cortisol
Virilizing syndrome	Hirsutism, clitoromegaly, temporal balding, increased muscle mass, amenorrhea, male precocious puberty, advanced bone age in children	Dehydroepiandrosterone sulfate (DHEAS), testosterone, 17-OH progesterone
Feminizing syndrome	Gynecomastia, loss of libido	Estradiol, prolactin, testosterone
Hyperaldosteronism	Hypertension, hypokalemia	Plasma renin activity, plasma aldosterone concentration, plasma electrolytes, 18-OH corticosterone
Mixed syndromes	Combinations of features above	Testing as appropriate based on clinical features

Data from Ayala-Ramirez M, Jasim S, Feng L, et al. Adrenocortical carcinoma: clinical outcomes and prognosis of 330 patients at a tertiary care center. *Eur J Endocrinol*. 2013;169(6):891-899.

invasion of the inferior vena cava. Although FDG-PET scan is a sensitive tool for detecting malignant tissue, its low specificity limits its usefulness. However, FDG-PET can play an important role in the identification of metastatic disease in the setting of known ACC^(88, 89) (Figs. 43-22 and 43-23).

Pathology

Weiss proposed a scoring system consisting of nine criteria to aid in the diagnosis of adrenal cancer, and this has proved helpful in assessing malignant potential (Fig. 43-24). The criteria include: (1) mitotic rate

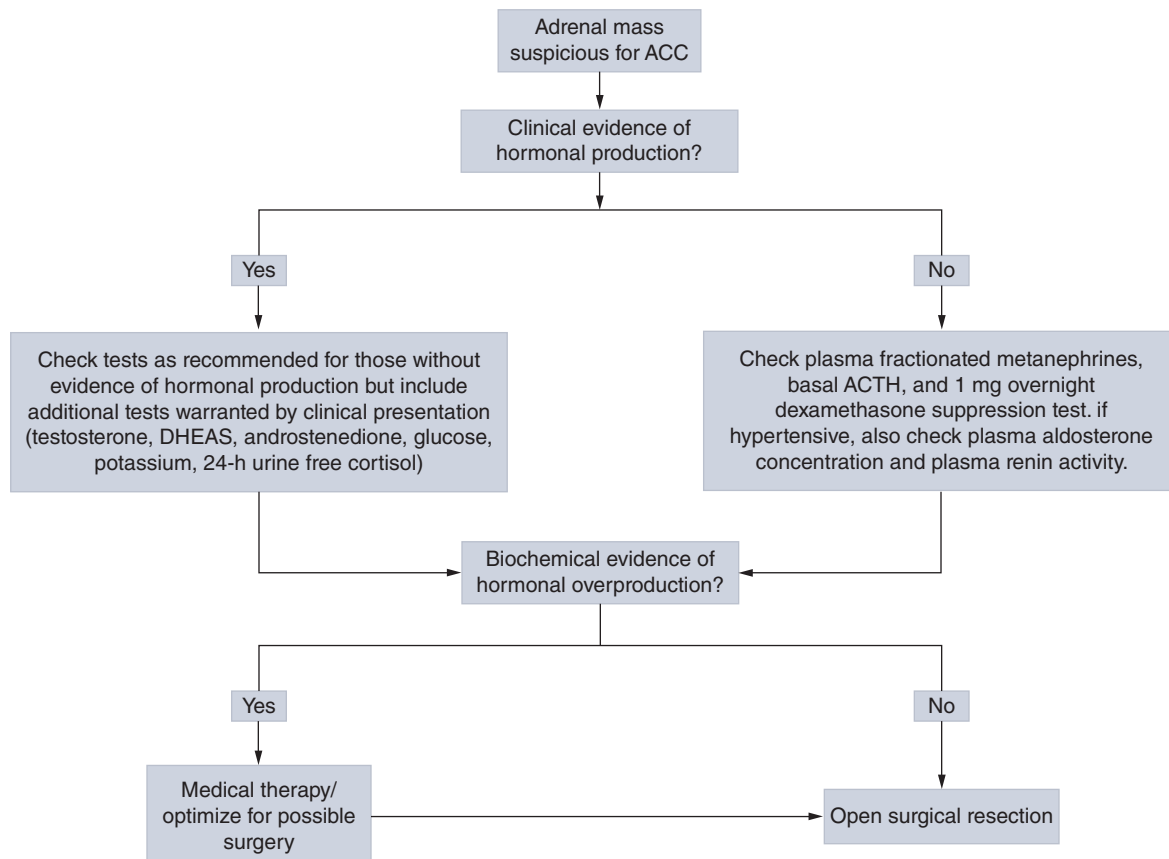

FIGURE 43-21 Hormonal testing for adrenocortical carcinoma (ACC). ACTH, adrenocorticotrophic hormone; DHEAS, dehydroepiandrosterone sulfate.

FIGURE 43-22 Coronal images from computed tomography (CT; left) and fluorodeoxyglucose–positron emission tomography/CT (right) showing left-sided adrenocortical carcinoma (white arrows).

greater than 5 mitoses per 50 high-power fields in the most active areas of the tumor, (2) atypical mitoses, (3) venous invasion, (4) clear cells comprising 25% or less of the tumor, (5) tumor necrosis, (6) nuclear grade

3 or 4 tumor (Fuhrman method), (7) diffuse (solid) architecture in more than one-third of the tumor, (8) invasion of sinusoidal structures, and (9) capsular invasion. The presence of three or more of these nine features is highly suggestive of ACC⁽⁹⁾. Despite this system, there remain borderline cases in which a systematic approach is needed to make a definitive diagnosis. The staging of ACC is detailed in Table 43-11. We have also found the use of Ki-67 expression useful in assessing prognosis.

In general, FNA of suspected ACC is not recommended due to the risk of seeding the needle track with tumor. However, FNA may be considered after pheochromocytoma has been ruled out in the context of a known primary malignant tumor with possible metastasis to the adrenal gland (ie, small cell lung cancer, breast cancer, renal cell cancer, and gastric cancer).

FIGURE 43-23 Fluorodeoxyglucose (FDG) positron emission tomography (PET) scan (coronal view) of a patient with adrenocortical carcinoma (ACC) showing FDG-avid left adrenal mass (white arrow) with bone metastases (arrowhead).

FIGURE 43-24 Liver metastases from adrenocortical carcinoma.

Table 43-11 Staging for Adrenocortical Carcinoma (ACC)

Stage	AJCC	ENSAT
I	Primary tumor ≤5 cm with no nodal or distant metastasis	Primary tumor ≤5 cm with no nodal or distant metastasis
II	Primary tumor >5 cm with no extra-adrenal spread	Primary tumor >5 cm with no extra-adrenal spread
III	Primary tumor not invasive but lymph node metastasis present or Primary tumor locally invasive without lymph node metastasis	Primary tumor not invasive but lymph node metastasis present or Primary tumor locally invasive or invading adjacent organs but without distant metastasis (lymph node metastasis may be present)
IV	Tumor locally invasive with lymph node metastasis or Tumor invading adjacent organs or Distant metastasis present	Distant metastasis present (no other requirements)

Data from Lughezzani G, Sun M, Perrotte P, et al. The European Network for the Study of Adrenal Tumors staging system is prognostically superior to the international union against cancer-staging system: a North American validation. *Eur J Cancer*. 2010;46(4):713-719; and Asare EA, Wang TS, Winchester DP, Mallin K, Kebebew E, Sturgeon C. A novel staging system for adrenocortical carcinoma better predicts survival in patients with stage I/II disease. *Surgery*. 2014;156(6):1378-1386.

Nonetheless, FNA is only recommended if it will alter the treatment strategy.

Genetics

An association has been observed between ACC and Li-Fraumeni syndrome, Lynch syndrome, Beckwith-Wiedemann syndrome. Very rarely has ACC been seen in association with MEN1, familial adenomatous polyposis, neurofibromatosis type 1, and Carney complex⁽⁹¹⁾. As a result, it is important to keep this in mind

when seeing patients with these syndromes as well as to keep these syndromes in mind when seeing patients with ACC (Table 43-12).

Prognosis

A diagnosis of ACC carries high mortality. A review of the National Cancer Institute's SEER database found a 1-year cause-specific mortality rate of 58% and a 5-year rate of 88%⁽⁸⁶⁾. However, long-term survival

Table 43-12 Genetic Syndromes Associated With Adrenocortical Carcinoma

Syndrome	Gene(s)	Inheritance	Common Clinical Findings
Li-Fraumeni syndrome	<i>TP53</i>	Autosomal dominant	Sarcoma, breast cancer, leukemia, brain tumors, radiation-induced cancers
Beckwith-Wiedemann syndrome	Multiple	Majority of cases are sporadic	Macrosomia, macroglossia, cleft palate, omphalocele, advanced bone age, Wilms tumor, hepatoblastoma
MEN1	<i>MEN1</i>	Autosomal dominant	Parathyroid adenoma, pituitary adenoma, pancreatic islet cell tumors, carcinoid, angiofibromas, collagenomas
Familial adenomatous polyposis	<i>APC</i>	Autosomal dominant	Colon polyps/cancer, pancreatic cancer, thyroid cancer, medulloblastomas, osteomas
Lynch syndrome	<i>MLH1, MLH2, MSH6, PMS2</i>	Autosomal dominant	Colorectal cancer, endometrial cancer, ovarian cancer, glioma, gastric cancer
Carney complex	<i>PRKAR1A</i>	Autosomal dominant	Primary pigmented nodular adrenocortical disease, lentigines, testicular cancer (Sertoli cell), thyroid cancer, pancreatic cancer, atrial myxoma
Congenital adrenal hyperplasia	<i>CYP21A2</i>	Autosomal recessive	Ambiguous genitalia, precocious puberty, infertility, hirsutism, electrolyte abnormalities

Data from Else T, Kim AC, Sabolch A, et al. Adrenocortical carcinoma. *Endocr Rev*. 2014;35(2):282-326; Libe R, Arlt W, Louisset E, et al. A feminizing adrenocortical carcinoma in the context of a late onset 21-hydroxylase deficiency. *J Clin Endocrinol Metab*. 2014;99(6):1943-1944; and Varma T, Panchani R, Goyal A, Maskey R. A case of androgen-secreting adrenal carcinoma with non-classical congenital adrenal hyperplasia. *Indian J Endocrinol Metab*. 2013;17(Suppl 1):S243-S245.

is possible in these patients if complete resection with tumor-free margins can be achieved. At our institution, the 5-year survival rate has been found to be 38%, with a median overall survival of 3.21 years for all patients. As is seen in many other cancers, survival is inversely correlated with disease stage at diagnosis. For example, those with stage I disease had a mean survival of 24.1 years as compared to 0.89 years for those with stage IV disease ⁽⁸⁷⁾.

Therapy

Surgical

Complete surgical resection is the most important treatment for ACC and offers the best chance for prolonged disease-free survival. If ACC is suspected, laparoscopic adrenalectomy is not recommended because it can result in early locoregional recurrence and peritoneal carcinomatosis. Furthermore, it may decrease the ability to achieve tumor-free margins or adequate lymph node dissection ⁽⁹²⁾. Tumor encasement of the celiac axis, aorta, or proximal superior mesenteric artery may make the tumor unresectable. In contrast, the presence of tumor thrombus in the inferior vena cava or renal vein, or tumor invasion of the pancreas, spleen, or kidney is not a contraindication for complete resection in selected patients. Although there is limited evidence of benefit from resection of the primary tumor in the presence of metastatic disease, there may still be a role for resection of the primary tumor and all visible metastases

in an otherwise young, healthy patient, especially in cases of symptomatic hormonally active tumors.

In corticosteroid-producing ACC, there is speculation that preoperative blockade of steroid production using agents such as ketoconazole or metyrapone may reduce postoperative morbidity. In these cases, the contralateral adrenal gland is usually atrophic, and patients may require peri- and postoperative corticosteroid replacement. In fact, relative adrenal insufficiency may last for months following successful resection.

Chemotherapy

In 1949, it was found that oral administration of the insecticide dichlorodiphenyltrichloroethane (DDT) to dogs caused selective necrosis of zona fasciculata and zona reticularis of the adrenal cortex. Since 1960, a DDT analog known as mitotane has been used to treat ACC. Research has shown that maintaining mitotane levels of 14 to 20 mg/L improve recurrence-free survival but not necessarily overall survival ⁽⁹³⁾. Mitotane is believed to be useful in the adjuvant setting and also for inoperable disease. Mitotane has even been used successfully in a small number of patients in the neoadjuvant setting, resulting in improved surgical outcomes ⁽⁹⁴⁾. In addition to adrenal toxicity, mitotane also increases corticosteroid-binding globulin and enhances steroid clearance. As a result, there are increased glucocorticoid requirements during mitotane therapy, and failure to adequately replace glucocorticoids can result in adrenal crisis. Furthermore, lipid changes have been well described in patients taking mitotane ⁽⁹⁵⁾ (Fig. 43-25).

FIGURE 43-25 These are chest x-rays of a patient with metastatic adrenocortical carcinoma. These images demonstrate the extent of disease before mitotane (*left*) and after mitotane (*right*).

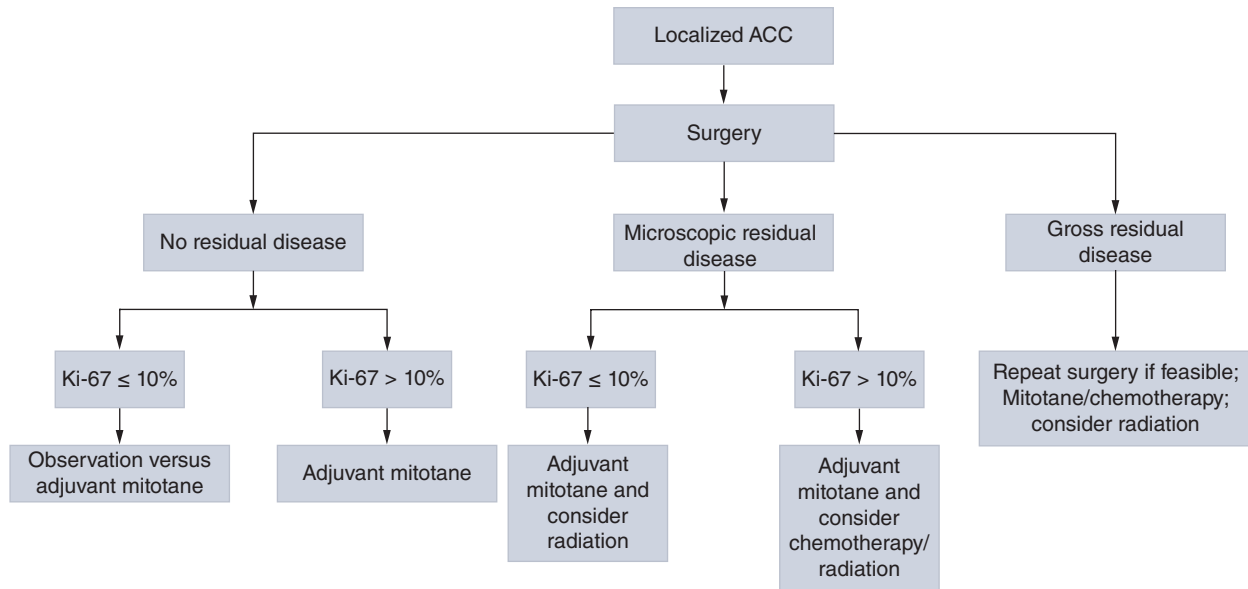

FIGURE 43-26 Management of localized adrenocortical carcinoma (ACC).

In terms of other chemotherapeutic agents, an international phase III study (FIRM-ACT) was carried out to compare mitotane plus EDP (etoposide, doxorubicin, cisplatin) with mitotane plus streptozotocin. In this study, it was found that mitotane-EDP showed better tumor response (23% vs 9%) and PFS (5.3 vs 2.1 months). However, there was no significant improvement in overall survival (⁹⁶). Our

current practice in managing ACC is summarized in Figs. 43-26 and 43-27.

Targeted therapies are also a fertile area for clinical investigation. Potential candidates include insulin-like growth factor-1R inhibitors, epidermal growth factor receptor inhibitors, multitarget TKIs, mammalian target of rapamycin (mTOR) inhibitors, and agents targeting steroidogenic factor-1 (^{97, 98}). Enrollment in

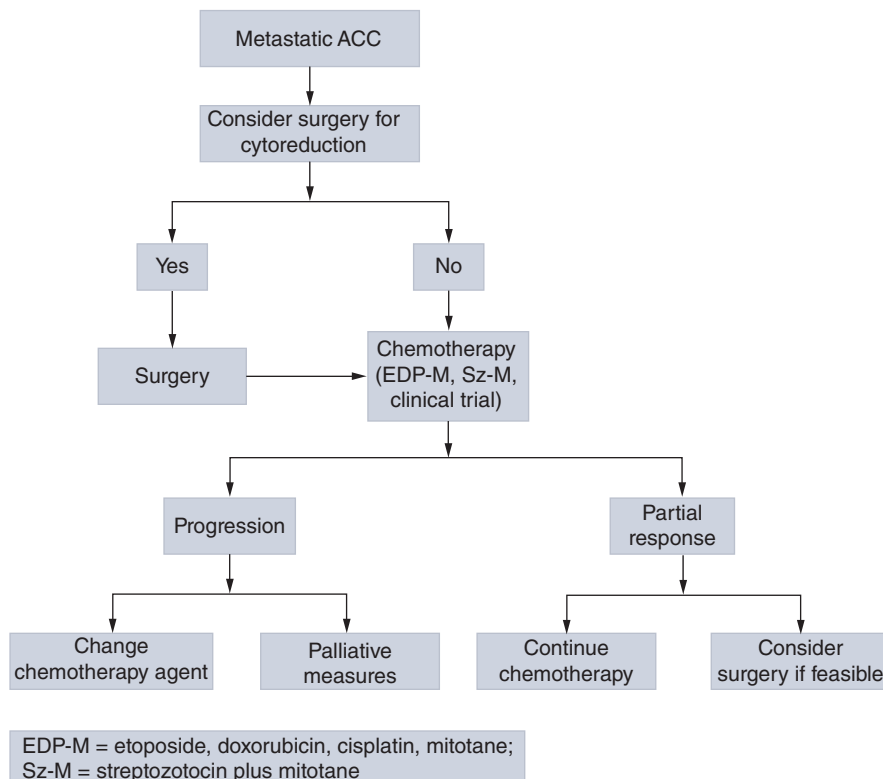

FIGURE 43-27 Management of metastatic adrenocortical carcinoma (ACC).

clinical trials for use of investigational agents is favored to help answer important clinical questions regarding safety and efficacy.

Radiation and Radiofrequency Ablation

Adrenocortical carcinoma is generally considered a radio-resistant tumor, and adjuvant radiation may not reduce the risk of recurrence or increase overall survival⁽⁹⁹⁾. At the University of Texas MD Anderson Cancer Center, radiation treatment is used in selected patients with metastatic ACC for palliation⁽¹⁰⁰⁾. Percutaneous image-guided RFA has also been attempted in the setting of unresectable primary or metastatic ACC. This procedure may be useful for short-term, local control of small adrenal tumors, but further data are needed to elucidate the long-term efficacy and potential impact on survival.

The Acquired Immunodeficiency Syndrome–Related Cancers

Adan Rios
Fredrick B. Hagemeister

THE CHANGING INCIDENCE OF MALIGNANCIES IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS DISEASE

The relationship between malignancies and acquired immunodeficiency syndrome (AIDS) changed in 1996 when highly active antiretroviral therapy (HAART) was introduced in industrial nations. Thanks to the United Nations and other philanthropy programs, HAART has also been successfully introduced into a number of developing nations (¹). Africa, the pandemic epicenter, is the exception, due to the epidemic magnitude on that continent and its significant political and social turmoil. Prior to 1996, epidemiologists noted specific malignancies afflicting patients with AIDS, with a risk proportional to host immune status. Before HAART, AIDS patients could be separated into two groups: patients with an opportunistic infection as their first manifestation of AIDS (60%) and those with a malignancy as its mode of presentation (40%) (²).

Of those with an AIDS-related malignancy, up to 90% would have Kaposi sarcoma (KS) and the rest non-Hodgkin lymphomas (NHLs), including primary central nervous system lymphoma (PCNSL) and systemic diffuse large B-cell lymphoma (DLBCL). Despite an increase in human papilloma virus (HPV)-related invasive cervical cancers in women with high-grade uterine cervical dysplasia, recent findings of a lack of clear association between cervical cancer and human immunodeficiency virus (HIV)-related

immunosuppression questions the validity of including cervical cancer among AIDS-defining or associated malignancies (³). After HAART, previously obvious relationships between AIDS and some malignancies have been challenged. An example is HIV-related Burkitt lymphoma, initially associated with AIDS-induced immunosuppression. Investigators have found that HAART improvement of immunity is associated with significant reductions in KS, PCNSL, and systemic DLBCL, but this is not the case with Burkitt lymphoma. Together with invasive cervical cancer, the incidence of Burkitt lymphoma has remained stable across the pre- and post-HAART eras, increasing its proportional frequency. Epithelial dysplasia and squamous cell carcinomas of the anal canal, rectum, and oral cavity are also observed in men infected by HIV. There has been a post-HAART era increase in Hodgkin lymphoma (Epstein-Barr virus related), lung cancer, and nonmelanoma skin cancer, with implications related to the complex relationship between immunity, aging, chronic antigenic stimulation, and viral oncogenesis. Overall, the excess risk of a malignancy in HIV disease is observed mostly in cancers with an established or suspected infectious cause (⁴).

In this chapter, we first discuss HIV and its effect on the immune system. We then concentrate on malignancies associated with AIDS immunosuppression. We include a discussion of malignancies (Burkitt lymphoma and HPV-related cancers) not directly associated with HIV immunosuppression occurring with a high enough incidence in HIV-infected patients to merit study.

HUMAN IMMUNODEFICIENCY VIRUS DISEASE

Historical Significance of the Virus

The AIDS pandemic came into the medical world in 1980 with the publication in the Center for Diseases Control and Prevention (CDC) journal *Morbidity and Mortality Weekly Report* of a series of patients afflicted by de novo opportunistic infections, mostly *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia and cytomegalovirus (CMV) infections (⁵). At about that time, these conditions were known to occur in immunodeficient patients. It was followed by a report of KS in 26 homosexual men thought to be immunologically healthy. The number of similar cases increased exponentially throughout the United States and Europe, with reports from other parts of the world confirming a new pandemic with an epicenter in sub-Saharan Africa. The high number of cases with similar clinical presentations gave way to a new syndrome, the acquired immunodeficiency syndrome, or AIDS. Twenty-five years after, much is known and much is to be learned about the cause of the syndrome, HIV, and its complications, including opportunistic infections and malignancies (⁶).

Human immunodeficiency virus disease is caused by infection of a human subject with a retrovirus, HIV. Human immunodeficiency virus is only transmitted through blood or unprotected sexual contact, causing a progressive destruction of the immune system with occurrence of opportunistic infections and malignancies. When an opportunistic infection or a malignancy occurs, it signals a significant degree of immunodeficiency. The association of opportunistic infections and immune suppression is well established in the medical literature and clinical practice. The relationship between immune surveillance dysfunction and development of malignancies has also been described in the medical literature. In the early 1970s, kidney transplantation programs in Canada reported an increased incidence of malignancies in patients treated with the immunosuppressant azathioprine (⁷). Similar reports indicated that pharmacologically immune-suppressed patients had increases of several folds of magnitude of certain types of cancers and opportunistic infections. Typically, they had KS or lymphoproliferative malignancies, although other types of malignancies were also reported. In a sense, these patients had a chemically induced AIDS, whereas HIV patients have a biologically induced AIDS.

Origin of the Disease

Human immunodeficiency virus was discovered in 1983 (⁸), dispelling much of the mystery surrounding AIDS. Acquired immunodeficiency syndrome (AIDS) in humans is caused by a retrovirus, HIV, a lentivirus (Latin *lentus*, meaning “slow,” + virus), endemic in

African primates, which entered the human population as a result of a cross-species transmission or zoonosis. Two types of HIV have infected humans: HIV-1 and HIV-2. The HIV-1 virus originated from chimpanzees infected by a retrovirus, the SIVcpz (the chimpanzee simian immunodeficiency virus), and HIV-2 originated from sooty mangabeys monkeys, endemically infected by another retrovirus, SIVsm. SIVcpz is the product of recombination in chimpanzees of two monkeys' retroviruses preyed upon by chimpanzees: the SIVrcm and the SIVgsn (the red capped mangabeys, *Cerocebus torquatus*, and the great spot-nosed monkeys, *Ceropithecus nictitans*, respectively). These viruses do not cause disease in their natural hosts and were named simian immunodeficiency viruses, or SIV, after their genetic and structural similarities with HIV. Each HIV type (1 and 2) is phylogenetically classified in groups and clades; HIV-1 has three groups, M (major), N (non-M, non-O), and O (outlier), with the predominant group M comprising 11 clades A to K, and HIV-2 has six clades, A to F. The HIV-1 and HIV-2 clades can recombine giving origin to genetically complex viral quasiespecies. Transmission from animals to humans occurs when infected animals enter in contact with humans as a result of hunting and butchering (SIVcpz from chimpanzees) or through contact with infected animals used as domestic pets (sooty mangabeys monkeys) (⁹).

The HIV-2 virus is endemic and contained in coastal West Africa. The HIV-1 virus is endemic in west equatorial Africa with several clades from the group M responsible for the majority of worldwide infections. In the Western world, HIV-1B is responsible for over 90% of infections, whereas in Africa, subtypes A, C, D, and G, and in Asia, subtype C and the circulating recombinant forms (CRFs) 01 and 02 can be found. The disease is diagnosed by detecting serum anti-HIV antibodies using an enzyme-linked immunoabsorbent assay (ELISA) test. The initial result can be corroborated by a repeated Elisa test (Explanation: saying “with another Elisa test” implies a different type of ELISA) or by a Western blot blood test. The amount of replicating virus can be measured by quantitative polymerase chain reaction (PCR) or via signal amplification such as branch-DNA HIV viral load test (¹⁰).

Status of the Pandemic and Its Effects on the Immune System

Human immunodeficiency virus disease and AIDS are responsible for a human tragedy of incalculable proportions. Since the pandemic's beginning, there have been over 25 million deaths and more than 50 million infected persons, including those who have died. The estimated rate of new infections is 7,500 new infections per day. Most of these new infections occur in developing nations, affecting many women and children. The most frequent modes of transmission are

unprotected sex and intravenous (IV) drugs. The main epicenter of the pandemic continues to be sub-Saharan Africa, with new epicenters in the former Soviet Union, China, India, and Latin America. In the United States, minority groups such as Hispanics and African Americans as well as younger generations of gay men are disproportionately affected by HIV⁽¹¹⁾.

Human immunodeficiency virus is an enveloped diploid RNA virus (two RNA ribbons per particle), each with an armamentarium of enzymes essential for the virus life cycle. The viral particle membrane is composed of human leukocyte antigen (HLA) groups, other cell surface membrane proteins, and the viral protein gp120 in a trimer form. Among the enzymes within the viral particle are reverse transcriptase, integrase, and proteases. Eighty percent of transmitted mucosal HIV infections are established by a single Transmitted/Founder (T/F) variant, or Transmitted/Founder virus. The other 20% are transmitted by two to five variants (ie, IV drug users). These T/F viruses have specific phenotypic characteristics, including enhanced infectivity, higher envelope content, more efficient binding of dendritic cells, and relative resistance to interferon (IFN)- α ⁽¹²⁾. Once HIV enters a susceptible host, the viral envelope spikes (gp120 trimers) bind to receptors (CD4) and co-receptors (CCR-5) of cells of the immune system, entering through a membrane fusion. The particle content is released into the cytoplasm, and viral RNA is transcribed into DNA. This viral DNA is then randomly integrated into the genome of the infected cell. Through a complex process of transcription activators and as result of the frequent replication cycles of the immune system's cells, new viral particles are generated. These new particles are released through budding and lysis, continuing to infect new susceptible cells with this process, occurring at an unusually fast pace. Infection with HIV is characterized in simian models of AIDS and in man by a rapid destruction of memory cells of the gut-associated lymphoid tissue (GALT). This process occurs in days to few weeks in animal models and in weeks in man. GALT harbors the majority of body lymphocytes in comparison to the 2% to 5% of lymphocytes located in the peripheral circulation.

The result of GALT's destruction, together with the activation of B cells and inhibition of the immune system function by HIV viral gene products such as the vif protein, which inhibits the APOBEC3 gene family, implicated in the control of HIV infection including the production of neutralizing antibodies, inducing a severe immune dysfunction and depletion. (This is an important piece of information that address the mechanistic question of why we have such a difficult time developing neutralizing antibodies against HIV)⁽¹³⁾. Once HIV is integrated into the genome of the susceptible cells, there is a gradual destruction of the immune system, leading to a progressive status of immunodeficiency, with development of opportunistic infections and

tumors. This early senescence of the immune system is implicated in changes at a molecular level resulting in loss of control of oncogenic viruses and associated with the malignant transformations observed in AIDS.

ACQUIRED IMMUNODEFICIENCY SYNDROME-DEFINING MALIGNANCIES

Kaposi Sarcoma

Epidemiology

Kaposi sarcoma was described by Dr. Moritz Kaposi in 1872 as an indolent dermatologic disease characterized by the appearance of purplish nodules or plaques, particularly in the lower extremities of older men of Eastern European, Mediterranean, or Jewish descent (classical KS). Canadian investigators were one of the first ones to note in the 1970s that KS occurred in renal transplant patients exposed to immunosuppressant regimens (ie, azathioprine; transplant or iatrogenic KS). Their observations included reports of remissions when immunosuppressant regimens were temporarily discontinued, suggesting a relationship between immunodeficiency and the malignancies. They also noted a high incidence of NHL. In the 1960s, British investigators reported an aggressive lymphadenopathic form of KS confined to equatorial Africa (African KS). This form occurred in younger patients with aggressive involvement of lymph nodes and appearance of nodules and plaques of the lower extremities that rapidly became ulcerated. With the CDC *Morbidity and Mortality Weekly Report* of 26 gay men with KS, the disease became one of the hallmarks of the AIDS epidemic (epidemic or AIDS-related KS).

In contrast to the classical form, the AIDS-related KS lesions appear with an aggressive pattern of distribution that includes the trunk, arms, and face in addition to the lower extremities⁽¹⁴⁾. Prior to antiretroviral therapies, patients died of a combination of tumor progression and opportunistic infections. Despite HAART, KS continues to be a prevalent cancer among HIV-infected patients, although HAART has significantly changed the incidence of the disease. From 1990 to 1995, the incidence of KS in the United States was 1,838.9 cases per 100,000 person-years in contrast to 334.6 cases per 100,000 person-years from 1996 to 2002. In the United States and Europe, AIDS-related KS has been almost exclusively diagnosed in homosexual men, suggesting that its prevalence may vary among different categories of AIDS patients. In Africa, where the human herpesvirus 8 (HHV-8), or KS herpesvirus (KSHV), is endemic, the male-to-female ratio of AIDS-related KS in some countries is 2:1, almost the same ratio observed in transplant- or iatrogenic-related KS. Thus, in the presence of profound immune suppression, factors that made the disease more prevalent

in males than in females prior to the AIDS pandemic appear to be of little relevance. What is clear is that the incidence of AIDS-related KS is related to the degree of the immune suppression of the infected hosts, with most afflicted patients having CD4⁺ cell counts of 200 CD4⁺ cells/ μ L or less.

The Viral Etiology of Kaposi Sarcoma

The etiologic agent of all forms of KS is HHV-8, also called KSHV ⁽¹⁵⁾. Early in the pandemic, other viruses or agents were implicated as the cause of AIDS-related KS, including CMV. In 1994, sequences of a new herpes-like virus were isolated from the lesions of an AIDS-related KS patient. Using a subtractive PCR technique called representative differential analysis, investigators found sequences isolated from KS lesions homologous but not identical to other known herpesviruses, and thus it was named HHV-8, because it became the eighth known herpesvirus. Not all patients infected with HHV-8 develop KS; however, viral DNA and seroconversion can be detected in patients prior to the development of KS, confirming the role of HHV-8 as the cause of all forms of KS and the relationship of its pathogenesis to immunosuppression in addition to other cofactors.

Human herpes virus 8 belongs to the γ -herpesvirus subfamily and the subgroup γ -2 or rhadinovirus (from the Latin term *rhadino*, referring to the tendency of the viral genome to break apart when it is isolated) and is the first human virus of this subfamily identified. The detection of the infection relies on the presence of antibodies against viral antigens using immunofluorescence assays based on the use of B lymphocytes as the antigen source or ELISA with recombinant immunogenic proteins or peptides of HHV-8. The infection seroprevalence mirrors the geographic distribution of AIDS-related KS, with the highest infection rates in central African countries (80%), rates of 25% to 50% among homosexual men in the Western world, and an intermediate level in the Mediterranean regions. The adult general population of blood donors in North America and Europe has an HHV-8 seroprevalence ranging from 0% to 8%. In addition to being the etiologic agent of AIDS-related KS, HHV-8 has been associated with two other lymphoproliferative disorders: primary effusion lymphoma (PEL, a subset of body cavity-based lymphomas [Fig. 44-1], subsequently called PELs) and multicentric Castleman disease ⁽¹⁵⁾.

FIGURE 44-1 Scan in a patient with primary effusion lymphoma (PEL) showing multiple sites of increased fluorodeoxyglucose activity and a large right pleural effusion.

Pathogenesis of Kaposi Sarcoma

Human herpes virus 8 incorporates a significant number of host genes such as cyclin D and growth factor interleukin (IL)-6⁽¹⁶⁾. These genes participate in the replication, survival, and transformation of the infected tumor cells. The viral K1 gene kaposin and viral G protein–coupled receptor (vGPCR) have transformation potential. Others deregulate cell growth and lead to transformation including viral IL-6, viral IL-10, viral cc-class chemokines, and viral FLICE-inhibitory protein (vFLIP). The expression of the different key genes is related to the latency and lytic cycles of HHV-8. During the latency phase, genes such as *LANA-1* (latency-associated nuclear antigen 1), in addition to the maintenance of latency, inactivate p53, inhibiting apoptosis. In addition, a viral cyclin prevents cell cycle arrest by cyclin-dependent kinases, pRB and vFLIP, avoiding the activation of the Fas death receptor pathway. During the lytic phase, homologues of replication genes including the K1 kaposin gene, a Bcl-2 homologue, a viral G protein–coupled receptor gene (vGPCRP), a viral homologue of IL (IL-6), and viral macrophages and IFN regulatory factors become active. Some of these genes have immunosuppression functions, such as the inhibition by vFLIP including cytotoxicity of T cells against HHV-8–infected cells and the inhibition of HHV-8 class 2 major histocompatibility complex (MHC)-mediated T-cell activation by K1⁽¹⁷⁾. Finally, other viral proteins such as K3 and K5 downregulate the presentation of MHC class 1 molecules on the cell surface.

Pathology of Kaposi Sarcoma

The histology of KS is characterized by the abundance of spindle cells in a matrix of neovascular formation and a rich background of mononuclear inflammatory cells and collagen. Vascular spaces are dilated and contain extravasated erythrocytes. Involvement of the reticular dermis, reflected by patchy lesions and the involvement of all the layers of the skin, clinically presents as nodular or plaque lesions that can coalesce, interfering with the lymphatic circulation, and are histologically and clinically associated with surrounding hemorrhage and subcutaneous edema. The spindle KS cells are rich in endothelial factor VIII. Recent microarray studies have demonstrated that the origin of the KS cell is from a virally transformed lymphatic endothelial cell. Kaposi sarcoma spindle cells express angiogenic/inflammatory cytokines and growth factors, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), IL-1, and IL-6, among others. Kaposi sarcoma cells also overexpress receptors for cytokines, suggesting growth through autocrine or paracrine mechanisms. They also proliferate in response to IL-1, IFN- γ , IL-6, and tumor necrosis factor (TNF), which are abundantly present in the serum of patients with poorly controlled HIV infection, and

matrix metalloproteinases (MMPs), enzymes involved in the destruction of extracellular matrix proteins required for angiogenesis and metastasis. In AIDS-related KS, Tat (the trans-activator of transcription protein) stimulates KS spindle and endothelial cell replication, promoting an increase in the concentrations of bFGF. This, in turn, upregulates the integrins $\alpha_5\beta_1$ and $\alpha_v\beta_3$, receptors for fibronectin and vitronectin, which are highly expressed in AIDS-related KS.

Clinical Features of Kaposi Sarcoma

Most patients with AIDS-related KS have CD4⁺ cell counts of 200 CD4⁺ cells/ μ L of blood, with an increased number and aggressiveness of lesions in those who are more severely immunosuppressed. There are periods of exacerbation alternated with quiescence related to oscillations of the patient's immunity. Kaposi sarcoma rarely invades the central nervous system. This is of biological interest because many other human malignancies are characterized by the invasion of the central nervous system⁽¹⁸⁾.

The distribution of skin lesions in patients with AIDS-related KS often follows the Langer's folds of the skin. The occurrence of lesions in acral regions of the body such as the tip of the nose is common. The evolution of the skin lesions correlates with the patient's immune system status. In the pre-HAART era, severe involvement of the skin of the face by raised purplish lesions was frequent. With KS progression, there is frequent involvement of the gastrointestinal tract. Lesions of the palate and gums are often the first ones to be noted, and diarrhea and occasional bleeding can suggest KS involvement of the gastrointestinal tract. In the case of involvement of the lower extremities, progressive edema with nodular and coalescing plaque lesions can cause significant discomfort and pain. Prior to HAART, this was a frequent and serious complication of KS, because "elephantiasis" secondary to the progression of KS was extremely difficult to treat. Advanced cases often involve ulceration of lesions, particularly when located in the lower extremities. Lymph node involvement is frequent, and when there is only generalized lymph node involvement, a biopsy is required for confirmation of diagnosis. In advanced cases, lung involvement is manifested by bilateral basilar infiltrates mixed with a nodular appearance; however, severe hemoptysis or gastrointestinal bleeding is infrequent. During the early years of the epidemic, a significant number of patients experienced involvement by large masses of KS in vital organs such as the liver and heart, and death was due to from progression of their KS tumors and associated opportunistic infections.

Staging and Prognostic Factors for Kaposi Sarcoma

The usual TNM system used in other solid tumors is not easily applicable to AIDS-related KS. A system

Table 44-1 TIS Staging System for AIDS-Related Kaposi Sarcoma and Risk Status

Characteristics	Good Risk (0)	Poor Risk (1)
	All of the Following	Any of the Following
Tumor (T)	Tumor confined to skin and lymph nodes and/or minimal oral disease ^a	Tumor-associated edema or ulceration; extensive oral KS; gastrointestinal KS; KS in other nonnodal viscera
Immune system (I)	CD4 cells ≥150/mm ³	CD4 cells <150/mm ³
Systemic illness (S)	No history of opportunistic infection or thrush; no B symptoms ^b ; performance status ≥70 (Karnofsky)	History of opportunistic infection and/or thrush; B symptoms; performance status <70 (Karnofsky); other HIV-related illness (eg, neurologic disease, lymphoma)

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; KS, Kaposi sarcoma.
^aMinimal oral disease defined as nonnodular KS confined to the palate.
^bB symptoms: fever, drenching night sweats, and/or >10% involuntary weight loss.
Reproduced, with permission, from Levine AM, Tulpule A. Clinical aspects and management of AIDS-related Kaposi's sarcoma. *Eur J Cancer*. 2001;37:1288-1295.

based on the work of Chachoua and colleagues was proposed in 1989 by the AIDS Clinical Trial Group (ACTG) (Table 44-1). This staging system included the extent of tumor involvement, the immune status measured by the level of CD4⁺ cell count, and presence or absence of any systemic illness (B symptoms). In addition to a complete physical examination, it included a complete blood count, serum chemistries, HIV viral load, panendoscopy of the gastrointestinal tract, computed tomography (CT) of the abdomen and pelvis, and when indicated, the performance of bronchoscopy when pulmonary involvement by KS was suspected. Biopsies of skin or lymph nodes were also suggested when indicated to rule out entities that could be similar in presentation, such as bacillary angiomatosis or pyoderma gangrenosum. After HAART, the extent of disease and the presence of HIV systemic symptoms became the most important prognostic factors; however, pulmonary involvement by KS still carries a particularly poor prognosis. Correlations with the levels of HIV viral load and the status of HHV-8 infection

are under study in relationship to their impact on survival (¹⁹).

Therapy of Kaposi Sarcoma

Highly Active Antiretroviral Therapy

Highly active antiretroviral therapy brought a dramatic decrease in the incidence of AIDS-related KS. Highly active antiretroviral therapy consists of the administration of a combination of agents with anti-HIV activity, including inhibitors of HIV reverse transcriptase and protease inhibitors. The consensus of experts in the field about frontline components of HAART is periodically published in *Guidelines for the Use of Antiretroviral Agents in HIV-1 Infected Adults and Adolescents* by the Department of Human and Health Services (DHHS; available online by visiting the DHHS website). For patients in whom KS is part of the initial diagnosis of AIDS, HAART therapy should be started irrespective of the extent of the disease. For patients with minimal tumor burden, HAART initiation constitutes frontline therapy of their AIDS-related KS. This approach can control these lesions for long periods of time, often more than 1 year, and in many instances results in complete disappearance of KS lesions (²⁰). Patients with extensive disease or visceral involvement can receive systemic chemotherapy in addition to HAART.

Radiation Therapy for Kaposi Sarcoma

Radiotherapy can be useful for treatment of minimal local disease and when the use of systemic treatment other than HAART is not indicated. It can also be used as an adjunct treatment modality for patients in whom the administration of chemotherapy leads to incomplete results, enhancing the beneficial effects of the systemic treatment. Depending on the general condition of the patient and the size of the lesions to be treated, doses range from the administration of a single fraction to fractionated doses over periods of 2 to 4 weeks. For single lesions and frail patients, the administration of a single 800-cGy dose can be used. Radiotherapy can be used for cosmetic reasons, although this should be done carefully to avoid secondary side effects such as postradiation cataracts in the case of periorbital lesions. For larger lesions or when the therapeutic intent is cosmetic, fractionated doses between 200 and 4,000 cGy are effective and carry less risk. For patients receiving systemic therapy, radiotherapy can be an adjuvant for the treatment of complicated single lesions, particularly when they are bleeding, ulcerated, or painful, or when they affect the well-being of the patient. Such is the case of patients with disseminated disease receiving systemic treatment and in whom oral lesions may affect eating due to local pain or size.

Local Therapy Other Than Radiotherapy for Kaposi Sarcoma

In the modern era, the use of local therapies such as cryotherapy and laser therapy may have a role for patients with few and small lesions. The use of surgery may be appropriate in selected cases such as large skin lesions or when there are complications (bleeding or obstruction of a hollow viscus). Other treatments, such as intralesional injection of chemotherapeutic agents, particularly of the oral cavity, and application of alitretinoin gel, have been abandoned and replaced by a more sophisticated use of radiotherapy techniques, HAART, and systemic chemotherapy.

Immunomodulators in Therapy of Kaposi Sarcoma

After the demonstration of the activity of IFN- α in hairy cell leukemia and renal cell cancer in 1984⁽²¹⁾, there was an impetus to use the same doses of IFN in patients with AIDS-related KS. Low doses of IFN- α effective against hairy cell leukemia and renal cell carcinoma were ineffective against AIDS-related KS (Rios A, personal observation). A dose-response study unequivocally demonstrated the therapeutic effect of IFN- α in KS when used at doses of 20 to 30 MU/m²^(22, 23). A different situation was observed with IFN- γ . Under the angiogenic stimuli of IFN- γ , KS has the capacity to replicate, resulting in a deleterious impact on patients treated with this agent in pilot studies. As a result of these trials, recombinant IFNs α -2a (Roferon-A) and α -2b (Intron-A) were approved for the systemic treatment of patients with AIDS-related KS. Expanded use of these agents has revealed their true activity to be in the range of 15% to 20%.

Interferon can block the synthesis of viral proteins and the budding of viral particles from infected cells in addition to other complex pleiotropic effects. Interferon actions are accompanied by significant systemic side effects including tiredness, fatigue, anorexia, hepatotoxicity, and severe myelosuppression. With the development of HAART and the use of more effective systemic chemotherapy regimens in the treatment of AIDS-related KS, the interest in the use of IFN- α in the treatment of AIDS-related KS has declined.

Chemotherapy for Kaposi Sarcoma

Indications for the use of systemic chemotherapy in AIDS-related KS includes extensive skin, mucocutaneous, and visceral involvement by tumor. In patients who require systemic chemotherapy, local radiotherapy is used to treat local complications in addition to systemic disease. The introduction of HAART has resulted in better and more durable responses with increased tolerability and durability than those observed prior to HAART.

Before the discovery of antiretrovirals, a variety of chemotherapeutic agents had modest to significant

activity as monotherapy for KS. These agents included etoposide, vinblastine, vincristine, bleomycin, doxorubicin, vinorelbine, and epirubicin, which induced responses in 40% to 69% of patients. After HAART, ABV (doxorubicin 20 mg/m², bleomycin 10 U/m², and vincristine at maximum doses of 1 to 2 mg) became the first standard treatment of AIDS-related KS. It produced a response rate of 60%, with complications and tolerance depending on the performance status and general condition of the patient⁽²³⁾. Antiretroviral and other supportive therapies with growth factors (granulocyte-macrophage colony-stimulating factor [CSF] and granulocyte CSF [G-CSF]) paired with vigorous prophylaxis of opportunistic infections reduce the risks of treatment. Complications of ABV were the expected ones with systemic chemotherapy including the potential for cardiac toxicity induced by doxorubicin.

The ABV regimen was followed by the introduction of agents considered today the standard of care for AIDS-related KS, including liposomal encapsulated anthracyclines (doxorubicin and daunorubicin) and taxanes (paclitaxel). The last of these promotes apoptosis and downregulates Bcl-2 protein expression in KS cells in vitro and in KS-like lesions in mice. In addition, it has an important antimitotic effect associated with its capacity for the disruption of tubulin activity during mitosis.

The current treatment of AIDS-related KS is based on the combination of an anthracycline (liposomal doxorubicin 20 mg/m² or liposomal daunorubicin 40 mg/m² but *not both* together) with paclitaxel 25 mg/m² with or without bleomycin or vincristine. Escalation of the dose of liposomal doxorubicin is not recommended due to a syndrome of desquamation of the skin of the palms and soles of the feet, known as palmar-plantar erythrodysesthesia. In contrast, the dose of liposomal-encapsulated daunorubicin can be increased to up to 60 mg/m² or even higher for patients who tolerate lower doses. This is of particular relevance in patients with advanced disease or significant pulmonary involvement and for whom prompt control and achievement of a quick therapeutic response is of great importance (Fig. 44-2).

Future Therapies for Kaposi Sarcoma

Only patients with early disease and relatively good performance status consistently achieve durable remissions with current therapies for KS. For the rest of the patients, only palliation and stabilization of disease is achieved with current treatments. For these reasons, efforts are under way to develop new therapies based on the knowledge of the pathophysiology of the disease. For example, because angiogenesis is an important component of AIDS-related KS, agents such as thalidomide and anti-VEGF agents such as bevacizumab are of great interest in the therapy of this disease. Metalloprotease inhibitors are also of

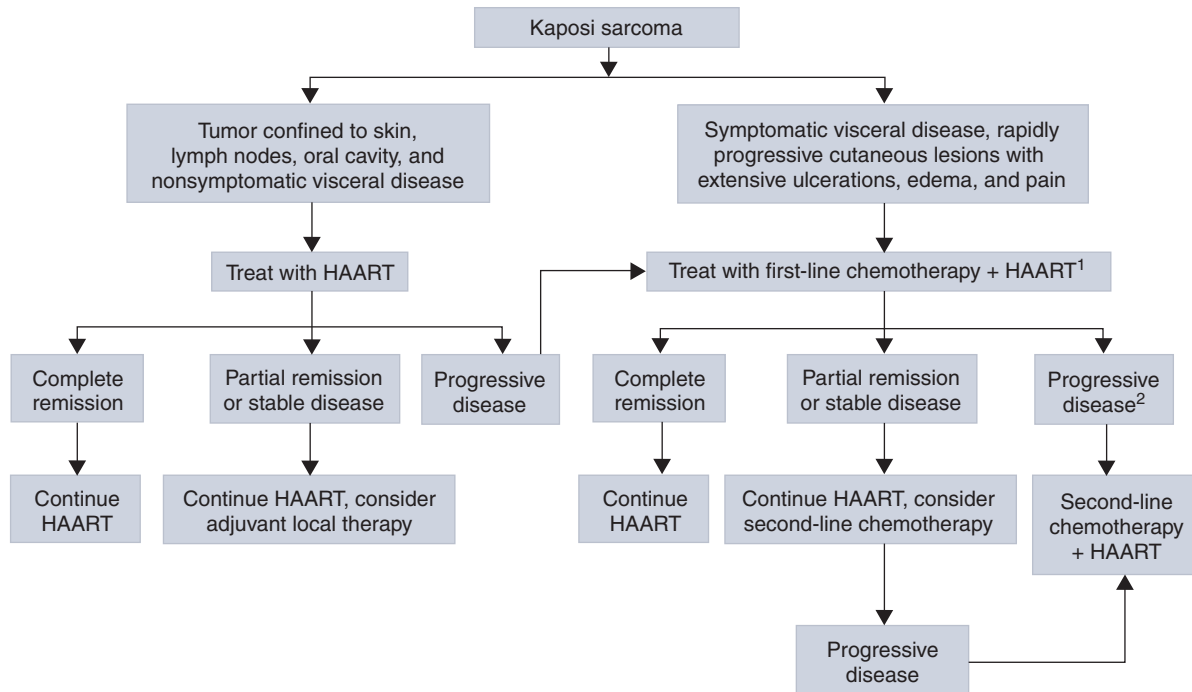

FIGURE 44-2 Algorithm for the management of acquired immunodeficiency syndrome (AIDS)-related Kaposi sarcoma. ¹Monthly evaluation of Kaposi sarcoma clinical response and estimation of CD4⁺ cell count and HIV-RNA levels. ²Highly active antiretroviral therapy (HAART) regimen should be changed in the case of immunovirologic failure. (Reproduced, with permission, from Catellan AM, Trevenzoli M, Aversa SM. Recent advances in the treatment of AIDS-related Kaposi sarcoma. *Am J Clin Dermatol.* 2002;3:451-462.)

great interest, and active clinical trials are in progress. Viruses associated with the production of malignancies tend to constitutively activate the nuclear factor- κ B (NF- κ B) pathway, and agents that can inhibit this pathway such as bortezomib may be of some value. Inhibition of signaling cell receptors implicated in the stimulation of angiogenesis such as platelet-derived growth factor receptor (PDGFR) and C-kit receptor by agents such as imatinib, an orally administered tyrosine kinase inhibitor, approved by the US Food and Drug Administration (FDA) for treatment of chronic myeloid leukemia and gastrointestinal stromal tumor, is being investigated.

There is significant interest in the development of therapies against the latent phase of HHV-8, the most common form of HHV-8 in KS cells, which does not respond to standard antiherpetic drugs such as foscarnet and cidofovir. This area of research has led to potential development of a vaccine against HHV-8. Despite all these new potential therapeutic developments, the impact of HAART in the incidence of AIDS-related KS cannot be overemphasized. The development of more potent and less toxic HAART regimens and the acceptance of earlier therapeutic intervention against HIV seem to be the main paths to control the epidemic of AIDS-related KS.

Acquired Immunodeficiency Syndrome-Related Non-Hodgkin Lymphoma: Systemic Non-Hodgkin Lymphoma

Epidemiology

Non-Hodgkin lymphoma is the second most frequent AIDS-associated malignancy. Both KS and NHL were occurring with an incidence almost linear in its relationship to the patient's immunodeficiency status (²⁴). In 1985, high- or intermediate-grade B-cell NHLs were considered part of the spectrum of AIDS-related malignancies. Eighty percent of AIDS-related NHLs were systemic (peripheral) lymphomas, involving nodal or extranodal sites, with 15% to 20% originating in the primary central nervous system (PCNSL). A small proportion, less than 3%, of systemic AIDS-related NHL patients had PELs, known as body cavity lymphomas. In general, the risk of AIDS-related NHL in patients with HIV appears to be higher in those who have poor immune function with average CD4⁺ cell counts of 150 CD4⁺ cells/ μ L of blood.

A viral relationship is implicated in the development of AIDS-associated lymphomas. Epstein-Barr virus (EBV) contributes to the development of most of these tumors, although HHV-8 is associated with

the development of PEL⁽²⁴⁾. There is no relationship between the risk of development of AIDS-related NHL and modes of HIV transmission. The incidence of pre-HAART AIDS-related NHL was 60 to 200 times higher than in a matched HIV-seronegative population; the relative risk was higher for PCNSL. Age, nadir of CD4⁺ cell count, and absence of anti-HIV therapy were critical factors that predicted the development of AIDS-related NHL. In the pre-HAART era, 80% of these NHLs, including systemic and PCNSL cases, were immunoblastic variants associated with CD4⁺ cell count depletion and EBV infection. In the post-HAART era, there has been a 30% reduction of peripheral cases and a 70% reduction in PCNSL, indicating the impact of immune reconstitution in the incidence of immunosuppression-related lymphomas. In contrast, the incidence of Burkitt lymphoma and of centroblastic DLBCL has remained stable without significant change from the pre- to the post-HAART eras⁽²⁵⁾. When comparing the AIDS-related lymphomas with non-AIDS-related NHL, the former tend to be of higher histologic grade, with increased frequency of B symptoms, extranodal presentations, and an increased incidence of leptomeningeal and primary CNS involvement⁽²⁶⁾. In the post-HAART era, the World Health Organization (WHO) has expanded the categories of lymphomas that can occur in HIV patients to include extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (MALT lymphoma), peripheral T-cell lymphoma (PTCL), and classical Hodgkin lymphoma (HL), as well as lymphomas that more specifically occur in AIDS patients, including plasmablastic lymphomas of the oral cavity, polymorphic B-cell lymphomas (posttransplant lymphoproliferative disorder–like), and PEL⁽²⁷⁾. Finally, the demographics of AIDS-related NHL patients have changed in the last decade, reflecting changes in the demographics of the AIDS epidemic, with increasing incidence in Hispanic and African American patients and patients who have acquired HIV through heterosexual contact (Table 44-2).

Pathogenesis of Acquired Immunodeficiency Syndrome–Related Non-Hodgkin Lymphomas

The development of NHLs in HIV patients is similar to that of malignancies associated with other congenital or posttransplant immunodeficiency disorders^(28, 29). In such conditions, most of the malignancies consist of NHL and KS. In the case of HIV, immunodeficiency and cofactors, including oncogenic viruses, chronic antigenic stimulation, and cytokine overproduction, are responsible for the development of AIDS-related NHL malignancies. In contrast to AIDS-associated KS, no one has yet found HIV sequences in tumor cells

of AIDS-related NHLs⁽³⁰⁾, although PCR analysis has revealed the presence of HIV in infiltrating T cells. For patients with severe HIV immunodeficiency, the oncogenic nature of both EBV and HHV-8 is responsible for the development of the immunoblastic subtype of DLBCL, PCNSL, plasmablastic lymphoma of the oral cavity, and PEL. The last of these often results from coinfection with HHV-8 and EBV. These lymphomas are the result of active oncogenic viruses released from control by an effective immune surveillance.

Epstein-Barr virus is central to the pathogenesis of AIDS-related NHLs, including those that are related to immunodeficiency and those that occur with a reconstituted immune system, such as centroblastic DLBCL and Burkitt lymphoma. The EBV genome presence is very high in immunodeficiency-associated AIDS-related NHLs (100%)⁽³¹⁾, although it can only be detected in approximately 60% of centroblastic DLBCLs and 30% of Burkitt lymphomas. This suggests that other factors, including other common latent or chronic viral infections, may be involved in the development of these tumors.

In EBV-infected cells, the EBV virus is, for the most part, in a state of latency with brief periods of lytic activity. The malignant transformation of B cells occurs in the latent phase, requiring multiple molecular events⁽³²⁾. Epstein-Barr virus contributes to the cellular transformation process through expression of genes with oncogenic activity such as *LMP-1*, *LMP-2*, *EBNA-1*, and *EBNA-2*. There is also expression of small EBV-encoded, nonpolyadenylated nuclear RNAs (EBERs), all of which participate in the oncogenic transformation phenomenon. These proteins can rescue cells from apoptosis by mimicking cell receptors such as CD40 and B-cell receptor. For example, *LMP-1* (latent membrane protein-1) is capable of replacing the function of CD40 in germinal B cells which otherwise would follow an apoptotic fate.

The Impact of Highly Active Antiretroviral Therapy on Distribution of Acquired Immunodeficiency Syndrome–Related Non-Hodgkin Lymphoma

In the post-HAART era there has been a decline in the incidence of NHLs associated with immunodeficiency due to AIDS. In contrast, the incidence of centroblastic DLBCL and Burkitt lymphoma appears to be similar before and after introduction of HAART. Factors influencing the pathogenesis of these diseases include an increase in regulatory cells of the immune system, associated with recovery of the immune status of the host, and effects of chronic antigenic stimulation by HIV with a resultant overproduction of cytokines. The existence of more than one pathogenic mechanism for

the occurrence of AIDS-related NHLs can be inferred from the variety of genetic abnormalities displayed by the malignant cells (³³). The number and type of these genetic abnormalities vary according to the anatomic site and tumor histology. They include *c-myc* rearrangement, *bcl-6* gene rearrangement, *ras* gene mutations, and *p53* mutations/deletions (³⁴).

Pathology of Systemic Non-Hodgkin Lymphomas

The hallmark of AIDS-related NHL is a high-grade histology, regardless of the histologic subtype, including diffuse large cell, immunoblastic, and small noncleaved cell lymphomas and Burkitt and Burkitt-like lymphomas. The cells of PEL express CD45, activation-associated antigens such as HLA-DR, CD30, CD38, CD71, epithelial membrane antigen, and CD 138/syndecan-1.

Primary effusion lymphoma cells often lack B-cell antigens and *c-myc* gene rearrangements and mutations and uniformly contain HHV-8 and frequently also contain EBV (^{33,34}). Other hematologic neoplasms, including low-grade B-cell lymphomas and lymphocytic leukemia, multiple myeloma/plasmacytomas, T-cell neoplasms, and various acute myeloid leukemias and myeloproliferative disorders, have been reported in patients with HIV infection. However, there is no evidence that the incidence of these neoplasms has increased in parallel with the AIDS epidemic (³⁵⁻³⁹).

Clinical Features of Systemic Non-Hodgkin Lymphomas

Patients with AIDS-related NHLs usually present with advanced stages of the disease and B symptoms,

Table 44-3 Ann Arbor Staging Classification for Hodgkin Lymphoma

Stage	Characteristics
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (IE).
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (IIIE).
III	Involvement of lymph node regions on both sides of diaphragm (III) or localized involvement of an extralymphatic organ or site (IIIE) or spleen (IIIS) or both (IIISE).
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement. The organ(s) involved should be identified by a symbol: A, asymptomatic; B, fever, sweats, weight loss >10% of body weight.

Data from Carbone PP, Kaplan HS, Mushoff K, et al. Report of the Committee on Hodgkin's Disease Staging. *Cancer Res.* 1971;31:1860-1861.

including fever, loss of weight, night sweats, and enlarged lymph nodes or masses. Over 60% of the patients will present with stage III or IV disease. Frequent extranodal sites of involvement are bone marrow, CNS parenchyma and meninges, lungs, and spleen. Patients with PEL present with ascites or a pleural effusion and less frequently with a pericardial effusion. Masses are typically absent in the presentation of PEL, although occasionally a mass may accompany the development of the effusion⁽⁴⁰⁾ (see Fig. 44-1).

The staging of patients with AIDS-related NHL is similar to non-HIV patients with NHL and should be reported according to the Ann Arbor system (Table 44-3). The International Prognostic Index has been validated in pre-HAART studies, and significant changes in treatment outcomes have occurred since the initiation of HAART⁽⁴¹⁾. Complete blood count, β_2 -microglobulin, lactic dehydrogenase, and complete blood chemistries should be performed, and a radiologic staging should include magnetic resonance imaging (MRI) of the brain and positron emission tomography (PET)/CT scan. Patients in remission after two courses of treatment will tend to remain in remission for the duration of induction therapy. Patients with Burkitt types of lymphoma should have a bone marrow aspiration and biopsy and a diagnostic lumbar puncture. All patients should be screened for hepatitis B, because the exacerbation of this virus by the use of rituximab or chemotherapy can be prevented by screening patients for hepatitis B surface antigen and hepatitis B core

antibody and treating those found to have positive results. Hepatitis B surface antigen–positive patients or patients who have a history of hepatitis B with a positive e antigen should be treated for hepatitis B prior to the administration of rituximab. For those with only positive core antibodies, measurements of HBV DNA and of the presence or absence of anti-hepatitis B surface antibodies are important in guiding the decision to intervene⁽⁴²⁾.

Before HAART, the presence of an opportunistic infection, less than 100 CD4⁺ cells/ μ L of blood, bone marrow involvement, and increased age predicted for a poor survival, with patients often suboptimally treated due to poor tolerance to standard doses of chemotherapy. After HAART, two factors have become predictors of poor survival: a CD4⁺ cell count of less than 100 cells/ μ L and high-intermediate International Prognostic Index scores⁽⁴³⁾.

Therapy for Acquired Immunodeficiency Syndrome–Related Systemic Non-Hodgkin Lymphoma

Prior to HAART, all regimens had in common reduced doses of chemotherapy. After 1996, it became clear that patients on HAART can receive standard doses of chemotherapy. The outcomes of treatment in the presence of HAART are related to the subtype of lymphoma and the specific treatment rather than the immunodeficiency status of the patient (Table 44-4). Vigorous prevention of infections with prophylactic antibiotics, aggressive use of growth factors (G-CSF and pegylated G-CSF), and rituximab where indicated have improved the outcomes for these patients (Table 44-5). Although investigators were originally concerned that rituximab might compromise the immune status of patients with CD20⁺ B-cell lymphomas, studies have demonstrated that rituximab can safely be used for patients with ≥ 50 CD4⁺ cells/ μ L of blood.

Regimens commonly used to treat patients with AIDS-related DLBCL include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or rituximab plus CHOP (R-CHOP), R-CDE (rituximab, cyclophosphamide, doxorubicin, and etoposide), and dose-adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride) or dose-adjusted EPOCH plus rituximab (EPOCH-R). Progression-free survival rates at 2 years for these different treatment regimens are 70% for R-CHOP and R-CDE and approximately 90% for dose-adjusted EPOCH-R⁽⁴⁴⁻⁵⁰⁾. In the case of Burkitt lymphoma, CHOP and similar regimens are not recommended because the response is poor. Burkitt lymphoma should be treated with R-HyperCVAD (rituximab plus cyclophosphamide, vincristine, doxorubicin, and dexamethasone)^(51, 52) or R-CODOX-M/IVAC (rituximab

Table 44-4 Summary of Selected HIV-Related Lymphoma Trials

AZT, azidothymidine; CDE, cyclophosphamide, doxorubicin, and etoposide; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CR, complete response; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating hormone; HAART, highly active antiretroviral therapy; m-BACOD, methotrexate with leucovorin, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone; MTX/LV, methotrexate and leucovorin; NR, not reported; OI, opportunistic infection; ORR, overall response rate; OS, overall survival; R, rituximab.

^a0% during chemotherapy, 9% after.

plus cyclophosphamide, doxorubicin, vincristine, methotrexate/ifosfamide, etoposide, high-dose cytarabine) ⁽⁵³⁾. Either protocol can achieve remissions of more than 92% and a 2-year overall survival rate of 49% (Figs. 44-3 and 44-4). Recent data suggest that dose-adjusted EPOCH-R also has excellent activity against Burkitt lymphoma, establishing this regimen as a potential new standard of care. This regimen known as SC(for short)-RR (Rituximab days 1 and 5)-DA-EPOCH for HIV-related Burkitt lymphoma consists of a 4-day infusion of etoposide (50 mg/m²/d), vincristine (0.4 mg/d), and doxorubicin (10 mg/m²/d) admixed in the same solution, along with prednisone, at a dose of 60 mg/m²/d orally on days 1 to 5. Cyclophosphamide is given at a dose of 750mg/m² as 2-hour infusion on day 5. Rituximab is given at a standard dose of 375 mg/m² on days 1 and 5. Filgrastim is given subcutaneously starting on day 6 until the absolute neutrophil count is 5,000/μL (post nadir). Cyclophosphamide is increased or decreased from the previous course dose if the absolute neutrophil count nadir is over 500/μL or less than 500/μL ANC, respectively. Importantly, only cyclophosphamide is dose-adjusted for hematologic toxicity. Patients receive one cycle after complete remission is established for a minimum of three cycles and a maximum of six cycles (Table 44-6). All patients receive intrathecal chemotherapy ⁽⁵⁴⁾. For patients with relapsed or refractory lymphoma, R-ICE

(rituximab, ifosfamide, carboplatin, and etoposide) or R-ESHAP (rituximab, etoposide, methylprednisolone, cytarabine, and cisplatin) can be of value. Patients with disease responsive to salvage therapy can be considered for high-dose chemotherapy and autologous stem-cell transplantation or experimental therapies ⁽⁵⁵⁾.

Acquired Immunodeficiency Syndrome–Related Non-Hodgkin Lymphoma: Primary Central Nervous System Lymphoma

Epidemiology and Pathogenesis

Primary CNS lymphoma became an AIDS-defining malignancy in 1983. Primary CNS lymphoma accounted for up to 15% of NHLs in HIV-infected patients compared to only 1% of NHLs in the general population. In the pre-HAART era, typical patients were men who were younger (median age, 40 years) than their immunocompetent counterparts, with CD4⁺ cell counts of less than 50 cells/μL of blood. The impact of HAART was evidenced by a significant decrease in the disease incidence after 1996 (from 313.2 per 100,000 person-years to 77.4 per 100,000 person-years) ⁽³⁾. The development of PCNSL is related to the effect of HIV immunodeficiency on the activity of EBV. The virus does not replicate in CNS tissue. Thus,
